Harwood-Nuss'
CLINICAL PRACTICE OF EMERGENCY MEDICINE

SIXTH EDITION

Editor-in-Chief

Allan B. Wolfson, MD
Professor and Vice Chair for Education
Department of Emergency Medicine
University of Pittsburgh
Program Director
University of Pittsburgh Emergency Medicine Residency
Pittsburgh, Pennsylvania

Associate Editors

Robert L. Cloutier, MD, MCR
Associate Professor of Emergency Medicine and Pediatrics
Co-Director, Pediatric Emergency Medicine Fellowship
Assistant Program Director, Emergency Medicine Training Program
Oregon Health and Science University
Portland, Oregon

Gregory W. Hendey, MD

Professor and Chief of Emergency Medicine
UCSF Fresno Medical Education Program
Community Regional Medical Center
Fresno, California

Louis J. Ling, MD
Professor of Emergency Medicine
University of Minnesota Medical School
Medical Toxicologist
Hennepin Regional Poison Center
Minneapolis, Minnesota
Senior Vice President for Hospital-based Accreditation
Accreditation Council for Graduate Medical Education
Chicago, Illinois

Carlo L. Rosen, MD
Associate Professor
Harvard Medical School
Program Director and Vice Chair for Education
Department of Emergency Medicine
Associate Director of Graduate Medical Education
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Jeffrey J. Schaider, MD
Professor, Department of Emergency Medicine
Rush Medical College
Chairman, Department of Emergency Medicine
Cook County Health and Hospital System
Chicago, Illinois

---

This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contradictions, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

LWW.com

To my family, friends, mentors, and colleagues, and to the many residents and students who continue to teach me so much.
Allan B. Wolfson, MD

To my wife Nicola and my children, Jared and Joanna, for their patience and support of my time-consuming endeavors; and to my parents, Rene and Charlotte, for their earliest support of my career aspirations.
Robert L. Cloutier, MD, MCR

To Lisa, Eric, and Adam for the love and support they continue to give me. And to the residents and faculty at UCSF Fresno for making my job so much fun for so many years.
Gregory W. Hendey, MD

Thanks to the authors for sharing their valuable insight and wisdom; to Beth, Eric, Ali and Amanda for their never-ending understanding and love; and to the faculty and residents at Hennepin County Medical Center who have taught me so much. Special thanks to Ann for picking me for her program, not so many years ago.
Louis J. Ling, MD

To Cathy, Sofia, and Sam for being so supportive. And to the memory of my father, John F. Rosen, MD. And to the residents and faculty at Beth Israel Deaconess Medical Center with whom I am proud to work.
Carlo L. Rosen, MD

This book is dedicated to my wife Anna and my children, Jacob and Isaac. Without their support and love, nothing would be possible.
Jeffrey J. Schaider, MD

Mount Sinai Hospital
New York, New York

Thomas Grosheider, MD
Emergency Medicine Specialist
Department of Emergency Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Sandra Grossman, MD, MS

Associate Professor of Medicine
Harvard Medical School
Vice Chair for Health Care Quality
Director of Observation Medicine
Department of Emergency Medicine
Harvard Medical Faculty Physicians
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Shamai A. Grossman, MD, MS
Associate Professor of Medicine
Harvard Medical School
Vice Chair for Health Care Quality
Director of Observation Medicine
Department of Emergency Medicine
Harvard Medical Faculty Physicians
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Gregory T. Guldner, MD, MS
Director of Research Education
Associate Professor
Department of Emergency Medicine
Loma Linda University Medical Center & Children's Hospital
Loma Linda, California

Abigail Hankin-Wei, MD, MPH
Assistant Professor
Department of Emergency Medicine
Emory University
Atlanta, Georgia

W. Ricks Hanna, Jr., MD
Pediatric Emergency Medicine Specialist
Pediatric Emergency Department
LeBonheur Children's Hospital
Memphis, Tennessee

Matt Hansen, MD
Assistant Professor
Department of Emergency Medicine
Oregon Health and Science University
Portland, Oregon

Carson R. Harris, MD
Professor Emeritus
Department of Emergency Medicine
University of Minnesota
Minneapolis, Minnesota

N. Stuart Harris, MD, MFA
Assistant Professor of Surgery
Department of Emergency Medicine
Harvard Medical School
Chief
Division of Wilderness Medicine
Department of Emergency Medicine
Massachusetts General Hospital
Boston, Massachusetts

Danielle Hart, MD
Assistant Professor of Emergency Medicine
University of Minnesota Medical School
Director of Interdisciplinary Simulation Center
Associate Emergency Medicine Program Director
Hennepin County Medical Center
Minneapolis, Minnesota

David Hartman, MD
Assistant Professor
Core Faculty
Western Michigan School of Medicine Emergency
Residency Program
Homer Stryker Western Michigan School of Medicine
Staff Physician

Bronson Methodist Hospital
Kalamazoo, Michigan

Richard S. Hartoch, MD
Assistant Professor
Department of Emergency Medicine
Oregon Health Sciences University
Portland, Oregon
Asistant Professor
Department of Emergency Medicine
Veterans Affairs Medical Center
Portland Oregon

Stephen C. Hartsell, MD
Professor (Clinical) of Surgery
Director of Education and Global Health Projects
Division of Emergency Medicine
Department of Surgery
University of Utah School of Medicine
Salt Lake City, Utah

Micelle J. Haydel, MD
Clinical Associate Professor of Medicine
Program Director, LSU Emergency Medicine Residency
Louisiana State University Health Science Center
New Orleans, Louisiana

Stephen R. Hayden, MD
Professor of Clinical Medicine
Program Director, Residency Program
Department of Emergency Medicine
University of California
Editor-in-Chief, *Journal of Emergency Medicine*
Medical Center
San Diego, California

Kennon Heard, MD
Associate Professor

Department of Emergency Medicine
University of Colorado School of Medicine
Attending Physician
Emergency Medicine
University of Colorado Hospital
Aurora, Colorado

Benjamin S. Heavrin, MD, MBA
Assistant Professor
Emergency Medicine
Vanderbilt University Medical Center
Nashville, Tennessee

Tarlan Hedayati, MD
Assistant Professor
Department of Emergency Medicine
Rush Medical College
Assistant Program Director
Department of Emergency Medicine
John H. Stroger, Jr. Hospital of Cook County
Chicago, Illinois

Alan C. Heffner, MD
Associate Clinical Professor
University of North Carolina
School of Medicine
Director of Medical ICU
Department of Emergency Medicine
Department of Internal Medicine
Carolinas Medical Center
Charlotte, North Carolina

Robin R. Hemphill, MD, MPH
Chief Patient and Risk Awareness Officer
Veterans Health Administration
Director
Veterans Affairs National Center for Patient Safety

Ann Arbor, Michigan

Sean O. Henderson, MD
Vice Chair
Department of Emergency Medicine
University of Southern California
University of Southern California Medical Center
Los Angeles, California

Gregory W. Hendey, MD
Professor and Chief of Emergency Medicine
UCSF Fresno Medical Education Program
Community Regional Medical Center
Fresno, California

Marissa A. Hendrickson, MD
Assistant Professor
Department of Pediatrics
University of Minnesota Medical School
Pediatric Emergency Medicine Physician
University of Minnesota Amplatz Children's Hospital
Minneapolis, Minnesota

Phyllis L. Hendry, MD
Associate Professor
Departments of Pediatrics and Emergency Medicine
University of Florida Health Science Center
Pediatric Emergency Medicine Rotation Coordinator
Department of Emergency Medicine
Shands Jacksonville
Jacksonville, Florida

Philip L. Henneman, MD
Professor of Emergency Medicine
Baystate Medical Center
Springfield, Massachusetts
Tufts University School of Medicine
Boston, Massachusetts

Martin I. Herman, MD
Professor, Pediatrics
Florida State University
Attending, Pediatric Emergency Medicine
Sacred Heart Children's Hospital
Pensacola, Florida

Robert S. Hockberger, MD
Professor of Clinical Medicine
Department of Medicine/Emergency Medicine
David Geffen School of Medicine at UCLA
Westwood, California
Chair Emeritus
Department of Emergency Medicine
Harbor-UCLA Medical Center
Torrance, California

Jerome R. Hoffman, MD, MA
Professor
Department of Medicine/Emergency Medicine
University of California Los Angeles School of Medicine
Attending Physician
Emergency Medicine Center
University of California Los Angeles Center for the Health Sciences
Los Angeles, California

Robert S. Hoffman, MD
Professor of Emergency Medicine and Medicine
Director, Division of Medical Toxicology
Departments of Emergency Medicine and Medicine
NYU School of Medicine
New York, New York

Judd E. Hollander, MD
Associate Dean for Strategic Health Initiatives
Sidney Kimmel Medical College
Vice Chair, Finance and Healthcare Enterprises

Department of Emergency Medicine
Thomas Jefferson University
Philadelphia, Pennsylvania

James F. Holmes, MD, MPH
Associate Professor
Department of Emergency Medicine
UC Davis School of Medicine
Sacramento, California

Christopher P. Holstege, MD
Professor
Departments of Emergency Medicine and Pediatrics
University of Virginia School of Medicine
Director
Blue Ridge Poison Center
University of Virginia Health System
Charlottesville, Virginia

Jeffrey Hom, MD, MPH
Associate Director of Research
Pediatric Emergency Department
Clinical Associate Professor of Pediatrics and Emergency Medicine
Departments of Pediatrics and Emergency Medicine
Stony Brook University School of Medicine
Stony Brook, New York

Mark A. Hostetler, MD, MPH
Professor, Department of Child Health
University of Arizona College of Medicine
Associate Division Chief, Pediatric Emergency Medicine
Phoenix Children's Hospital
Phoenix, Arizona

Debra Houry, MD, MPH
Vice Chair for Research
Department of Emergency Medicine
Emory University

Atlanta, Georgia

Hoori Hovanessian, MD
Associate Medical Director, Emergency Department
EDAP Director
Presbyterian Intercommunity Hospital
Whittier, California

John M. Howell, MD
Clinical Professor
Department of Emergency Medicine
The George Washington University
Washington, DC
Director of Academic Affairs
Department of Emergency Medicine
INOVA Fairfax Hospital/BestPractices, Inc.
Falls Church, Virginia

David S. Howes, MD
Professor
Department of Medicine and Pediatrics
University of Chicago
Program Director Emeritus
Section of Emergency Medicine
University of Chicago Medical Center
Chicago, Illinois

J. Stephen Huff, MD
Professor of Emergency Medicine and Neurology
Department of Emergency Medicine
University of Virginia
Attending Physician
Department of Emergency Medicine
University of Virginia Hospital
Charlottesville, Virginia

Jennifer C. Huffman, MD
Pediatric Neurologist

Randall Children's Hospital
Portland, Oregon

Jason Imperato, MD, MBA
Assistant Professor
Department of Medicine
Harvard Medical School
Boston, Massachusetts
Director of Operations
Department of Emergency Medicine
Mount Auburn Hospital
Cambridge, Massachusetts

Christine B. Irish, MD
Associate Medical Director
Director of Emergency Ultrasound
Department of Emergency Medicine
Maine Medical Center
Portland, Maine

Alexander Isakov, MD, MPH
Executive Director
Office of Critical Event Preparedness and Response
Emory University
Associate Professor and Director
Section of Prehospital and Disaster Medicine
Department of Emergency Medicine
Emory University School of Medicine
Atlanta, Georgia

Kenneth V. Iserson, MD, MBA
Professor Emeritus
Department of Emergency Medicine
The University of Arizona
Tucson, Arizona

Paul Ishimine, MD
Associate Clinical Professor

Departments of Emergency Medicine and Pediatrics
UC San Diego Health System
Fellowship Director
Division of Emergency Medicine
Rady Children's Hospital, San Diego
San Diego, California

Anja K. Jaehne, MD
Research Fellow
Department of Emergency Medicine
Henry Ford Hospital
Detroit, Michigan

Andy Jagoda, MD
Professor and Chair
Department of Emergency Medicine
Mount Sinai School of Medicine
New York, New York

Ashika Jain, MD
Assistant Professor
Emergency Department
SUNY Downstate Medical Center
Physician
Emergency Medicine/General Surgery
Kings County Hospital Center
Brooklyn, New York

Nazreen Jamal, MD
Assistant Professor
Departments of Pediatrics and Emergency Medicine
George Washington University School of Medicine and Health Services
Attending Physician
Emergency Medicine
Children's National Medical Center
Washington, DC

David Jerrard, MD
Associate Professor
Department of Emergency Medicine
University of Maryland
Baltimore, Maryland

Paul Jhun, MD
Assistant Clinical Professor of Emergency Medicine
Department of Emergency Medicine
University of California, San Francisco
San Francisco, California

Ian D. Jones, MD
Associate Professor
Department of Emergency Medicine
Vanderbilt University Medical Center
Nashville, Tennessee

Alan E. Jones, MD
Professor
Emergency Medicine
University of Mississippi Medical Center
Vice Chairman
Research Director
Emergency Medicine
University of Mississippi Medical Center
Jackson, Mississippi

Michael S. Joo, MD
Ultrasound Director
University of Illinois Mercy Hospital
Chicago, Illinois

Jaime M. Jordan, MD
Clinical Instructor of Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California
Medical Education Fellow

Emergency Medicine
Harbor-UCLA Medical Center
Torrance, California

Madeline Matar Joseph, MD
Professor of Emergency Medicine and Pediatrics
Assistant Chair of Pediatrics
Department of Emergency Medicine
Chief, Pediatric Emergency Medicine Division
Medical Director, Pediatric Emergency Department
University of Florida Health Science Center—Jacksonville
Jacksonville, Florida

Amy H. Kaji, MD, PhD
Associate Clinical Professor
Department of Medicine
David Geffen School of Medicine at UCLA
Los Angeles, California
Associate Clinical Professor
Department of Emergency Medicine
Harbor-UCLA Medical Center
Torrance, California

Ejaaz A. Kalimullah, MD
Assistant Professor
Division of Pulmonary and Critical Care Medicine
Department of Emergency Medicine
Loyola University Stritch School of Medicine
Maywood, Illinois

Nicholas C. Kanaan, MD
Division of Emergency Medicine
Department of Surgery
University of Utah
Salt Lake City, Utah

Dana M. Kaplan, MD
Child Abuse Fellow

Department of Pediatrics
Warren Alpert Medical School of Brown University
Department of Pediatrics
Hasbro Children's Hospital
Providence, Rhode Island

Richard M. Kaplan, MD, MS
Allegheny General Hospital
Vice Chair of Academic Affairs
Clerkship Director
Pittsburgh, Pennsylvania
Adjunct Clinical Professor
Emergency Medicine
Drexel University College of Medicine
Temple University School of Medicine
Philadelphia, Pennsylvania

John S. Kashani, DO
Emergency Medicine Attending
Director of Toxicology Services
St. Josephs Regional Medical Center
Patterson, New Jersey

Kenneth D. Katz, MD
Medical Toxicology Section
Department of Emergency Medicine
Lehigh Valley Health Network
Allentown, Pennsylvania

John F. Kelly, DO
Professor
Department of Emergency Medicine
Jefferson Medical College
Associate Chair
Department of Emergency Medicine
Albert Einstein Medical Center
Philadelphia, Pennsylvania

Naghma S. Khan, MD
Associate Professor
Departments of Pediatrics and Emergency Medicine
Emory University School of Medicine
Chief
Department of Emergency Medicine
Children's Healthcare of Atlanta
Atlanta, Georgia

Basem F. Khishfe, MD
Ultrasound Division
Department of Emergency Medicine
John H. Stroger, Jr. of Cook County
Chicago, Illinois

Brent R. King, MD, MMM
Chief Medical Officer and Physician in Chief
Nemours/Alfred I. DuPont Hospital for Children
Wilmington, Delaware

Rudy J. Kink, MD
Assistant Professor
Department of Pediatrics
University of Tennessee
Le Bonheur Children's Medical Center
Memphis, Tennessee

Niranjan Kissoon, MD
University of British Columbia and British Columbia Children's Hospital Professor
Acute and Critical Care, Global Child Health Department of Pediatrics
Faculty of Medicine
The University of British Columbia
Vice President
Medical Affairs
British Columbia Children's Hospital

Vancouver, Canada

Nicholas E. Kman, MD
Associate Professor
Department of Emergency Medicine
The Ohio State University College of Medicine
Columbus, Ohio

Kevin J. Knoop, MD, MS
Assistant Professor
Military and Emergency Medicine
Uniformed Services University of the Health Sciences
Bethesda, Maryland
Commanding Officer
USNS COMFORT Medical Treatment Facility
Norfolk, Virginia

Christine E. Koerner, MD
Associate Professor of Emergency Medicine
Chief of the Division of Pediatric Emergency Medicine
University of Texas Medical School at Houston
Children's Memorial Hermann Hospital-Houston
Houston, Texas

Paul Kolecki, MD
Associate Professor
Department of Emergency Medicine
Jefferson Medical College
Attending Physician
Department of Emergency Medicine
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Maybelle Kou, MD
Associate Clinical Professor
Department of Emergency Medicine
George Washington University School of Medicine
Washington, DC

Fellowship Director, Aliteri Pediatric Emergency Medicine Fellowship
Department of Emergency Medicine
Falls Church, Virginia

Richard S. Krause, MD
Clinical Assistant Professor
Emergency Medicine
University at Buffalo, School of Medicine and Biomedical Sciences
Buffalo, New York

Lara K. Kulchycki, MD
Clinical Instructor
Division of Emergency Medicine
Department of Surgery
Stanford University School of Medicine
Stanford, California
Assistant Medical Director
Department of Emergency Medicine
Santa Clara Valley Medical Center
San Jose, California

Nathan Kuppermann, MD, MPH
Professor
Departments of Emergency Medicine and Pediatrics
Bo Tomas Brofeldt Endowed Chair
Department of Emergency Medicine
UC Davis School of Medicine
Principal Investigator
PRIME Node
Pediatric Emergency Care Applied Research Network (PECARN)
Sacramento, California

Manon Kwon, MD
Assistant Professor
Department of Emergency Medicine
Keck School of Medicine of USC

Clinical Faculty
Emergency Medicine, Los Angeles County
Los Angeles, California

Joseph Lang, MD
Assistant Professor
Department of Emergency Medicine
Eastern Virginia Medical School
Staff Physician
Emergency Physicians of Tidewater
Norfolk, Virginia

Patrick M. Lank, MD
Instructor
Department of Emergency Medicine
Northwestern University
Feinberg School of Medicine
Chicago, Illinois

James L. Larson Jr., MD
Medical Director
Department of Emergency Medicine
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Bonnie Lau, MD
Clinical Instructor
Department of Emergency Medicine
University of California, San Francisco
Medical Education Fellow
Department of Emergency Medicine
UCSF Medical Center
San Francisco, California

Lois Kaye Lee, MD, MPH
Assistant Professor
Department of Pediatrics
Harvard Medical School

Attending Physician
Department of Medicine
Boston Children's Hospital
Boston, Massachusetts

Eric Legome, MD
Professor
Clinical Emergency Medicine
SUNY Downstate College of Medicine
Chief
Department of Emergency Medicine
Kings County Hospital Center
Brooklyn, New York

Jerrold B. Leikin, MD
Clinical Professor of Medicine
University of Chicago Pritzker School of Medicine
Chicago, Illinois
Director of Medical Toxicology
North Shore University Health Systems OMEGA
Glenbrook Hospital
Glenview, Illinois

Christopher A. Lewandowski, MD
Clinical Professor of Emergency Medicine
Department of Emergency Medicine
Wayne State University
Residency Director
Vice Chair
Department of Emergency Medicine
Henry Ford Hospital
Detroit, Michigan

Edward K. Lew, MD
Clinical Instructor
Division of Emergency Medicine
Stanford University School of Medicine

Stanford, California

Matthew R. Lewin, MD, PhD
Director
Center for Exploration & Travel Health
Institute for Biodiversity Science and Sustainability
California Academy of Sciences
San Francisco, California

Trevor Lewis, MD
Assistant Professor
Department of Emergency Medicine
Rush Medical College
Medical Director
Department of Emergency Medicine
John H. Stroger, Jr. Hospital of Cook County
Chicago, Illinois

Rhett Lieberman, MD, MPH
Assistant Professor of Pediatrics
University of Pittsburgh School of Medicine
Division of Pediatric Emergency Medicine
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Eric W. Ling, MD, MA
Attending Faculty Emergency Physician
Department of Emergency Medicine
Regions Hospital
Minneapolis, Minnesota

Louis J. Ling, MD
Professor of Emergency Medicine
University of Minnesota Medical School
Medical Toxicologist
Hennepin Regional Poison Center
Minneapolis, Minnesota
Senior Vice President for Hospital-based Accreditation

Accreditation Council for Graduate Medical Education
Chicago, Illinois

Jeffrey F. Linzer Sr., MD
Associate Professor
Department of Pediatrics and Medicine

Assistant Dean
Jefferson Medical College
Chief Academic Officer
Office of Academic Affairs
Einstein Healthcare Network
Philadelphia, Pennsylvania

Mark S. McIntosh, MD
Associate Professor
Department of Emergency Medicine
Division of Pediatric Emergency Medicine
College of Medicine–Jacksonville

University of Florida
Jacksonville, Florida

Margaret McKenzie, MD
Assistant Professor of Obstetrics and Gynecology
Obstetrics and Gynecology
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University
Head
Section of Gynecology
Obstetrics and Gynecology
Cleveland Clinic
Cleveland, Ohio

Moss Mendelson, MD
Associate Professor
Department of Emergency Medicine
Eastern Virginia Medical School
Attending Physician
Emergency Physicians of Tidewater
Norfolk, Virginia

Leslie Mihalov, MD
Division Chief
Associate Professor of Pediatrics
The Ohio State University
Section Chief
Pediatric Emergency Medicine
Nationwide Children's Hospital
Colmbus, Ohio

James R. Miner, MD
Chief of Emergency Medicine
Hennepin County Medical Center
Professor of Emergency Medicine
University of Minnesota Medical School
Minneapolis, Minnesota

Alicia B. Minns, MD
Assistant Clinical Professor
Department of Emergency Medicine
University of California, San Diego
San Diego, California

Rakesh D. Mistry, MD, MS
Associate Professor of Pediatrics
Department of Pediatrics
University of Colorado School of Medicine
Attending Physician
Section of Emergency Medicine
Children's Hospital
Denver, Colorado

Katherine M. Mizelle, MD
Associate Professor
Department of Pediatrics
The Ohio State University
The Heart Center
Nationwide Children's Hospital Clinical
Columbus, Ohio

Cynthia Mollen, MD
Associate Professor
Department of Pediatrics
Perelman School of Medicine
University of Pennsylvania
Attending Physician
Division of Emergency Medicine
Department of Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Ernest E. Moore, MD
Professor
Department of Surgery

University of Colorado School of Medicine
Attending Surgeon
Denver Health Medical Center
Denver, Colorado

Johanna C. Moore, MD
Assistant Professor
Department of Emergency Medicine
University of Minnesota
Attending Faculty Emergency Physician
Department of Emergency Medicine
Hennepin County Medical Center
Minneapolis, Minnesota

Gregory J. Moran, MD
Professor of Clinical Medicine
University of California Los Angeles School of Medicine
Department of Emergency Medicine and Division of Infectious Diseases
Olive View-UCLA Medical Center
Los Angeles, California

Maria Moreira, MD
Program Director
Denver Health Residency in Emergency Medicine
Associate Professor
University of Colorado School of Medicine
Denver, Colorado

Lawrence Mottley, MD, MHSA
Assistant Professor
Department of Emergency Medicine
Harvard Medical School
Vice Chairman
Department of Emergency Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts

William R. Mower, MD, PhD
Professor
Department of Medicine
UCLA Emergency Medicine Center
Attending Physician
Department of Emergency Medicine
Ronald Reagan UCLA Medical Center
Los Angeles, California

Michael F. Murphy, MD
Chair
Department of Anesthesiology and Pain Medicine
University of Alberta
Zone Chief
Anesthesiology and Pain Medicine
Edmonton Zone
Edmonton, Alberta, Canada

Paul I. Musey, MD
Clinical Instructor
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, North Carolina

Kristine A. Nanagas, MD
Assistant Professor
Emergency Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Christian M. Neff, MD, MPH
Utah Emergency Medicine Physician
Murray, Utah

Lewis S. Nelson, MD
Professor of Emergency Medicine
Director, Fellowship in Medical Toxicology
New York University School of Medicine

New York, New York

Lauren M. Nentwich, MD
Assistant Professor
Department of Emergency Medicine
Boston University
Attending Physician
Department of Emergency Medicine
Boston Medical Center
Boston, Massachusetts

Ken J. Neuburger, MD
Clinical Assistant Professor
Department of Emergency Medicine
Thomas Jefferson University
Attending Physician
Department of Emergency Medicine
Co-Director of the Chest Pain Center
Director of Travel Medicine and Immunization Services
Director of Observation Unit (CDU)
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Ann P. Nguyen, MD
Clinical Assistant Professor
Department of Emergency Medicine
UMDNJ-New Jersey Medical School
Newark, New Jersey
Attending Physician
Emergency Trauma Department
Hackensack University Medical Center
Hackensack, New Jersey

Constance G. Nichols, MD, MS
Clinical Associate Professor
Department of Emergency Medicine
University of Massachusetts Medical School

Attending Physician
Department of Emergency Medicine
UMass Memorial Medical Center
Worcester, Massachusetts

Flavia Nobay, MD
Associate Professor of Emergency Medicine
Program Director
Department of Emergency Medicine
University of Rochester
Rochester, New York

Erik K. Nordquist, MD
Assistant Professor
Department of Emergency Medicine
Rush University
Assistant Program Director
Department of Emergency Medicine
Cook County Hospital
Chicago, Illinois

Valerie C. Norton, MD
Medical Director
Scripps Mercy Emergency Department
President
Pacific Emergency Providers
San Diego, California

Michele M. Nypaver, MD
Associate Professor
Department of Emergency Medicine
Department of Pediatrics
University of Michigan Health System
Ann Arbor, Michigan

Jennifer A. Oakes, MD
Associate Professor
Department of Emergency Medicine

Albany Medical College
Albany, New York

Karen J. O'Connell, MD
Medical Assistant Professor of Pediatrics and Emergency Medicine
The George Washington University School of Medicine and Health Sciences
Attending Physician
Pediatric Emergency Medicine
Division of Emergency Medicine
Children's National Medical Center
Washington, DC

Glenn R. Oettinger, PharmD
Clinical Specialist
Department of Emergency Medicine
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Jonathan S. Olshaker, MD
Professor and Chairman
Department of Emergency Medicine
Boston University School of Medicine
Chief
Department of Emergency Medicine
Boston Medical Center
Boston, Massachusetts

Lila N. O'Mahony, MD
Associate Professor
Department of Pediatrics
University of Washington
Attending Physician
Department of Emergency Medicine
Seattle Children's Hospital
Seattle, Washington

Jennifer A. Oman, MD, RMDS

Associate Clinical Professor
Department of Emergency Medicine
University of California, Irvine
Irvine, California
Program Director
Department of Emergency Medicine
University of California, Irvine
Orange, California

Joseph P. Ornato, MD
Professor and Chairman
Department of Emergency Medicine
Virginia Commonwealth University
Virginia Commonwealth University Health System
Richmond, Virginia

Benjamin S. Orozco, MD
Assistant Professor
Department of Emergency Medicine
University of Minnesota
Faculty Physician
Department of Emergency Medicine
Hennepin County Medical Center
Minneapolis, Minnesota

David T. Overton, MD, MBA
Professor and Chairman
Department of Emergency Medicine
Western Michigan University School of Medicine
Kalamazoo, Michigan

S. Margaret Paik, MD
Associate Professor
Department of Pediatrics
The University of Chicago
Department of Pediatrics
Comer Children's Hospital

Chicago, Illinois

Lisa R. Palivos, MD
Assistant Professor
Department of Emergency Medicine
Rush Medical College
Attending Physician
Department of Emergency Medicine
John H. Stroger Jr. Hospital of Cook County
Chicago, Illinois

Anuj A. Parikh, MD
Clinical Assistant Professor
Department of Emergency Medicine
University of Tennessee
College of Medicine Chattanooga
Chattanooga, Tennessee

Paul M. Paris, MD, UD (Hon.)
Professor Emeritus
Department of Emergency Medicine
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Denis R. Pauze, MD
Associate Professor of Emergency Medicine and Pediatrics
Department of Emergency Medicine
Albany Medical College
Vice Chair—Operation
Albany Medical Center
Albany, New York

Abigail R. Pease, MD
Department of Emergency Medicine
Alameda County Medical Center
Oakland, California

Don W. Penney, MD

Professor of Emergency Medicine
Medical College of Georgia
Augusta, Georgia

Andrew D. Perron, MD
Professor and Residency Program Director
Department of Emergency Medicine
Maine Medical Center
Portland, Maine

Shawna J. Perry, MD
Associate Professor, Associate Chair
Department of Emergency Medicine
Virginia Commonwealth University School of Medicine
Director
Patient Safety Systems Engineering
Virginia Commonwealth Health Systems
Richmond, Virginia

Ryan C. Petering, MD, CAQSM
Assistant Professor
Department of Family Medicine
Oregon Health & Sciences University
Portland, Oregon

Anne L. Peters, MD
Director
Clinical Diabetes Programs
Professor, Keck School of Medicine of USC
Los Angeles, California

Kelli Petronis, MD
Assistant Professor
Department of Pediatrics
Eastern Virginia Medical School
Pediatric Emergency Medicine
Children's Hospital of the King's Daughters
Norfolk, Virginia

Raymond Pitetti, MD
Associate Professor of Pediatrics
Associate Division Chief
Department of Pediatrics
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, Pennsylvania

Anthony F. Pizon, MD
Associate Professor
Department of Emergency Medicine
University of Pittsburgh School of Medicine
Chief
Medical Toxicology
Emergency Medicine
UPMC Presbyterian Hospital
Pittsburgh, Pennsylvania

Rick Place, MD
Associate Clinical Professor
Emergency Medicine
George Washington University
Washington, DC
Emergency Medicine
Inova Fairfax Hospital
Falls Church, Virginia

Timothy F. Platts-Mills, MD, MSc
Assistant Professor
Department of Emergency Medicine
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Peter T. Pons, MD
Professor Emeritus
Department of Emergency Medicine
The School of Medicine at University of Colorado, Denver
Department of Emergency Medicine

Denver Health Medical Center
Denver, Colorado

Erika L. Powell, MD
Medical Director
Emergency Department
Heart of Lancaster Regional Medical Center
Lancaster, Pennsylvania

Susan B. Promes, MD, MBA
Professor and Chair of Emergency Medicine
Department of Emergency Medicine
Penn State University
Milton S. Hershey Medical Center
Hershey, Pennsylvania

Dan Quan, DO
Clinical Assistant Professor of Emergency Medicine
University of Arizona College of Medicine
Attending Physician, Medical Toxicologist
Department of Emergency Medicine
Maricopa Medical Center,
Phoenix, Arizona

Nadeem U. Qureshi, MD
Associate Professor
Department of Pediatrics
St. Louis University School of Medicine
Pediatric Attending
Department of Emergency Medicine
Cardinal Glennon Children's Hospital
St. Louis, Missouri

Dunisha G. Ranasuriya, MD
Assistant Professor
Emergency Medicine
Cooper Medical School of Rowan University
Attending Physician

Pediatric Emergency Medicine
Cooper University Hospital
Camden, New Jersey

Cyrus Rangan, MD
Director, Toxicology and Environmental Assessment
Los Angeles County Department of Public Health
Keck School of Medicine of USC
Medical Toxicology Consultant
Children's Hospital of Los Angeles
Los Angeles, California

Joseph Ravera, MD
Department of Emergency Medicine
Harbor-UCLA Medical Center
Torrance, California

Eric F. Reichman, PhD, MD
Associate Professor of Emergency Medicine
Medical Director of the Surgical and Clinical Skills Center
Department of Emergency Medicine
University of Texas Health Science Center at Houston-Medical School
Attending Physician
Department of Emergency Medicine
Memorial Hermann Hospital-TMC
Houston, Texas

Landen Rentmeester, MD
Assistant Clinical Professor
Department of Emergency Medicine
Division of Medical Toxicology
University of California San Diego
San Diego, California

Marc C. Restuccia, MD
Associate Clinical Professor of Emergency Medicine
University of Massachusetts Medical School

Medical Director
Life Flight
UMass Memorial Medical Center
Worcester, Mass

Clifford Rice, MD
Co-Director Emergency Ultrasound
Associate Program Director
NorthShore University HealthSystem
Division of Emergency Medicine
Clinical Assistant Professor
University of Chicago
Pritzker School of Medicine
Chicago, Illinois

Emanuel P. Rivers, MD, MPH
Vice Chairman and Research Director
Department of Emergency Medicine
Attending Staff
Emergency Medicine and Surgical Critical Care

Northwestern Memorial Hospital
Chicago, Illinois

Preface

This sixth edition of *Harwood-Nuss' Clinical Practice of Emergency Medicine* continues in the tradition of its predecessors as an up-to-date, authoritative, and concise single-volume source that covers essentially all areas of emergency medicine. It serves as a ready reference for the clinician at the bedside, and also as an educational resource for trainees and more experienced emergency medicine practitioners.

Our goal has been to produce an eminently readable book that emphasizes critical thinking in everyday emergency practice. The contributing authors are practicing emergency physicians with years of practical bedside experience, impressive academic qualifications, and wide-ranging expertise in their subjects. As in previous editions, the chapters are clinically focused and practical, not only highlighting traditional teaching and accepted evidence-based practice but also examining what remains controversial or under investigation.

As emergency medicine has changed, so has this book. The table of contents has been revised and many chapters have been completely rewritten to take into account new approaches to many emergency conditions. The most popular and distinctive features of the book, including the **Common Pitfalls** section and the **Critical Interventions** summary, have been expanded to include a **Key Testing** section in almost every chapter.

The entire text is available in an online edition which includes additional text, tables, and figures, as well as a large set of accompanying review questions and answers, now numbering more than 1,200 expertly edited items, which provides an unmatched additional resource for study or review.

Finally, this preface would be incomplete if it did not acknowledge our debt to Dr. Ann Harwood-Nuss, who served as editor-in-chief for the first three editions of this book. Her vision and dedication continue to inspire our efforts.

Allan B. Wolfson, MD
Editor-in-Chief

Contents

Introduction: The Approach to the Patient in the Emergency Department

Robert L. Wears

SECTION I • Resuscitation

JEFFREY J. SCHAIDER

1 Airway Management

Tarlan Hedayati and Michael F. Murphy

2 Airway Procedures

Eric F. Reichman

3 Cardiopulmonary Arrest

Christopher Ross and Theresa M. Schwab

4 Shock

Emanuel P. Rivers, David Amponsah, John Gallien, and Anja K. Jaehne

5 Vascular Access

Eric F. Reichman

SECTION II • High-Risk Chief Complaints

CARLO L. ROSEN

6 Chest Pain

Judd E. Hollander

7 Abdominal Pain

Diane M. Birnbaumer and Daniel P. Runde

8 Shortness of Breath

C. Keith Stone

9 Syncope

Shamai A. Grossman and Christopher M. Fischer

10 **Fever**
Sarah A. Sterling and Alan E. Jones

11 **Altered Mental Status and Coma**
J. Stephen Huff and Marcus L. Martin

12 **Headache**
Jonathan A. Edlow

13 **Weakness**
Andy Jagoda

14 **Dizziness**
Jonathan A. Edlow

SECTION III • Pain Management and Procedural Sedation
CARLO L. ROSEN

15 **Acute Pain Management**
Steven Rosenzweig, Bernard L. Lopez, and Glenn Oettinger

16 **Chronic Pain Syndromes**
Michael A. Turturro and Paul M. Paris

17 **Procedural Sedation and Analgesia**
Robert J. Vissers and James R. Miner

SECTION IV • Trauma
CARLO L. ROSEN

PART 1 GENERAL CONSIDERATIONS

18 **General Principles of Trauma**
Eric Legome and Ashika Jain

19 **Trauma Airway Management**
Timothy J. Fortuna and John H. Burton

20 **Traumatic Shock**
Christopher B. Colwell and Ernest E. Moore

21 Wound Management
Judd E. Hollander and Adam J. Singer

PART 2 SPECIFIC INJURIES

22 Head Injuries
James F. Holmes and Cindy H. Chang

23 Maxillofacial Injuries
Katie Sprinkel and Stephen Colucciello

24 Dental Injuries
Kip Benko

25 Eye Trauma
Kevin J. Knoop and William Dennis

26 Blunt Neck Trauma
Edward Ullman

27 Penetrating Neck Trauma
Julie Mayglothling

28 Cervical Spine Fractures
William R. Mower and Jerome R. Hoffman

29 Thoracolumbar Spine Fractures
Amy Kaji and Robert S. Hockberger

30 Spinal Cord Injuries
Brian D. Mahoney

31 Blunt Chest Trauma
Richard L. Byyny

32 Penetrating Chest Trauma
Stephen J. Wolf

33 Blunt Abdominal Trauma
Eric L. Legome and Joseph P. Freedman

34 Penetrating Abdominal Trauma
Michael J. Breyer

35 Genitourinary Trauma
Carrie D. Tibbles

36 Peripheral Vascular Injuries
Maria E. Moreira and Peter T. Pons

PART 3 ORTHOPAEDIC TRAUMA

37 Approach to Musculoskeletal Injuries
Andrew D. Perron and Carl A. Germann

38 Shoulder Injuries
Scott C. Sherman

39 Elbow Injuries
Andrew D. Perron and Carl A. Germann

40 Wrist and Forearm Injuries
James R. Gardner and Carl R. Chudnofsky

41 Hand Injuries
David Q. Bell and Douglas Doehrman

42 Pelvic Fractures
Carrie D. Tibbles and Michael Gibbs

43 Hip and Femur Injuries
Carl A. Germann and Megan L. Fix

44 Knee Injuries
Christine B. Irish and Christopher T. Bowe

45 Ankle and Foot Injuries
Kaushal Shah and Natasha Desai

PART 4 SPECIAL CONSIDERATIONS

46 Burns
Adam J. Singer and Steven Sandoval

47 Replantation
James L. Larson, Jr

48 Acute Compartment Syndrome

Andrew D. Perron, Christopher T. Bowe, and Christine Irish

49 Ballistics
Jason Imperato and Leon D. Sanchez

50 Blast Injuries
David W. Callaway and Leon D. Sanchez

51 Hanging and Strangulation Injuries
Leon D. Sanchez and Richard E. Wolfe

52 Trauma in Pregnancy
Bonnie Lau and Susan B. Promes

53 Trauma in Older Adults
Timothy F. Platts-Mills and Sasha D. Adams

SECTION V • Eye Emergencies
GREGORY W. HENDEY

54 The Eye Examination
Matthew R. Babineau and Leon D. Sanchez

55 Common Ophthalmic Medications
Kimberly Schertzer

56 The Red Eye
Megann Young

57 Corneal Abrasion and Foreign Bodies
Lori A. Weichenthal

58 Acute Vision Loss
Catherine A. Marco

59 Diplopia
Kurt Brueggemann and James A. Comes

60 Acute Eye Infections
Tricia C. Loo

61 Acute Angle-Closure Glaucoma
Stacy Sawtelle

SECTION VI • ENT and Dental Emergencies

GREGORY W. HENDEY

62 Dental Emergencies

Rawnica L. Ruegner

63 Head and Neck Infections

Manon Kwon

64 Temporomandibular Pain and Dislocation

Darria Long Gillespie

65 Upper Airway Obstruction

Louisa S. Canham and Jonathan Fisher

66 Sore Throat

Michael F. Murphy

67 Sinusitis and Rhinitis

Hagop M. Afarian

68 Ear Infections in Adults

Michael Cole and Sukhjit S. Takhar

69 Epistaxis

Trevor J. Lewis

70 Vertigo

Brian Chinnock

71 Acute Hearing Loss and Tinnitus

Carolyn Chooljian

72 Complications of Tracheostomies

Valerie Dobiesz, Samreen Vora, and Carissa Tyo

SECTION VII • Pulmonary Emergencies

JEFFREY J. SCHAIDER

73 Respiratory Failure

Micelle J. Haydel

74 Pneumonia

Gregory J. Moran and David A. Talan

75 Pleural Effusion
Micelle Haydel

76 Asthma
Lauren M. Smith

77 Chronic Obstructive Pulmonary Disease
David S. Howes and Leah W. Skjei

78 Spontaneous Pneumothorax and Pneumomediastinum
Susan M. Dunmire

79 Pulmonary Embolism
Prathap Sooriyakumaran and Jeffrey A. Tabas

80 Hemoptysis
Sanjay Bhatt

81 Sarcoidosis
Sanjay Bhatt

SECTION VIII • Cardiac Emergencies
JEFFREY J. SCHAIDER

82 Acute Coronary Syndrome
Christopher Ross and Theresa Schwab

83 Congestive Heart Failure and Cor Pulmonale
Christopher I. Doty

84 Bradydysrhythmias
David Hartman and David T. Overton

85 Tachydysrhythmias
Scott R. Votey and Eric Silman

86 Pacemakers and Implantable Cardioverter–Defibrillators
Robert M. Rodriguez

87 Valvular Heart Disease

Joseph P. Ornato

88 **Infective Endocarditis**
Benjamin S. Heavrin, Ian D. Jones, and Corey M. Slovis

89 **Acute Pericarditis and Cardiac Tamponade**
Richard Byyny and Howard A. Bessen

90 **Hypertension**
Philip Shayne and Edward Stettner

SECTION IX • Vascular Emergencies
GREGORY W. HENDEY

91 **Nontraumatic Carotid and Vertebral Artery Disorders**
Brian Chinnock

92 **Thoracic Aortic Dissection and Aneurysm**
Shawna J. Perry

93 **Abdominal Aortic Aneurysm**
Matthew R. Lewin and Stephen P. Samuel

94 **Mesenteric Ischemia**
Stephanie A. Taft

95 **Peripheral Arterial Disease**
Dusadee Sarangarm and Darren Braude

96 **Deep Venous Thrombosis and Thrombophlebitis**
Carolyn Chooljian

97 **Vascular Graft Complications**
Hoori Hovanessian

SECTION X • Gastrointestinal Emergencies
GREGORY W. HENDEY

98 **Esophageal Disorders**
Kathryn A. Volz and Leon D. Sanchez

99 **Upper Gastrointestinal Bleeding**
Michael A. Cole and Sukhjit S. Takhar

100 Lower Gastrointestinal Bleeding
Kenny V. Banh

101 Peptic Ulcer
Dale S. Birenbaum and Justin D. Britton

102 Jaundice
Gus M. Garmel and Tobias D. Barker

103 Acute Diseases of the Biliary Tract
Boris Garber and Lance D. Wilson

104 Hepatitis
Mark J. Ault and Joel M. Geiderman

105 Hepatic Failure and Cirrhosis
Stacie Zelman

106 The Liver Transplant Patient
Douglas W. Lowery-North and Scott R. Votey

107 Pancreatitis
Anuj A. Parikh and David C. Seaberg

108 Appendicitis
Brian K. Snyder

109 Bowel Obstruction
Philip L. Henneman and Susan P. Torrey

110 Hernias
Sharon E. Mace

111 Inflammatory Bowel Disease
Howard A. Werman, Sarah M. Greenberger, and Nicholas E. Kman

112 Diarrhea
Philip N. Salen and Lisa A. Spacek

113 Diverticular Disease
Janak K. Acharya

114 Anorectal Disorders
Wendy C. Coates

115 Gastrointestinal Foreign Bodies
Valerie C. Norton

116 Feeding Tubes
Philip Salen and Steven Solga

SECTION XI • Renal and Urologic Emergencies
GREGORY W. HENDEY

117 Hematuria
H. Gene Hern Jr., Abigail R. Pease, and Nicholas Gavin

118 Acute Kidney Injury
Danielle D. Campagne

119 Chronic Kidney Disease and Dialysis-Related Emergencies
Allan B. Wolfson

120 The Renal Transplant Patient
Louis G. Graff

121 Acute Scrotal Pain
Jonathan E. Davis and Michael A. Silverman

122 Penile Disorders
Douglas L. McGee

123 Urinary Tract Infection
Lara K. Kulchycki

124 Prostatitis
Herbert G. Bivins

125 Fournier Gangrene
Gregory W. Hendey

126 Urolithiasis
Stephen R. Hayden and Michael P. Wilson

127 Urinary Incontinence and Retention
Stephen J. Wolf

128 Genitourinary Stents and Catheters
Jonathan E. Davis

SECTION XII • Gynecologic Emergencies
GREGORY W. HENDEY

129 Pelvic Pain
Joseph C. Schmidt

130 Pelvic Inflammatory Disease
Alfred Sacchetti

131 Vaginal Bleeding in the Nonpregnant Patient
Eric Anderson and Margaret McKenzie

132 Vaginitis
Ericka L. Powell

133 Bartholin Gland Cyst's and Abscess
Flavia Nobay and Ryan P. Bodkin

134 Breast Masses and Infections
Minal Amin and John M. Howell

135 Sexual Assault
Carolyn Sachs

SECTION XIII • Obstetric Emergencies
GREGORY W. HENDEY

136 First-Trimester Vaginal Bleeding
Pamela L. Dyne

137 Ectopic Pregnancy
G. Richard Braen and Richard S. Krause

138 Hyperemesis Gravidarum
Lori Weichenthal

139 Postabortion Complications
Lynne McCullough

140 Hypertensive Disorders of Pregnancy

Jan Marie Shoenberger

141 **Third-Trimester Vaginal Bleeding**
Moss H. Mendelson

142 **Emergency Delivery**
Michael D. Burg

143 **Postpartum Emergencies**
Moss H. Mendelson and Joseph P. Lang

144 **Medical Treatment During Pregnancy**
Ryan P. Bodkin and Nicole M. Acquisto

SECTION XIV • Musculoskeletal Emergencies
GREGORY W. HENDEY

145 **Hand and Wrist Pain**
Gary M. Vilke

146 **Bursitis and Tendinopathy**
Ryan Friedberg

147 **Hand Infections**
Carl R. Chudnofsky and Melanie Loewenthal

148 **Low Back Pain**
David Della-Giustina

149 **Foot Disorders**
Valerie Dobiesz and Carissa Tyo

150 **Monoarticular Arthritis**
Alan C. Heffner

151 **Polyarticular Arthritis**
Richard S. Hartoch

SECTION XV • Neurologic Emergencies
JEFFREY J. SCHAIDER

152 **Organic Brain Syndrome**
Rebecca R. Roberts and Basem F. Khishfe

153 Headache
Benjamin W. Friedman

154 Subarachnoid Hemorrhage
Jonathan A. Edlow

155 Cerebrovascular Disease
Phillip A. Scott

156 Seizures
Andy Jagoda

157 Transient Global Amnesia
Richard M. Kaplan and Michael S. Joo

158 Peripheral Neuropathies
Phyllis A. Vallee and Christopher A. Lewandowski

159 Bell's Palsy and Trigeminal Neuralgia
Ross P. Berkeley

160 Myopathies and Disorders of Neuromuscular Transmission
Erik Nordquist

161 Demyelinating Disease
Edward K. Lew and Don W. Penney

162 Parkinsonism and Other Movement Disorders
Todd A. Taylor

SECTION XVI • Psychiatric Emergencies
JEFFREY J. SCHAIDER

163 Medical Clearance
Kerryann B. Broderick

164 Depression and Suicidal Ideation
Robert S. Hockberger and Joseph Ravera

165 Anxiety Disorders and Panic Attack
James A. Comes, Douglas A. Rund, and Basheer Lotfi-Fard

166 Schizophrenia and Bipolar Disorder

James A. Comes, Douglas A. Rund, and Basheer Lotfi-Fard

167 The Agitated or Violent Patient

Katherine Bakes and Vincent J. Markovchick

168 Factitious Illness, Malingering, and Conversion Disorder

Jeffrey S. Dubin and Mark Smith

169 Bereavement and Grief Reactions

INTRODUCTION

The Approach to the Patient in the Emergency Department

Robert L. Wears

> … in the physician or surgeon, no quality takes rank with imperturbability … Imperturbability means coolness and presence of mind under all circumstances, calmness amid storm, clearness of judgment in moments of grave peril, immobility, impassiveness, or, to use an old and expressive word, *phlegm.* It is the quality which is most appreciated by the laity though often misunderstood by them; and the physician who has the misfortune to be without it, who betrays indecision and worry, and who shows that he is flustered and hurried in ordinary emergencies, loses rapidly the confidence of his patients.
>
> —Sir William Osler, *Æquanimitas*

It is one thing to practice medicine in an emergency department (ED); it is quite another to practice emergency medicine. The effective practice of emergency medicine requires an approach, a way of thinking that differs from other medical specialties.

Its physical limitation to the ED is perhaps the least important of emergency medicine's characteristics. Five factors have led emergency physicians to develop a unique approach to the patient: the pressure of time and volume, the variety of conditions faced, the paucity of information, the limitation of therapeutic options, and the constraint of disposition.

TIME AND VOLUME PRESSURE

More than any other specialists, emergency physicians experience clinical work as turbulent flow in a constricted channel. In a true emergency, seconds to minutes may make the difference between life and death or serious disability. In these situations, emergency physicians, contrary to much of their previous training, must be prepared to "treat first and ask questions later."

Also, the time available for an emergency physician to evaluate and think about any given patient is severely limited by the demands of other patients being managed concurrently. In most practices, during the busiest part of the day an emergency physician has on average only 10 to 15 minutes per patient for evaluation, testing, treatment, disposition, and documentation. Whether this is adequate or not is immaterial; the reality is that no more time is available.

The combination of time and volume pressures forces emergency physicians to be much more aware of priorities among patients. Although trauma surgeons occasionally face triage conditions, emergency physicians are the only practitioners who routinely make (at least mental) triage decisions every day.

VARIETY OF CONDITIONS

As a specialty in breadth rather than depth, emergency physicians must manage a wider variety of conditions than any other specialists, save perhaps family practitioners in remote settings. In addition, unlike other specialists, emergency physicians must shift cognitive frames rapidly. Practicing emergency medicine is like carefully lining up a putt, then dropping the putter, picking up a tennis racket to return a volley or two, quickly sidestepping an onrushing tackler, and then returning to sink the putt.

PAUCITY OF INFORMATION

Emergency physicians frequently deal with episodes of real or perceived crises in patients of whose past course they are unaware. Old records are often unavailable, electronic records may be

available but of doubtful provenance (1), and patients' memories are limited in scope and reliability. The information-gathering options available in the ED are similarly limited. Only a small subset of the vast diagnostic armamentarium is available to the emergency physician within a reasonable time.

LIMITED THERAPEUTIC OPTIONS

Options for treatment are limited as well. Often, emergency physicians can provide only temporizing or symptomatic treatment, whereas definitive management must be deferred to another specialist. In addition, in emergency situations, the tolerance for therapeutic failures or misadventures is more limited than in nonemergencies.

Although one may not realize it when viewing the chaotic, turbulent activity of a busy ED, emergency medicine possesses a certain elegance enforced by these constraints. There is an attractive intellectual simplicity in meeting the challenge of providing timely, accurate care using primarily one's own hands and brain, supplemented by a few, limited laboratory and imaging tests.

CONSTRAINT OF DISPOSITION

Every patient interaction an emergency physician has must soon be ended. This forces emergency physicians to focus on the "bottom line." No matter how uncertain the diagnosis or how much extended observation or testing might help, every patient encounter in the ED ultimately reduces to three binary decisions: Is the patient sick or not sick? If sick, should I treat or not treat? Should I admit or discharge? These questions must be answered despite the lack of definitive information, the lack of time to collect or consider additional information, or the lack of availability of advice from colleagues and consultants.

A FRAMEWORK FOR APPROACHING THE ED PATIENT

There are many sources that outline the mechanics of history taking and physical examination, and this section does not discuss these

areas in detail. Instead, it concentrates on how they are different in emergency medicine.

The first question to be asked on initial approach to a patient in the ED is, “Do I need to resuscitate this patient?” Corollaries to this question are, “How great is the threat?” and “How soon must I act?” The first question is usually answered in the first few seconds at the bedside and is as often based on an overall *gestalt* of the chief complaint and the patient’s general appearance as on specific complaints or vital sign abnormalities.

In true emergencies, the usual sequence of history, physical examination, laboratory testing, and treatment is altered by the need to take rapid action. In the most extreme cases, the sequence becomes treatment, physical examination, laboratory testing, and history.

When action is urgently required, the emergency physician must commit to it unhesitatingly. This requires mental preparedness; there is no time to ponder the benefits and risks of the various options for managing acute upper airway obstruction. The thinking required must be invested ahead of time, and a plan of action internalized by the physician before the situation requiring it arises.

If action is to be effective, it often must be initiated before all the information bearing on the decision is available. This requires a “bias toward action” in the emergency physician’s mind. While this is occasionally a source of criticism from other specialists who fail to understand emergency medicine, in the proper circumstances it can save lives. A simplistic example of bias toward action is putting a patient with chest pain on a cardiac monitor on arrival to the ED; clearly the diagnosis of heart disease has not yet been made, so it is not certain that the monitor is truly “needed,” but we anticipate a potential need and act without waiting for confirmation. A more dramatic example is sudden upper airway obstruction, where the decision to perform a cricothyroidotomy must be made promptly; to wait until the need is clear may be to wait too long.

Part of the art of emergency medicine is the ability to reliably discriminate between cases requiring urgent action and those allowing a more measured approach. Maintaining a bias toward

action should not be used as an excuse for an indiscriminate, “shoot-from-the-hip” approach to the patient; it is a tool that the emergency physician must learn to use effectively.

BEDSIDE EVALUATION

If resuscitation or other urgent interventions are not required, the usual framework for patient evaluation (history, physical, laboratory, treatment, disposition) can be used. However, in the ED, certain factors require more or less emphasis or alteration (Table INT.1).

Table INT.1

Rules to Guide the Bedside Evaluation of the Emergency Department Patient

Introduce yourself to everyone
Shake hands
Sit down
Relieve pain early
Do not interrupt
Provide information
Explain what will happen
Provide updates
Be helpful

Patients and physicians in EDs are generally complete strangers, and thus patients have legitimate questions about the emergency physicians they have just met: Are they capable? Can they be trusted? Consequently, the first task faced by the emergency physician, even before information gathering begins, is to build a working relationship with the patient right away (2).

The initial contact the physician makes should be social—an introduction. This should include everyone in the room, and should be accompanied by physical contact—a handshake or touch. This establishes a tone of personal respect for the patient and helps enlist

the family, if present, in an alliance with the physician. As early as possible the physician should show empathy with the patient by acknowledging recognition of an apparent need. This can be done by an offer to relieve apparent pain, if appropriate.

The body language of the physician–patient encounter is important. Often in the ED, the standing physician presides over the supine, frequently disrobed patient, presenting an authoritarian image that can be threatening to patients. As often as possible, therefore, the physician should sit while conducting the initial interview, ideally bringing his or her head to the same level as the patient's (3). This is especially important in dealing with children, but should not be neglected in adult patients.

The information-gathering phase of the encounter should begin with a general, open-ended approach, such as, "How can I help you?" or "Tell me your story." More direct approaches, such as "What is your problem?" risk being misinterpreted. It is important to remember that both parties, not just the physician, are interested in gathering information at this time. Patients' desires for information, explanation, and reassurance are great, but are seldom met by physicians (4,5). One way emergency physicians can meet this almost insatiable need for information early in the encounter is by commenting about findings during the physical examination: "Your heart sounds normal," or "Your throat looks red" (2).

Given the time pressures of emergency medicine, physicians typically fear losing control of the interview and attempt to keep the patient focused and on target. Observations of physician–patient interactions show that patients are interrupted by the physician on average about 18 seconds after they begin to relate their history, but that if uninterrupted, 80% can get their story out within 1 minute (6). Physicians' time concerns are real, but if the physician dominates the interview, the patient will become passive and volunteer little (6); the physician will then have to spend additional time extracting information later. In addition, the chief complaint may not always be mentioned first; failure to wait for the true chief complaint to emerge can lead to false trails and lost time (2). Considering the gain in rapport with the patient and the potential

for mischief with early interruption, it seems wise for emergency physicians to discipline themselves to be quiet for the first 60 seconds of the interview.

The introduction of electronic records is a potentially intrusive factor in patient–physician communication. Initially there were concerns that physicians might be perceived as paying more attention to the computer than to the patient, although as this technology becomes more ubiquitous, patients will likely come to treat the physician–computer interaction as routine.

However, it is important that the bullet point, checkbox nature of electronic charting not be allowed to prevent the physician and patient from codeveloping the narrative of illness (or injury). Understanding about that nature of a patient's problem is acquired iteratively; early information leads to the development of a tentative structuring and categorization which guides further investigation, but which is itself modified according to newer information; the structure and categories change as understanding improves. But if the full narrative never comes into existence, this cycle of increasing understanding is broken, and the physician is left with a model of the patient's problem that has been prematurely frozen in an unfinished and perhaps even erroneous state (7,8). Thus, it is good practice to take a history and perform a physical examination before interacting with a charting template.

DISPOSITION

Once the initial assessment is complete, the physician should outline the plan to the patient, and should give an honest estimate of about how long it will take. It is also useful to provide some anticipatory guidance about the probable outcome, particularly in complex, chronic problems that are unlikely to be resolved in an ED evaluation. During the wait for laboratory results, consultations, or observation, the patient and family should be updated periodically on progress and asked if there is anything they need.

Finally, once a disposition is reached, the plan should be carefully and clearly communicated to the patient and family. Particularly if

the patient is to be discharged, specific instructions about follow-up and reasons to return to the ED should be covered. Because patients are likely to have difficulty remembering a series of detailed explanations or instructions (9), it is most helpful if they are given instructions in writing. Having a printed instruction sheet does not relieve the physician of the obligation to instruct the patient, but it does help to reinforce those instructions once the patient has left the ED.

A FRAMEWORK FOR DECISION MAKING IN EMERGENCY MEDICINE

Medicine is essentially about resolving ambiguity through action; in emergency medicine, this process is intensified. However, a great deal of medical decision making occurs at a subconscious level where it is inaccessible to the physician. Although formal decision-making models do not describe physicians' mental processes well, they can provide some useful insights into the nature of decision making in the ED.

MANAGEMENT, NOT DIAGNOSIS

Traditionally, medicine has focused on diagnosis as the clinician's central important task. Emergency medicine makes it clear that this is erroneous: In medicine in general, and especially in emergency medicine, the central task is not diagnosis, but management; not so much "what is going on?" as opposed to "what should we do now?" Often a diagnosis cannot be made under the constraints of an ED evaluation; the great insight that emergency physicians have contributed to their colleagues in other specialties is the notion that there need not always be a diagnosis. If one can be made, it is extremely helpful, but if not, decisions must still be made and actions must still be taken.

In addition, patients want more than simply a diagnosis. They want explanation and reassurance. For example, parents will not be satisfied to know that their child's abdominal pain is caused by gastroenteritis; they want to know that it is not appendicitis. Simply

providing the diagnosis, however correct, dismisses the parents' concerns and leaves them unsatisfied. By empathizing with their fears, the physician can strengthen rapport with the family and take a position as their friend and ally, rather than as a remote authority. Thus the intellectual task is to devise a reasonable plan of management, which may include, but not be limited to, making a diagnosis.

DECISION THRESHOLDS

The concept of "decision threshold" (10) clarifies some of the processes at work when emergency physicians make decisions and adds specificity to the often used but somewhat vague concept of "index of suspicion." Consider the following hypothetical scenario of the simplest possible situation in emergency medicine: There is only one disease under consideration and there are only two possible actions—to treat or not treat—based on the emergency physician's assessment of the patient. In this scenario, there are four possible outcomes: The patient either has the disease and may be treated or not treated, or does not have the disease and is treated or not treated. The optimal management decision depends on the values of these outcomes and on the probability that a particular patient (or group of patients) actually has the disease in question.

If the patient is almost certainly nondiseased (i.e., the probability of disease is near zero), then the correct decision is to not treat, because treatment entails costs and risks of its own. Conversely, if the patient surely has the disease (probability near 1), then the correct decision is to treat, because the costs and risks of treatment are outweighed by the negative consequences of failing to treat. Therefore, there must be some *threshold* probability between 0 and 1 at which the decision is a toss-up; that is, either choice will produce about the same outcome. This treatment threshold need not (and often does not) coincide with the diagnostic thresholds that clinicians traditionally have been taught. Consequently, the clinician's task is not necessarily to make a diagnosis, but to judge

whether the probability of disease is clearly over or clearly under the treatment threshold, and to act accordingly.

The threshold approach can be extended to more complex problems. For example, a more realistic scenario allows use of a diagnostic test to improve the physician's initial assessment. Now there are two decision thresholds. At very low probabilities of disease, it is better not to test and not to treat, because the outcome of large numbers of false positives erroneously treated outweighs that of the occasional diseased patient detected. Similarly, at very high probabilities, it is better not to test, but to treat everyone, because the consequences of large numbers of false negatives erroneously denied treatment outweigh the occasional nondiseased patient spared unnecessary treatment. At intermediate probabilities, testing and treating only those patients with a positive test will produce the best overall outcome. Thus, the clinician's task is to decide whether a given patient's probability of disease lies either below the no treat–test threshold, or above the test–treat threshold. Testing is useful only in changing the management decision in the area between the two thresholds. While there may be other benefits to testing besides producing a change in management (e.g., reducing uncertainty or clarifying prognosis) (11), the threshold approach provides a rationale for understanding physicians' differing choices when faced with seemingly similar clinical scenarios.

In framing decision making in this way, it is important to note that a very broad idea of "test" is used. Anything that helps physicians revise their assessments is considered a test in this sense, so therapeutic trials, periods of observation, clinical scoring systems, or practice guidelines could all be considered "tests" because they help physicians sort out the probabilities of diseases. There is interesting evidence that physicians' diagnostic and management performance improves when they can take advantage of the nonverbal cues that accompany face-to-face communication, even though this "test" occurs largely at a subconscious level (12).

One drawback of the threshold concept is that it can taken to the extreme and result in a very narrow, overrational approach to problem solving (13). However, the way in which emergency

physicians resolve the question of whether or not to act (or what actions to take) seems to be by the use of naturalistic or "event-driven" decision making (14). This contrasts strongly with the algorithmic or analytical decision-making process taught in medical school. Naturalistic decision making is effective in settings characterized by ill-defined problems; dynamic, uncertain environments; shifting, unclear, or competing goals; tight but nonlinear or hidden coupling between actions and their effects; time pressure; high stakes; and scant opportunity for learning by trial and error.

The decision-making process can be divided into several phases. First, the physician classifies the current situation as typical or atypical, based on the matching of critical cues to stored patterns or schemata. If the situation is typical, the stored patterns will evoke a customary set of responses. If it is not typical, variations of customary responses are considered first, and then novel, "one-of-a-kind" responses are considered. Clearly, experience is critical in developing a sufficiently rich set of stored schemata such that the vast majority of clinical problems can be recognized and dealt with by such a preplanned response.

Next, the physician engages in serial evaluation of the available courses of action, beginning with the most typical response, and evaluating each by mentally simulating the expected outcomes. Once a sufficiently satisfying action is discovered, it is implemented. In other words, there is generally not a search for the best of all possible responses, but for a sufficiently good response. The payoff for accepting a good, but not necessarily best, response is that decisions can be quick and almost effortless. In fact, a great deal of physicians' expertise seems to lie in their ability to constructively perceive the problem, which seems to lead automatically to a solution without much conscious effort. This contrasts sharply with the slow and laborious analytic approach of exhaustively considering all the possibilities and eliminating them one by one until the best option is identified.

Learning this method of decision making is not easy. It can be gained with experience supplemented by feedback and reflection,

and is generally communicated by narratives of meaningful cases (15). It does not appear to be attainable through application of formal analytical methods. Such methods have their place, but they have not proven useful in helping medical students or residents to become physicians.

Common Pitfalls

There are three common pitfalls in the approach to the patient in the ED.

- The first is tunnel vision. Here the physician, in single-minded pursuit of the disposition, fastens onto a single complaint (typically the first offered) without waiting to be sure that the patient's *chief* complaint has been elicited. A related error is the premature closure of hypothesis generation (e.g., assuming that chest pain is caused by myocardial ischemia without first mentally ruling out the possibilities of aortic dissection, pulmonary embolism, esophageal rupture, or pericarditis). This problem often afflicts the less experienced, who, once having reached a characterization of the problem, are reluctant to reopen consideration of it (16).
- The second pitfall is just the opposite: an inability to see the forest for the trees. Here the physician is unable to rank findings in any order of importance, is reluctant to close off hypothesis generation, or is unable to integrate the findings into a small number of possible explanations. This is frequently manifested by procrastination in decision making, perhaps hidden behind a cascade of laboratory testing. The ability to simultaneously entertain a modest number of possible explanations for the patient's problem without prematurely settling on one, or letting the number in contention grow too large, is the "golden mean" between these two problems.
- The final pitfall is failure to attend to the patient. Time "gained" by failing to attend to the social interaction with patient and family is likely to be lost later, as missing information may not be extracted except by persistent questioning, leaving the

physician at risk of pursuing many false leads before happening across the true trail. More important, perhaps, is to remember that the doctor–patient interaction remains at its most fundamental level a meaningful *social* encounter, on which all healing and care, in the broadest sense, are based.

CHAPTER 1

Airway Management

Tarlan Hedayati and Michael F. Murphy

Airway evaluation and management to ensure continuing and adequate gas exchange remain the first priority of resuscitation, taking precedence over other interventions. Further, it is widely recognized that a conceptual framework focused on rapid airway evaluation, critical action analysis and performance, and facility with an array of airway management techniques minimizes the risk of failure and improves outcome (1).

The failure to maintain a patent airway and the failure to affect adequate gas exchange are the cornerstones of emergency airway management. Decisions regarding how and when the airway will be managed depend on the integration of numerous factors including the skills and knowledge of the physician, the equipment available, the condition of the patient, and the anatomy of the airway.

There are only four ways to provide gas exchange for the patient who is not breathing:

1. Bag–mask ventilation (BMV)
2. Extraglottic device (EGD)
3. Endotracheal intubation (ETI)
4. Surgical airway (usually cricothyrotomy in emergency medicine)

Emergency ETI performed by emergency physicians has been the most discussed, researched, and published over the years (2).

By the early 1970s, ETI had become a skill integral to the practice of emergency medicine. It was generally accomplished either nasally or orally employing varying degrees of brute force. By the mid to late 1990s, most emergency practitioners employed neuromuscular

blockade in some form most of the time to facilitate oral ETI. It had become evident that neuromuscular blockade not only made the technical task of intubation easier and faster but that the complication rates were lower and the success rates higher. However, for many practitioners, the need to evaluate the airway for difficulty and the development of a systematic method of doing so lagged behind the clinical introduction of rapid sequence intubation (RSI). There was also the need to expand the rescue options beyond cricothyrotomy.

BMV, long considered to be the cornerstone of airway management (Chapter 2), is a critically important skill in emergency medicine. However, it has become apparent that BMV is a difficult skill to teach and maintain (3). In recent years, EGDs (e.g., laryngeal mask airways [LMA], King LT Airway), which are easily inserted and highly successful at achieving adequate gas exchange, have increasingly emerged as potential first-line gas exchange techniques.

The current challenges facing emergency airway managers include the following:

- Should EGDs supplant BMV as the first-line airway management technique?
- Which patients *should not* receive paralytics?
- Is cricoid pressure still recommended to prevent passive regurgitation and aspiration of gastric contents?
- How is the airway best rescued in the event intubation and/or ventilation is impossible or has failed?

THE DECISION TO INTUBATE

The following are the five generally accepted indications to secure an airway by ETI in emergency medicine practice:

1. Failure of the patient to maintain a patent airway
2. Failure of the patient to adequately protect the airway from aspiration
3. Failure of the patient to maintain adequate gas exchange (oxygen and carbon dioxide)

4. Need for the initiation of paralytic agents or therapeutic hyperventilation
5. Inability of the patient to adequately clear secretions

A sixth indication that is frequently invoked is intubation prior to transport, when it is reasonably anticipated that although an indication to intubate does not exist now, one may develop during the transport. This risk-to-benefit analysis recognizes the practicalities and challenges of intubating in a transport vehicle.

There are probably few other situations in emergency practice when judgment and knowledge of the anticipated clinical course of a disorder are as crucial to the emergency physician as the decision to intubate a patient (4).

EVALUATION OF THE PATIENT

Human beings protect their airway at all costs, triggering an extreme autonomic response when threatened. ETI stimulates a similar autonomic response. As such, potent medications are generally employed to attenuate the adverse responses to laryngoscopy and intubation such as hypertension, tachycardia, increased intracranial pressure (ICP), and bronchospasm. The emergency physician must attempt to balance the anticipated aggression of the response to intubation by selecting appropriate classes and dosages of medication to mitigate them. Underdosing may fail to mitigate an aggressive response; overdosing may produce hypotension or premature apnea.

The evaluation of the *patient* to be intubated is focused on the three crucial organ systems: The central nervous system (CNS), the cardiovascular system, and the respiratory system. The patient's hemodynamic stability, physiologic reserve of vital organ systems, and the anticipated response to laryngoscopy and intubation dictate which medications and what doses are required to maintain stability and mitigate adverse effects during the procedure.

EVALUATION OF THE AIRWAY

Airways that are difficult to manage are fairly common in emergency medicine with some estimates being as great as 20% of all emergency intubations. However, the incidence of intubation failure is quite uncommon (0.5% to 2.5%). Moreover, the disastrous situation of being able to neither intubate nor ventilate rarely occurs (0.1% to 0.5%) (2).

The most important way to avoid airway management failure is to predict when difficulty is likely to be encountered with BMV, ETI, EGD, or cricothyrotomy, particularly if one is relying on the latter two techniques to rescue the airway in the event of ETI or BMV failure.

The distinction among the terms difficult laryngoscopy, difficult ETI, difficult BMV, difficult EGD, difficult cricothyrotomy, and difficult airway is important. For instance, difficulty with BMV or an EGD when ETI is easily performed would not be described as a difficult airway. Rather, the narrative would describe each independently.

The failed airway is clearly defined as three failed attempts at intubation and/or failure to maintain oxygen saturations. The difficult airway is not so easily defined. Rather than a strict definition, the concept of the difficult airway has the following five "dimensions."

1. Difficult BMV
2. Difficult laryngoscopy
3. Difficult intubation
4. Difficult EGD
5. Difficult cricothyrotomy

These five dimensions can be reduced to the following four technical operations:

1. Difficult BMV
2. Difficult EGD
3. Difficult laryngoscopy and intubation
4. Difficult cricothyrotomy

The evaluation of the airway for difficulty in an emergency must be done quickly, with care taken not to omit anything important. Mnemonics are efficient memory aid strategies, so one for each

technical operation has been crafted to permit a rapid and complete evaluation (Table 1.1).

TABLE 1.1
Mnemonics Useful in Evaluating the Airway for Difficulty

Difficult Bag–Mask Ventilation: MOANS
- M: Mask seal, male sex, Mallampati
- O: Obese or upper airway obstruction
- A: Aged
- N: No teeth
- S: Snores, "stiff"

Difficult Extraglottic Device: RODS
- R: Reduced mouth opening
- O: Upper airway obstruction
- D: Distorted airway
- S: "Stiff"

Difficult Laryngoscopy and Intubation: LEMON
- L: Look externally
- E: Evaluate 3–3–2
- M: Mallampati
- O: Upper airway obstruction
- N: Neck mobility

Difficult Cricothyrotomy: SMART
- S: Surgery recent or remote
- M: Mass
- A: Access or anatomy
- R: Radiation
- T: Tumor

Difficult Bag–Mask Ventilation

If the emergency physician is uncertain that neuromuscular blockade-facilitated orotracheal intubation (RSI) will be successful, he or she must be confident that BMV or EGD-facilitated ventilation is possible or at the very least that a cricothyrotomy can be performed rapidly.

The five indicators of difficult BMV (5,6) can be easily recalled for rapid use in the emergency setting by using the mnemonic MOANS (Table 1.1) (7).

- *Mask seal, Male sex, Mallampati.* Bushy beards, crusted blood on the face, or a disruption of lower facial continuity are the most common examples of conditions that may make an adequate mask seal difficult. Male sex and Mallampati scores of 3 or 4 have also been associated with difficult mask ventilation.
- *Obese or obstructed.* Patients who are obese (body mass index [BMI] >26 to 28 kg/m^2) are often difficult to ventilate adequately by bag and mask. Parturients at term; patients with angioedema, Ludwig angina, upper airway abscesses (e.g., peritonsillar), or epiglottitis; and others ought to be considered at this juncture.
- *Advanced age.* Patient age older than 55 to 57 years is associated with a higher risk of difficult BMV, perhaps because of a loss of muscle and tissue tone in the upper airway with age.
- *No teeth.* An adequate mask seal may be difficult in the edentulous patient, perioral tissues tend to cave into the structurally unsupported mouth.
- *Stiff or snores.* Patients with high airway resistance or diminished pulmonary compliance are exceedingly difficult to adequately manage with a bag and mask, as are patients who snore.

Difficult Extraglottic Devices

Four factors may indicate that EGDs may be unsuccessful at rescuing the airway and may be remembered using the RODS mnemonic (Table 1.1) (8):

- *Restricted mouth opening.* Depending on the EGD to be employed, a certain amount of oral access is critical to employ the device.
- *Obstruction.* Upper airway obstruction at the level of the larynx or lower will not be bypassed through the use of an EGD.
- *Disrupted or distorted anatomy.* The “seat and seal” of the EGD may be compromised by a disrupted or distorted airway. In

addition, a seal may be exceedingly difficult or impossible to achieve in the face of a fixed flexion deformity of the neck (9).

- *Stiff lungs or cervical spine.* Ventilation with an EGD may be difficult or impossible in the face of substantial increases in airway resistance (e.g., severe asthma) or decreases in pulmonary compliance (e.g., pulmonary edema). In addition, patients unable to fully extend the neck may prove to be difficult to ventilate with EGDs due to improper positioning of the EGD.

Difficult Laryngoscopy and Intubation

Difficult laryngoscopy and intubation ordinarily implies that the operator had a poor view of the glottis. Cormack and Lehane (10) provided some clarity to the way physicians think of the "difficult airway" by parsing the act of intubation into its two subcomponents: Laryngoscopy and intubation. They also introduced the most widely used system of categorizing the degree of visualization of the larynx during laryngoscopy (Fig. 1.1) (7). Cormack–Lehane view grades 3 (epiglottis only visible) and 4 (no glottic structures at all visible) are often used as surrogates to represent difficult laryngoscopy and to predict difficult intubation. View grades 1 (visualization of the entire laryngeal aperture) and 2 (visualization of the posterior cords and arytenoids) are not typically associated with difficult intubation, although some grade 2's may be very anterior and difficult or impossible to intubate.

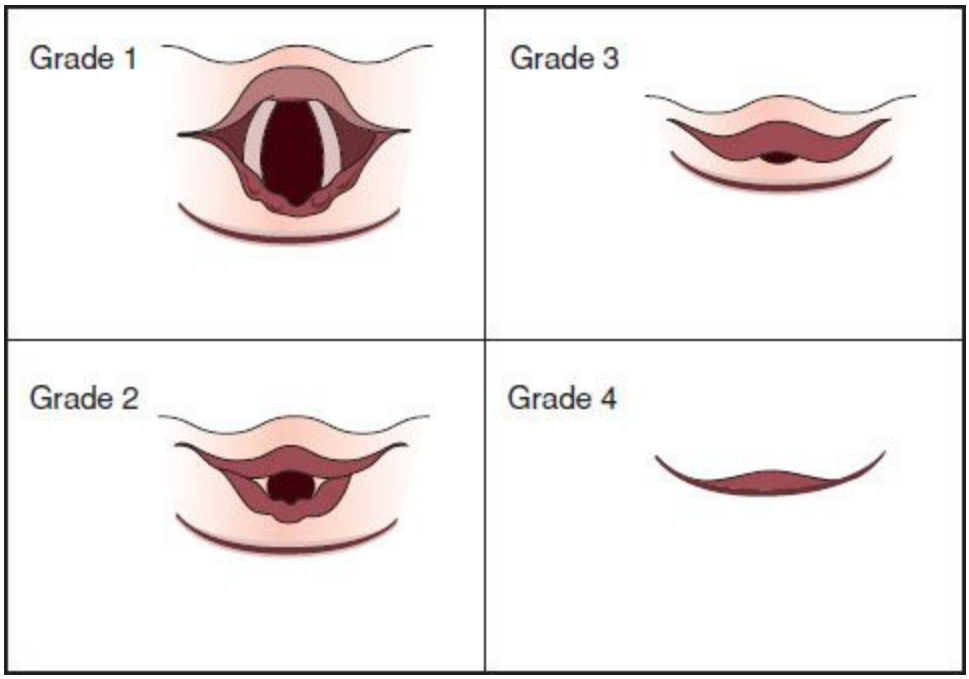

FIGURE 1.1 Cormack and Lehane system of categorizing the degree of visualization of the larynx during laryngoscopy.

The mnemonic LEMON (Table 1.1) is a useful guide to identifying as many of the risks as quickly as possible to meet the demands of an emergency situation.

- *Look externally.* If the airway looks difficult, it probably is! A litany of physical features is associated with difficult laryngoscopy and intubation, making the glottic aperture difficult to visualize. A small mandible may indicate that the tongue is "retrofitted" over the larynx; a large mandible elongates the pharyngeal axis, serving to extend the distance to the larynx beyond the visible horizon. Buck teeth block access to the oral cavity and also elongate the length of the oral axis. A high, arched palate is often associated with a long narrow oral cavity, making access a problem. A short neck may mean the larynx is positioned higher in the neck relative to the base of the tongue, making it more difficult to bring the glottis into view. Lower facial disruption interferes with adequate mask seal and may make the glottis impossible to find.

- *Evaluate 3–3–2.* This step recognizes the importance of the geometric relationships of various parts of the airway to successful intubation (11). One ought to be able to open one's mouth with the width of three of their own fingers, accommodate three of their own fingers between the tip of the mentum and the hyoid bone, and fit two fingers between the hyoid bone and the thyroid notch. The first "three" assesses the adequacy of oral access. The second "three" addresses the capacity of the mandibular space to accommodate the tongue on laryngoscopy. More than or less than three fingers are both associated with greater degrees of difficulty in visualizing the larynx at laryngoscopy. The former because the length of the oral axis is elongated; the latter because the mandibular space may be too small to accommodate the tongue, leaving it to obscure the view of the glottis. The final "two" identifies the location of the larynx in relation to the base of the tongue. If more than two fingers are accommodated, the larynx is further below the base of the tongue beyond the visible horizon. Fewer than two fingers may mean that the larynx is tucked up under the base of the tongue and may be difficult to expose. This condition is often called *anterior larynx*.
- *Mallampati score.* Mallampati determined that the degree to which the posterior oropharyngeal structures are visible is loosely associated with intubation success (12). He had patients sit on the side of the bed, open their mouths as widely as possible, and protrude their tongues as far as possible, without phonating. Figure 1.2 depicts how the scale is constructed. Although classes I and II patients are associated with low intubation failure rates, the importance with respect to the wisdom of using neuromuscular blockade rests with those patients in classes III and IV, particularly those in class IV where intubation failure rates may exceed 10%. By itself, the scale is neither sensitive nor specific; however, it is easily performed in an emergency and may reveal important information about access to the oral cavity and the potential for difficult glottic visualization.

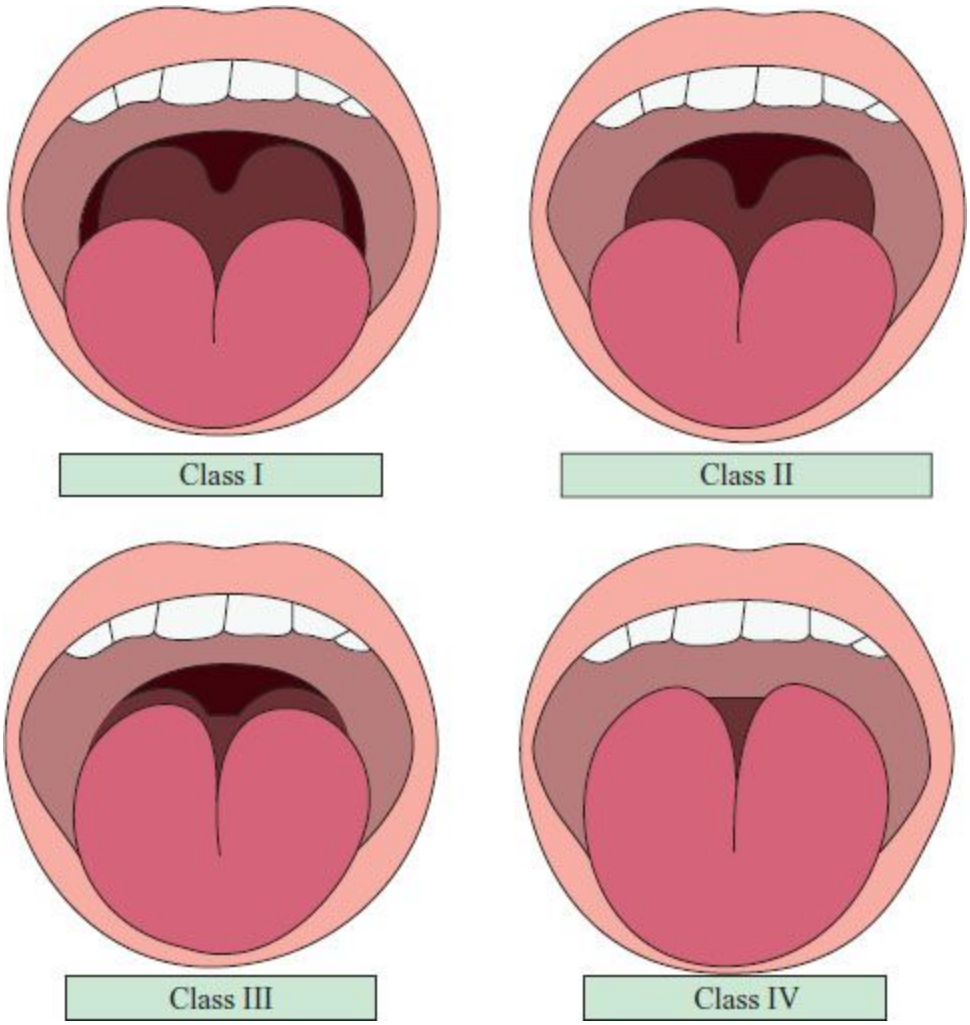

FIGURE 1.2 Mallampati score.

- *Obstruction.* Upper airway obstruction is always a difficult airway. The four cardinal signs of upper airway obstruction are muffled voice ("hot potato voice"), difficulty swallowing secretions (either because of pain or obstruction), dyspnea, and stridor. The first two signs do not ordinarily herald imminent total upper airway obstruction; dyspnea and stridor are much more sinister. The presence of stridor generally indicates that the airway has been reduced to 4.5 mm or less (13). Upper airway obstruction should always be managed with extreme care. The administration of small doses of opioids and benzodiazepines to manage anxiety may induce total obstruction due to diminished upper airway musculature tone.

- *Neck mobility.* The ability to position the head and neck is one of the factors employed to achieve an optimal view of the larynx. Although cervical spine immobilization, of and by itself, does not automatically lead to one, it should be considered in addition to other features indicating difficulty.

Difficult Cricothyrotomy

There are no absolute contraindications to performing an emergency cricothyrotomy. However, some conditions may make it difficult or impossible to perform the procedure. It is imperative to identify those conditions up front, particularly if one is relying on a rapidly performed cricothyrotomy as a rescue technique. The mnemonic SMART (Table 1.1) is used to quickly assess the patient for features that may indicate a difficult cricothyrotomy.

- *Surgery—Recent or remote:* The anatomy may be distorted making the airway difficult to find or access.
- *Mass:* A hematoma or infective process in the direct path of the cricothyrotomy produces a mass effect that may make the procedure technically difficult, but should never be considered a contraindication in a life-threatening situation.
- *Access or anatomy:* Obesity should be considered a surrogate for any problem that makes percutaneous access to the anterior neck problematic. A fixed flexion deformity of the cervical spine and halo traction make cricothyrotomy more difficult.
- *Radiation:* Past radiation therapy may distort tissues, making the procedure difficult.
- *Tumor:* Tumor in or around the airway may present difficulty from an access perspective as well as from bleeding.

No single indicator, combination of indicators, or weighted scoring system of indicators can be relied on to assure success or predict failure when it comes to oral intubation. Thus, emergency physicians must evaluate the airway for difficulty, identify those factors known to increase the degree of difficulty, match them to the skill, experience, and judgment of the individual performing the intubation, and make the following decision: Does this airway meet

the threshold of being sufficiently difficult to warrant using the difficult airway algorithm or is it safe to proceed directly to RSI?

RAPID SEQUENCE INTUBATION

"RSI is the administration, after preoxygenation, of a potent induction agent followed immediately by a rapidly acting neuromuscular blocking agent (NMBA) to induce unconsciousness and motor paralysis for tracheal intubation" (14). Attenuating the adverse responses to intubation, maintaining adequate oxygen saturations, and protecting the airway from aspiration are integral to the procedure.

The adage in anesthesia with respect to neuromuscular blockade to facilitate the orotracheal intubation of a patient who has some effective spontaneous ventilation has always been "don't take anything away from the patient that you cannot replace." Although such a rigid principle is not always consistent with the realities of emergency airway management, it is useful to remember.

The use of NMBAs assumes that the operator is entirely versed in BMV, the use of extraglottic rescue devices, airway evaluation for difficulty, and the performance of a surgical airway.

Walls and Murphy (14) have referred to the steps of RSI as the "Seven P's of RSI." It is a useful framework for discussing the procedure.

- *Preparation.* Establish IV access, place the patient on a cardiac monitor and pulse oximetry, and prepare intubation equipment.
- *Preoxygenation.* This is a crucial step, permitting oxygen saturations to remain acceptable during the period of apnea as the NMBA becomes fully effective. The goal is to replace the nitrogen in the patient's functional residual capacity (FRC, normally 30 mL/kg) with oxygen. The ability to do so varies with the time available, the ability of the oxygen delivery apparatus to deliver the high concentrations of oxygen used, and the patient's condition.
- *Pretreatment.* The goal of pretreatment is to attenuate the adverse responses to intubation, particularly the surges in heart

rate, blood pressure, ICP, and airway resistance. Ideally, the pretreatment medications ought to precede the induction agent by 3 minutes to be optimally effective. Not all patients are equally at risk from these responses. Based on the best available evidence and expert recommendations at least the following patients should be pretreated (15).

- Those suspected of having elevated ICP and imperfect autoregulation may benefit from lidocaine 1.5 mg/kg and fentanyl 3 to 13 μ/kg (ordinarily 3 to 5 μ/kg). In addition, a defasciculating dose of a nondepolarizing paralytic decreases fasciculations and reduces ICP. It has been taught that typically 1/10 of the intubating dose of any available paralytic agent will achieve this.
- Those with significant ischemic heart disease or major vessel dissection or rupture may benefit from fentanyl 3 to 13 &b.mu;/kg (ordinarily 3 to 5 &b.mu;/kg). Caution ought to be exercised in administering fentanyl to patients with compensated or uncompensated shock.
- Adults with significant existing reactive airway disease may benefit from lidocaine 1.5 mg/kg.
- Children up to the age of 10 years, or any patient with hemodynamically significant bradycardia and receiving succinylcholine may receive atropine 0.01 to 0.02 mg/kg (minimum 0.1 mg; maximum 0.5 mg). This recommendation is currently considered to be controversial and the administration of atropine is optional.

- *Paralysis with induction.* Induction and paralytic agents are rapidly administered intravenously. Induction agents have profound effects on all three vital organ systems: The CNS, cardiovascular system, and ventilation. These effects depend on the particular drug, the patient's underlying physiologic condition, and the dose and speed of injection of the drug. Because RSI requires rapid administration of the sedative induction agent, the choice of drug and the dose must be tailored to capitalize on desired effects, while minimizing adverse side effects (Table 1.2). In some cases, an amnestic dose

may be selected, rather than an induction dose. While the sedative induction dose might be tailored, the dose of the NMBA is not (e.g., succinylcholine 1 to 2 mg/kg; rocuronium 1 to 1.5 mg/kg).

- *Protection and positioning.* Though controversial, the use of cricoid pressure, or the Sellick maneuver, to prevent regurgitation and aspiration is maintained until proper placement of the endotracheal tube (ETT) is confirmed. Premature release of cricoid pressure is a common error and may place the patient at risk of aspiration, particularly if an inadvertent esophageal intubation has occurred. Cricoid pressure must be released immediately should active vomiting occur; otherwise, there is danger of esophageal rupture. Most experts on airway management agree that positioning the head and neck is an important step in gaining the best view of the larynx with conventional laryngoscopy. It has long been taught that the "sniffing the morning air" or "sipping English tea" positioning of the head and neck, when possible, is best. Although there is some dissension as to whether this positioning does indeed deliver the best view of the larynx, most agree that it is a reasonable place to start (16).
- *Placement and proof.* The tube is passed through the laryngeal cords. Proper ETT placement is confirmed and proven using physical examination as well as devices such as the end-tidal CO_2 detector.
- *Postintubation management* (PIM). The tube should be secured using commercially available devices or basic tape to prevent accidental extubation. If tape is used, then a "bite block" or oral airway should also be placed to avoid accidental cutting of the tube should the patient bite down. A postintubation chest radiograph is the standard practice to confirm placement of the tube and assess the depth of intubation. Finally, postintubation sedation with or without paralytics should be provided.

TABLE 1.2
Induction Agents and Dosage Selection

Induction Agent (mg/kg)	Stable Patient	Unstable Patient	Very Unstable Patient[a]
Etomidate	0.3	0.15–0.2	0.1
Propofol	1	0.5	0
Midazolam	0.3	0.1	0.01–0.02
Pentothal	3	1.5	0
Ketamine	1.5	1	0.5

[a]The recommended doses are empiric and intended to produce amnesia in patients who are severely ill. Some practitioners may elect to administer none of these agents in this situation.

APPROACH TO THE AIRWAY: HOW TO PROCEED

Once one has decided that intubation is indicated, one progresses rapidly to identifying exactly what kind of airway the patient has and how the practitioner will proceed:

- Is this a "crash" airway where the patient is unconscious, unresponsive, and near death (17)?
- Is this a difficult airway where one anticipates difficulty with BMV, laryngoscopy and intubation, EGD rescue, or cricothyrotomy?
- If neither of these exists, RSI is reasonable.
- Has a failed airway supervened?

This systematic approach to airway management in the emergency department encompasses all possible presentations. Identifying the type of airway to be managed permits the practitioner to select an appropriate course of action. Algorithms are presented below for each of these clinical presentations. Figure 1.3 depicts this conceptual framework (17).

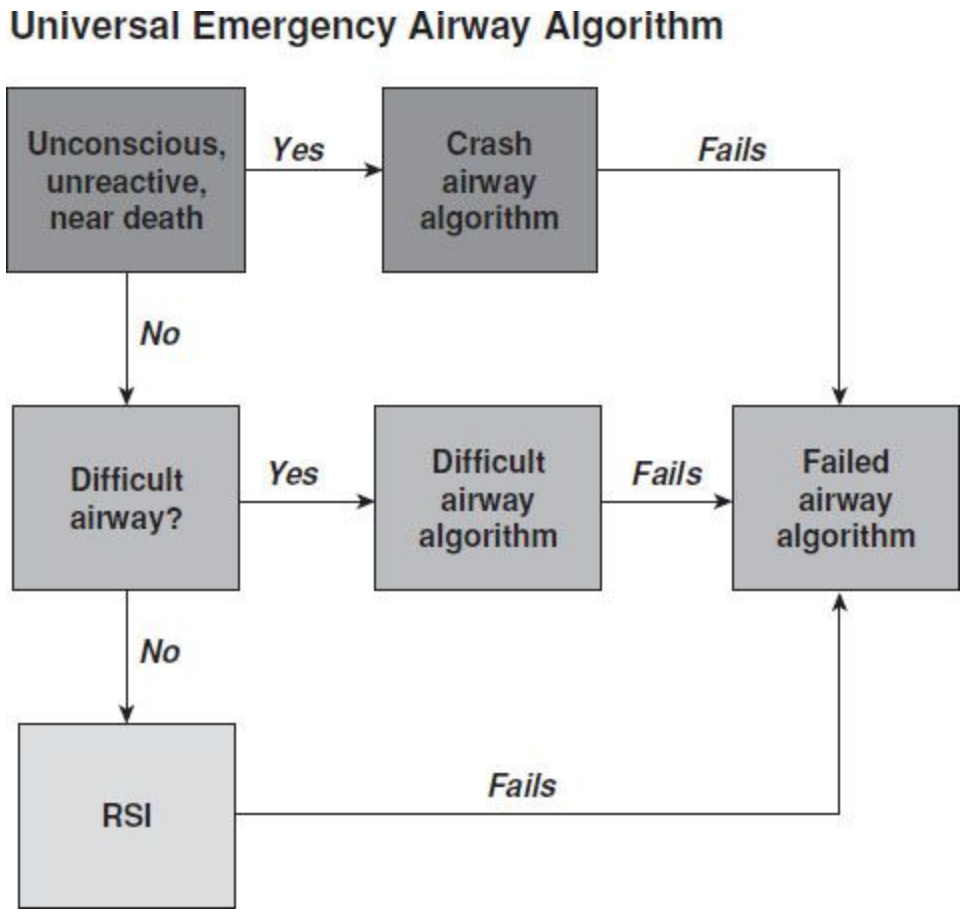

FIGURE 1.3 Universal emergency airway algorithm.

Crash Airway Algorithm

The patient who presents in an unresponsive state or is deemed unlikely to respond in any way to direct laryngoscopy is said to have a crash airway, and the crash airway algorithm (Fig. 1.4) is employed (17). Noteworthy points in the crash airway algorithm include the following.

- BMV is occurring as preparations are made to intubate.
- The initial action is to attempt oral intubation immediately via direct laryngoscopy without pharmacologic assist.
- If the first attempt at orotracheal intubation is unsuccessful, it is assumed that the patient is not optimally relaxed, and succinylcholine is administered in an increased dose.
- If BMV is unsuccessful at any time and if intubation has failed, a failed airway is present, and one proceeds to the failed airway

algorithm (Fig. 1.5).

- Once three attempts have failed, one proceeds to the failed airway algorithm (Fig. 1.5).

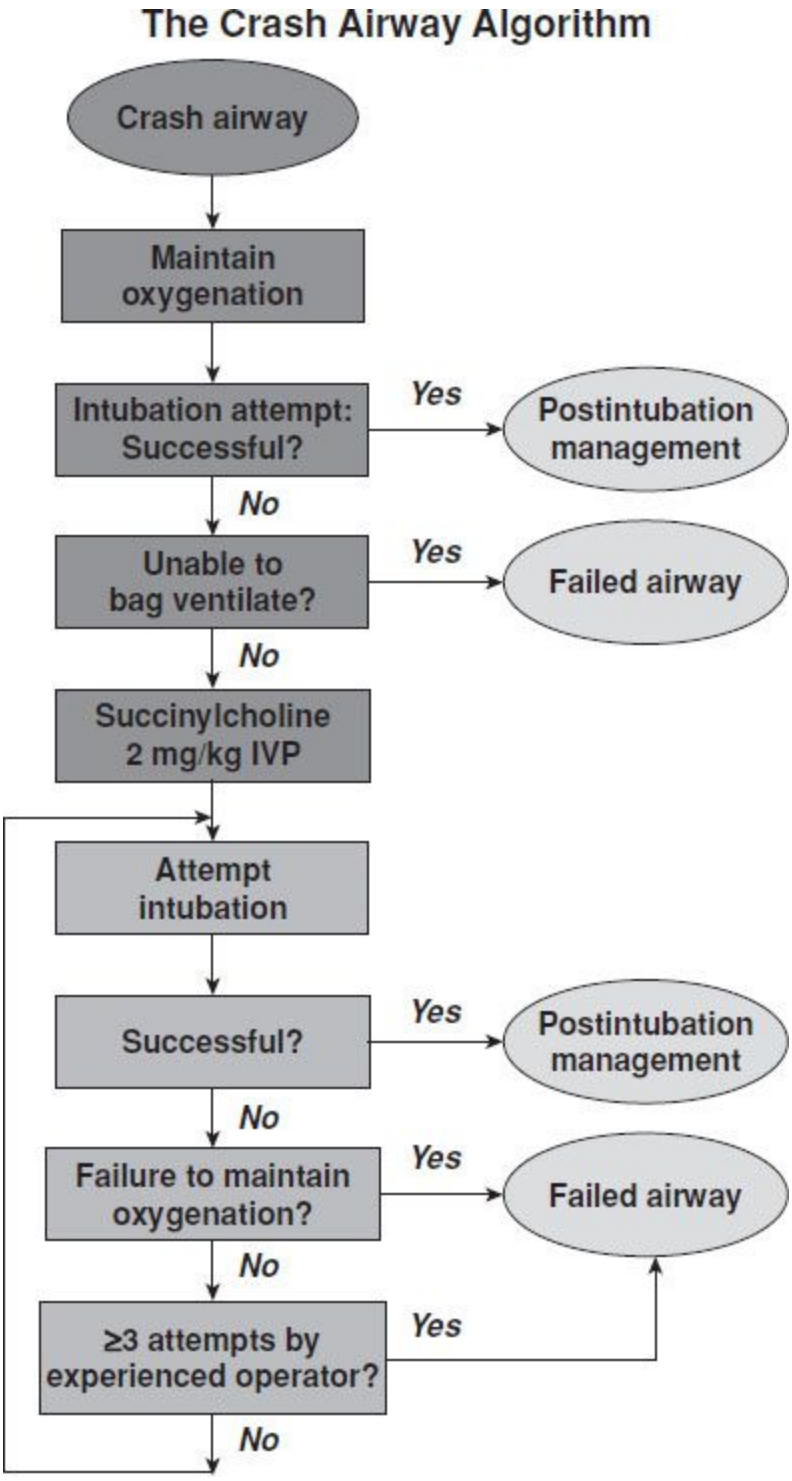

FIGURE 1.4 The crash airway algorithm.

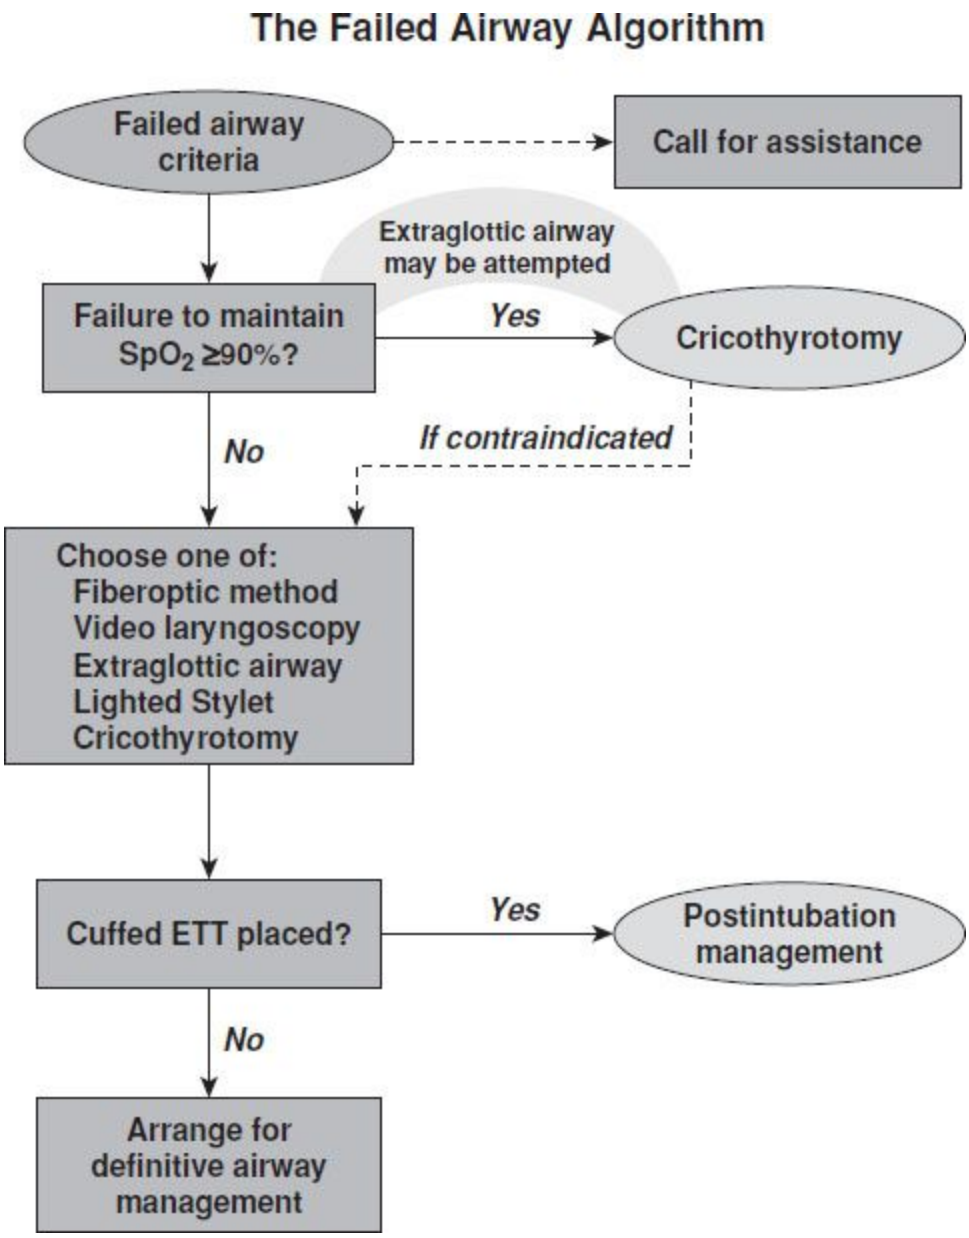

FIGURE 1.5 The failed airway algorithm.

Difficult Airway Algorithm

Should the situation not be a crash airway, one must determine whether it is a difficult airway. Although all emergency intubations are difficult to some degree, the evaluation of the airway for those features that reliably predict difficult BMV, difficult laryngoscopy, difficult EGD rescue, or difficult cricothyrotomy is extremely important. In the event the airway is judged to be difficult, the

difficult airway algorithm (Fig. 1.6) is used (17). The evaluation for difficulty is presented in the next section.

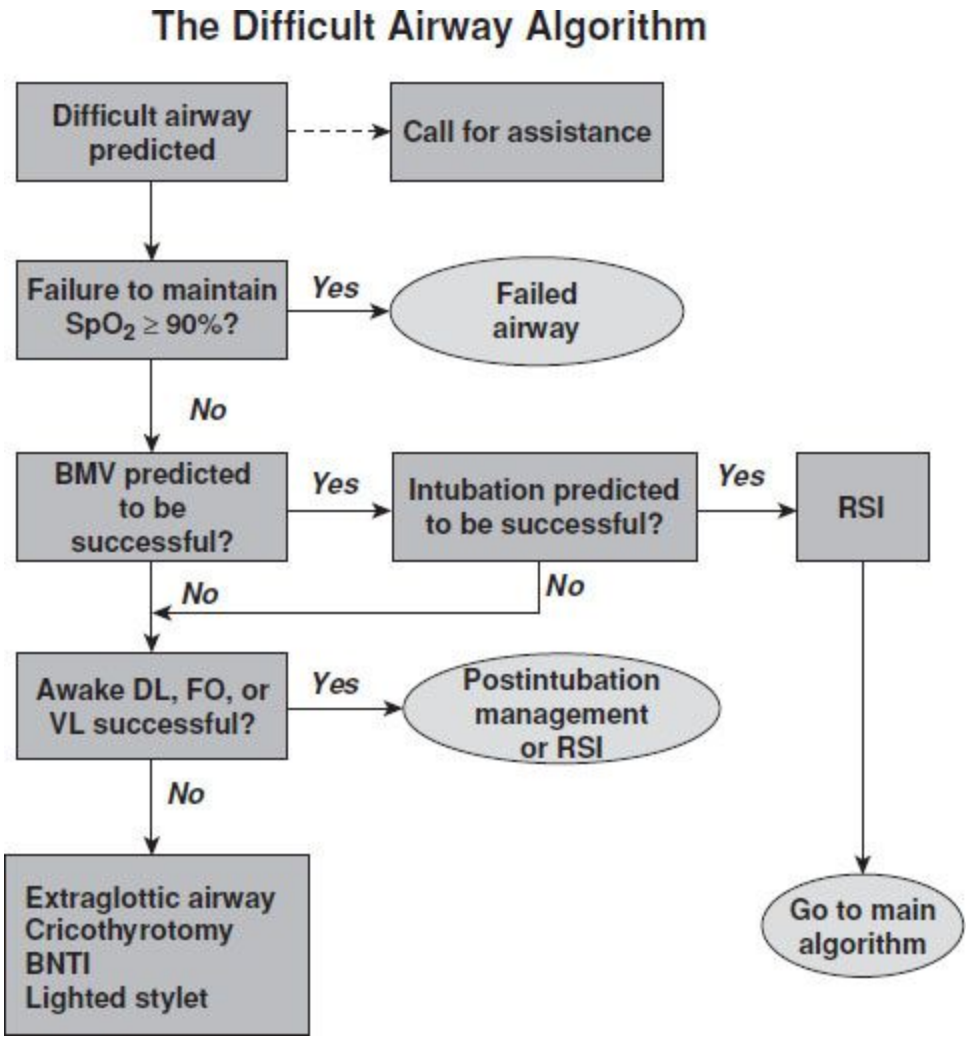

FIGURE 1.6 The difficult airway algorithm.

Noteworthy points in the difficult airway algorithm include the following:

- This iteration of the difficult airway algorithm recognizes that the emergency physician may be forced to act before a detailed evaluation of the airway can be performed. RSI is recommended, though this action must be accompanied by preparations to perform a surgical airway ("double set up") and to ensure the immediate availability of an EGD in the event of failure (18).

- Determine how much time is available. If ventilation and oxygenation are adequate, then a careful assessment and a planned approach can be undertaken. If not, does BMV provide adequate ventilation and oxygenation? If not, the situation is equivalent to a "can't intubate; can't oxygenate" failed airway, and one proceeds to the failed airway algorithm (Fig. 1.5) (17).
- If the patient can be adequately oxygenated, the next step is to consider RSI. If BMV or gas exchange rescue with EGD are deemed unlikely to succeed or if success at laryngoscopy and intubation is felt to be questionable, RSI is not recommended.
- Awake laryngoscopy is the cornerstone of difficult airway management. An "awake look" is intended to either intubate the nonparalyzed patient orally or identify whether the patient can be safely paralyzed and intubated using an RSI technique. An awake look in an emergency airway situation relies virtually entirely on the intravenous titration of systemically active sedation and topical anesthesia.
- If at any time oxygenation and ventilation become inadequate, the situation has become a failed airway. If oxygenation remains adequate, several options remain, all of which place a cuffed (in adults) ETT in the trachea.

In the absence of an identified crash or difficult airway, RSI is the method of choice for airway management in the emergency department.

Failed Airway Algorithm

The failed airway is easily defined as follows:

1. Three failed attempts at orotracheal intubation by a skilled intubator, or
2. Failure to maintain acceptable oxygen saturations.

The practical problem in day-to-day practice is recognizing failure when it occurs and changing gears rapidly to deal with it appropriately. Clinically, the failed airway presents itself in two ways.

1. Time is available: "Can't intubate; *can* oxygenate."

2. Immediate action is required: "Can't intubate; *can't* oxygenate."

Noteworthy points in the failed airway algorithm (Fig. 1.5) include the following (17):

- Unlike the difficult airway, when the placement of a cuffed tube in the trachea is the goal, the failed airway calls for immediate action to provide emergency oxygenation by whatever appropriate maneuvers are available, regardless of whether this action results in a secure, protected airway. The devices considered for the failed airway are somewhat different from, but inclusive of, the devices used for the difficult airway.
- When a failed airway has been determined to be present, the response is dictated by whether BMV is possible and adequate.
- A "can't intubate; *can't* oxygenate" situation mandates immediate cricothyrotomy. The airway manager may elect to attempt to rapidly place an alternative device, usually an EGD (17,19), simultaneously with the preparation for a cricothyrotomy, in the hope that a "can't intubate; *can't* oxygenate" situation can be converted into a "can't intubate; *can* oxygenate" situation.
- If at any time during the management of the failed airway adequate oxygenation and ventilation cannot be assured, immediate performance of a cricothyrotomy is mandated.

RESCUE DEVICES

Airway rescue devices can be divided into the following two groups, depending on the situation.

- "Can't intubate; *can't* oxygenate." Cricothyrotomy is the standard method of airway management in this situation. However, devices that can be inserted rapidly and are associated with high success rates include the Combitube and the intubating laryngeal mask airway (Fastrack). The advantage of the Fastrack compared to the Combitube is the ability to intubate through the Fastrack.
- "Can't intubate; *can* oxygenate." Videolaryngoscopes, flexible and rigid endoscopic devices, and nasotracheal intubation

require time to perform and are inappropriate in an emergency situation where ventilation and oxygenation must not be delayed.

SELLICK MANEUVER

Brian Sellick introduced cricoid pressure in 1961 as a protective measure, reasoning that backward pressure on the cricoid cartilage would occlude the upper esophagus and further reduce the incidence of aspiration. With widespread use of the technique in all arenas of airway management by the late 1980s, it assumed the status of “Standard of Care” in emergency patients and others at risk of aspiration.

However, scientific evidence that the maneuver actually reduces the incidence of aspiration remains lacking due to the rarity of clinically evident or significant aspiration, and it will likely remain that way. In the meantime, investigators have shown that the esophagus is not entirely obstructed by the Sellick maneuver. In addition, the maneuver is often not performed correctly, it attenuates lower esophageal sphincter tone, and it hinders placement of and ventilation through an LMA. It has also been found to produce partial or total airway obstruction that may hinder mask ventilation and ETI. Furthermore, cricoid pressure may lend a false sense of security if done incorrectly and some anesthetists have seen regurgitation in spite of its application. Three reviews on rapid sequence induction and cricoid pressure have pointed out that there have been no randomized controlled trials comparing the incidence of regurgitation on induction with and without cricoid pressure in patients at high risk of regurgitation (20).

On the positive side, there is evidence that the position of the esophagus during cricoid pressure is irrelevant, as the maneuver leads to compression of the upper esophagus and hypopharynx, providing some degree of protection from the passage of alimentary tract contents into the hypopharynx (21).

CONFIRMATION TECHNIQUES

Endoscopic bronchoscopy remains the gold standard of verifying correct ETT placement by permitting direct visualization of tracheal rings. Visualization of the ETT entering the larynx also provides a highly reliable method of verifying intratracheal placement. Detection of expired carbon dioxide provides reliable evidence of tracheal rather than esophageal intubation and is the standard of care in emergency medicine. In nonarrested patients, carbon dioxide detection is highly reliable, indicating correct placement 99% to 100% of the time (22). Soft drinks in the stomach that contain carbon dioxide may mimic the exhaled carbon dioxide from the lungs for a couple of breaths, the so-called “cola complication,” although this confounding result ought not to persist beyond six breaths.

The migration of an ETT from the trachea to the esophagus during the tosses and turns of transport is an ever present hazard. It has been demonstrated that the continuous monitoring of exhaled carbon dioxide during the prehospital phase of care minimizes the risk of such displacement going unrecognized (23).

As might be expected, carbon dioxide detection techniques tend to be less accurate in identifying correct placement of the ETT in patients with circulatory arrest, with reported false-negative rates (carbon dioxide not detected, tube in the trachea) as high as 30% to 35% (24). In this circumstance, the endotracheal placement of the tube can be evaluated by an esophageal detector device (EDD) that consists of a self-inflating suction bulb or syringe armed with an adapter to fit a standard ETT connector. The collapsed bulb or syringe rapidly fills with air if the ETT is in the trachea; it does not inflate if the tube is in the esophagus, with a specificity of approximately 99%. Use of this device instead of carbon dioxide detection is not recommended because of its failure to detect esophageal intubation in as many as 20% of cases (24).

Physical examination techniques used to confirm intratracheal placement of an ETT, although neither sensitive nor specific, remain important adjuncts to more elaborate techniques, particularly in the cardiopulmonary arrested patient. Auscultation of the chest for breath sounds and of the epigastrium for absence of air entry into

the stomach, observation of chest motion during ventilation, and condensation inside the ETT during exhalation are common, but notoriously unreliable, methods of ascertaining proper ETT placement.

In summary, although carbon dioxide detection remains the most reliable method of verifying tracheal placement of the ETT in prehospital care, the incorporation of multiple methods of confirmation is superior to any single method.

SUMMARY

RSI by emergency practitioners is associated with high success rates and low complication rates. The challenge is to recognize those patients who should not be paralyzed and to develop alternative skills to successfully manage those airways. There is no "recipe" of RSI pretreatment and induction medications that can be applied in every case. A careful assessment of risk and benefit is required in each patient to select the appropriate medication and its dose. An array of airway management skills is required to appropriately manage difficult airways and rescue failed airways.

CRITICAL INTERVENTIONS

- Evaluate the airway prior to airway intervention
- Preoxygenate patients prior to RSI
- Perform cricothyrotomy or insert ILMA in patients who cannot be ventilated or intubated
- Know when not to paralyze a patient
- Recognize airway management failure immediately

CHAPTER 2 Airway Procedures

Eric F. Reichman

Airway management is one of the most basic, crucial, and important aspects of emergency medicine. Without oxygen, the brain begins to die within minutes. The mission for airway management is to ensure airway patency, to protect the airway from contamination (blood, fluids, and/or food), to provide supplemental oxygen, and to institute positive pressure ventilation when spontaneous respirations are inadequate or absent. Airway management can be as simple as lifting a snoring patient's chin or as involved as awake fiberoptic-guided endotracheal intubation.

A thorough understanding of anatomy is essential for the performance of any medical procedure. Untoward events related to a procedure are often the result of inexperience and/or an inadequate understanding of the regional anatomy, and the airway procedures are no exception. From the evaluation of external anatomic landmarks to the performance of nerve blocks for fiberoptic intubation, understanding the anatomy of the airway will result in fewer attempts at intubation and improved success with fewer iatrogenic misadventures.

CLINICAL PRESENTATION

Airway intervention is required if there is uncertainty about whether the patient's airway patency, respiratory drive, or oxygenation can be maintained without intervention. Inadequate ventilation may occur for a variety of reasons. Spontaneously breathing patients may develop an airway obstruction caused by food, blood, secretions, or tissue obstruction as a result of the loss of the normal pharyngeal

tone. Unconscious patients should have their airway secured and receive mechanical ventilation. Despite spontaneous respiration, the unconscious patient is at risk for aspiration of gastric contents. The conscious patient with airway obstruction is in obvious distress and is more likely to have an obstruction caused by a foreign body, tissue swelling from an infection, laryngeal edema, cancer, or laryngospasm.

Endotracheal intubation can be performed to administer resuscitation medications, ensure a patent airway, deliver oxygen, isolate the airway, reduce the risk of aspiration of gastric or oral contents, suction the trachea, ventilate the patient, or apply positive pressure ventilation. Other indications include altered mental status, head injury requiring hyperventilation, hypoxemia, hypoventilation, apnea, lack of a gag reflex, and unconsciousness.

ED EVALUATION

Evaluation of the airway includes an internal and external examination. The internal examination should evaluate the patient's dentition, palate, and tongue. Note any protuberant incisors, loose teeth, broken teeth, dental work, and dental devices. Determine if the palate is normal, high and arched, or cleft. Determine if the tongue is elevated, larger, or wider than normal in comparison to the oral cavity. A common classification used by anesthesiologists to grade the difficulty of laryngoscopy and intubation involves the identification of the size the tongue in relation to the faucial pillars, the soft palate, and the uvula (1). External evaluation of the airway is a critical step to a successful intubation. External inspection should include mouth opening, atlantooccipital extension, and thyromental distance. External inspection should also identify obvious problems (e.g., cervical collars, face and/or neck trauma, severe micrognathia, massive obesity, etc.). Please refer to Chapter 1 for a more detailed discussion of this topic.

There are numerous differences between the adult's and the child's airway (2). The head-to-body ratio is larger in the child, which results in neck flexion when the child is supine. Placing a rolled towel under the child's shoulders will correct the flexion. Children

have a small mouth with a relatively large tongue when compared to an adult, making orotracheal intubation difficult. The presence of adenoidal tissue in the child makes nasotracheal intubation difficult and orotracheal intubation the preferred method. The most important difference is that the narrowest portion of the infant and child's airway is below the vocal cords at the cricoid cartilage. In an adult, the narrowest point is at the level of the vocal cords. An endotracheal tube (ETT) may pass through the vocal cords of a young child but might not advance past the cricoid cartilage because of normal anatomy. Forcing an ETT past the vocal cords might result in trauma to the airway and subsequent tracheal stenosis. The child's laryngeal inlet is narrow and more susceptible to obstruction. The U-shaped epiglottis and a more acute angle between the epiglottis and glottis cause the aryepiglottic folds to be more midline. Children have a relatively shorter trachea, making both right main bronchial intubation and accidental extubation much easier. The narrower diameter of the trachea with smaller spaces between the cartilaginous rings makes a tracheostomy more difficult to perform.

Traditional teaching holds that cuffed ETTs increase the risk of ischemic damage to the tracheal mucosa due to compression between the cuff and the cartilaginous rings. This resulted in the old mandate to use uncuffed ETTs in children younger than 8 years of age. There have been numerous advances in modern ETTs that are changing this orthodoxy (3). Current American Heart Association guidelines now recommend, but do not require, a cuffed ETT for children older than 28 days of age. In the first 28 days of life, the cricoid narrowing functions as a cuff. For children over 28 days of age, the cuffed ETT is just as safe as an uncuffed ETT. The high volume, low pressure cuffs found on currently available ETTs allow the cuff to produce a seal at much lower pressures. The use of cuffed ETTs is becoming more common in pediatric ICUs and emergency departments. Several studies have shown no increase in postintubation stridor or reintubation when cuffed ETTs are used in controlled settings with regular cuff pressure monitoring.

ED MANAGEMENT

Basic Airway Management

Basic airway management is a fundamental skill that must be mastered by all caregivers. With an oxygen source, a means to deliver positive pressure ventilation, attention to detail in positioning, and the use of airway adjuncts, it is usually possible to prevent hypoxia and hypercarbia in the apneic patient.

Patient Positioning

The first goal of airway management is the establishment of a patent airway. The importance of proper positioning cannot be overemphasized. The success of airway management is predicated on this very basic, but often overlooked, issue. Placing the patient in the "sniffing" position may correct many upper airway obstructions because of soft tissue impingement. The "sniffing" position is achieved by flexing the cervical spine approximately 15 degrees and extending the atlantooccipital joint maximally. This position can also be achieved with the chin-lift or jaw-thrust maneuvers. If the patient is obese or has large breasts, the normal sniffing position is often insufficient for relieving an airway obstruction. A ramp or shoulder roll placed under the upper back will result in the "sniffing" position.

Jaw-Thrust Maneuver

The jaw thrust is one of the most basic maneuvers and an initial method of establishing a patent airway. The jaw-thrust maneuver is a two-handed technique. The operator is positioned at the head of the patient and places his or her fingers on the angles of the mandible bilaterally, displacing it anteriorly (Fig. 2.1). A face mask may be simultaneously held in place with the operator's thumbs and index fingers.

FIGURE 2.1 The jaw-thrust maneuver. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Chin-Lift Maneuver

The chin lift is also one of the most basic maneuvers to establish a patent airway. The chin lift is performed by placing the fingers under the tip of the mandible and lifting the chin in an anterior and cephalic direction (Fig. 2.2). Do not place the fingers on the soft tissue of the submandibular space, because this will elevate the tongue and cause further obstruction. The patient's head may be tilted slightly posterior to aid in opening the airway.

FIGURE 2.2 The chin-lift maneuver. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Nasopharyngeal Airways

In addition to proper positioning, one can use various aids to overcome pharyngeal obstruction and facilitate effective ventilation (4). The most commonly used devices are oropharyngeal (oral) and nasopharyngeal (nasal) airways. Regardless of which device is chosen, it is important to place a large-enough airway to bridge the area of soft tissue impingement on the pharynx. Nasopharyngeal airways are soft-rubber or plastic tubes that are inserted through the nostril and into the oropharynx, just above the epiglottis. They are available in numerous sizes; the larger inner diameter is associated with the longer tubes. A size 30- to 32-French tube is appropriate for most adults. Nasopharyngeal airways can be safely placed in the conscious, semiconscious, and unconscious patients. They can also be used when an oropharyngeal airway cannot be placed (e.g., in cases of oral trauma, braces, seizures, trismus, etc.).

Insertion of a nasopharyngeal airway is a quick and rapid procedure. Choose the proper size nasopharyngeal airway. The

correct size is estimated by placing the airway next to the patient's face. Place the flared end of the airway near the tip of the patient's nose. The airway's tip should be at the external auditory canal. Liberally apply water-soluble lubricant or anesthetic jelly to the nasopharyngeal airway. If not contraindicated, apply a vasoconstrictor to the patient's nasal mucosa. Gently insert the nasopharyngeal airway with the beveled tip against the nasal septum to prevent it from getting caught on the turbinates laterally. Insert the airway completely until the flared tip is against the nostril, and rotate it 90 degrees so that it is concave upward. Slight rotation often facilitates the passage of the airway if resistance is encountered during insertion. Supplementary oxygen or positive pressure ventilation with a bag-valve-mask device can be started after the insertion of the airway.

Insertion of a nasopharyngeal airway is associated with complications. If too long, the airway may cause laryngospasm and vomiting. The airway may also be placed with its tip in the esophagus, resulting in gastric distention and subsequent aspiration. Nasal mucosal injury upon insertion can result in epistaxis and aspiration of blood.

Oropharyngeal Airways

The oropharyngeal airway is a semicircular plastic device that holds the tongue up and away from the posterior pharyngeal wall. The oropharyngeal airway is less traumatic and more easily placed than a nasopharyngeal airway. An oropharyngeal airway must only be used in an unconscious patient, or it may cause laryngospasm and vomiting. An 8-, 9-, or 10-cm oral airway is appropriate for most adults.

Insertion of the oropharyngeal airway is a quick and simple procedure. Choose the proper size of oropharyngeal airway. The correct size is estimated by placing the airway next to the patient's mouth. The distal tip should lie just above the angle of the mandible. Clear the mouth and oropharynx of any blood, secretions, or vomit. Open the patient's jaw, and separate the teeth. Insert the oropharyngeal airway curved side down. The tip will slide along the

palate. After insertion, rotate the airway 180 degrees so that the curve of the oropharyngeal airway follows the curvature of the tongue. An alternative method is to use a tongue blade to depress the tongue and then insert the oropharyngeal airway as above. If the tongue blade is used, the oropharyngeal airway may also be inserted with the curve side upward. Supplementary oxygen or positive pressure ventilation with a bag-valve-mask device can be started after the insertion of the airway.

Insertion of an oropharyngeal airway is not a benign procedure. The airway can push the tongue posteriorly and further obstruct the oropharynx if not inserted properly. Significant lacerations can occur if the lips or tongue are caught between the teeth and the oral airway. The airway can force the epiglottis closed against the vocal cords if it is too long, resulting in complete airway obstruction. Too small an airway will force the tongue against the pharynx, producing an obstruction.

Mask Ventilation

Once mastered, expertise with bag-mask ventilation (BMV) allays the urgency to intubate and permits one to rescue a failed intubation. BMV is a prerequisite to the use of neuromuscular blocking agents to facilitate intubation. Provided one takes steps to minimize the risks of gastric aspiration, BMV for prolonged periods is not unreasonable if intubation is not possible.

Face masks are made of clear plastic, have a soft seal, and have an anatomic shape that conforms to the contours of the patient's face. Typical adult sizes are 3, 4, or 5. The size must be large enough to completely cover the nose and mouth but not be so large as to allow a leak. The key to effective mask ventilation is ensuring a continually patent airway. A patent airway is initially achieved by placing the patient in the "sniffing" position coupled with a combination of chin lift, jaw thrust, oral airway, or nasal airway. Neglecting this key maneuver results in using excessive positive pressure ventilation in an attempt to compensate for an obstructed upper airway. A bag-mask device can deliver 50 to 100 cm of water pressure to the upper airway with an adequate mask seal, which is more than sufficient

pressure to insufflate the stomach if the airway is not optimally opened.

There are two ways to properly hold a face mask (4). The one-handed technique is performed with the nondominant hand (Fig. 2.3). Place the little, ring, and middle fingers under the side of the patient's mandible. Place the index finger and thumb on the bottom and top portion of the mask. This technique allows the operator to simultaneously lift the mandible and extend the atlantooccipital joint while applying enough downward pressure to create an airtight seal. The dominant hand is used to ventilate the patient with the bag-valve device. The bag-valve device is used to provide positive pressure ventilation. The device consists of a self-inflating bag connected to oxygen on one end and a one-way (nonrebreathing) valve on the other. The valve is connected to the mask or other airway device to allow one-way flow of oxygen.

FIGURE 2.3 The one-handed, one-person, mask-ventilation technique. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

A two-handed, two-person technique may be necessary in patients with facial hair, are obese, are elderly, or are edentulous. Both of the operator's hands are applied to the face mask to aid in the creation of a tight seal and proper airway alignment (Fig. 2.4). Place the index, middle, ring, and small fingers of the left hand on the body of the left half of the mandible. Position the right hand similarly on the right half of the mandible. Place the face mask on the patient's face. Apply both thumbs to the mask, and apply pressure to create a seal. Anteriorly elevate the mandible to perform the jaw-thrust maneuver. The second person applies positive pressure through the bag-valve device.

FIGURE 2.4 The two-handed, two-person, mask-ventilation technique. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

A standard adult resuscitation bag is 1,500 mL. The goal is to deliver 500 to 600 mL of tidal volume at a rate of 24 breaths/min. Smaller devices are available for children, infants, and neonates. Typical ventilation volumes are 5 to 8 mL/kg per breath. Provided the airway is patent, significant insufflation of the stomach is unlikely. The cadence should be similar to the "squeeze …release … release" cadence recommended by advanced cardiac life support (ACLS) but at a slightly faster pace.

The specific type of bag employed in BMV is also important (4). Recent studies demonstrate that bags that minimize dead space, incorporate unidirectional air flow valves (e.g., “duck bill” inspiratory valves), and use one-way expiratory valves to prevent the entrainment of room air during inspiration will deliver 90% to 97% oxygen to spontaneously breathing or ventilated patients. This delivery is in sharp distinction to improperly configured bags that will provide high oxygen concentration during active bagging but deliver only 30% oxygen during spontaneous patient breathing as a result of the entrainment of room air.

Complications of Basic Airway Management

The most serious complication of basic airway management is aspiration of gastric contents, resulting in an acute chemical pneumonitis. It is a significant risk when airway management is needed emergently or routinely in the pregnant, trauma, diabetic, or obese patient. Less-serious complications include soft tissue trauma to the lips, tongue, oral cavity, and eyelids. Tooth fractures or avulsions are uncommon but possible. Facial nerve dysfunction caused by pressure effects of the mask is transient. Corneal abrasions, conjunctival chemosis, and increased intraocular pressure are common with masks that are too large.

Intubation

Orotracheal Intubation

Orotracheal intubation is both common and life-saving. Orotracheal intubation is the primary and preferred method of airway management that every emergency physician must master (3). With proper preparation, definitive control of the airway can be obtained. Airway control assures that the patient can be oxygenated and ventilated when the patient cannot do this on his or her own.

Orotracheal intubation is relatively contraindicated in patients who do not need it, who are likely to be injured by the procedure, whose injuries make success unlikely, or in whom less-invasive techniques may suffice. Intubation may be difficult in patients with likely cervical spine injuries, severe arthritis, severe orofacial

injuries, deep airway obstruction, gross deformities of the head and neck, or a quickly changing obstruction (edema or an expanding hematoma). Choose a surgical airway if the manipulation or time required for oral endotracheal intubation puts the patient at risk for spinal injury or hypoxia.

The evaluation, preparation, and technique for orotracheal intubation are complex and essential. Firmly grasp the laryngoscope in the left hand. Insert the tip of the laryngoscope blade into the right side of the patient's mouth. Smoothly advance the blade inward while keeping pressure against the tongue. Move the blade toward the midline to trap and push the tongue to the left, "clearing a path" for your gaze.

Lift the patient's airway up and forward exactly along the long axis of the laryngoscope handle (Fig. 2.5). Do not "cock" or "crank back" on the laryngoscope handle with the wrist, or the back of the laryngoscope blade may break the maxillary incisors. If intubating with the curved Macintosh blade, advance the tip into the vallecula, lift the laryngoscope handle to raise the tongue–jaw–epiglottis unit (Fig. 2.5), visualize the vocal cords, and insert the ETT. If intubating with the straight Miller blade, insert the blade completely, lift the laryngoscope handle to raise the tongue–jaw–epiglottis unit (Fig. 2.6), visualize the vocal cords and airway, and insert the ETT. Advance the ETT until the cuff passes through the vocal cords and 2 to 3 cm into the trachea. Inflate the cuff, assess for proper placement, and secure the ETT in place.

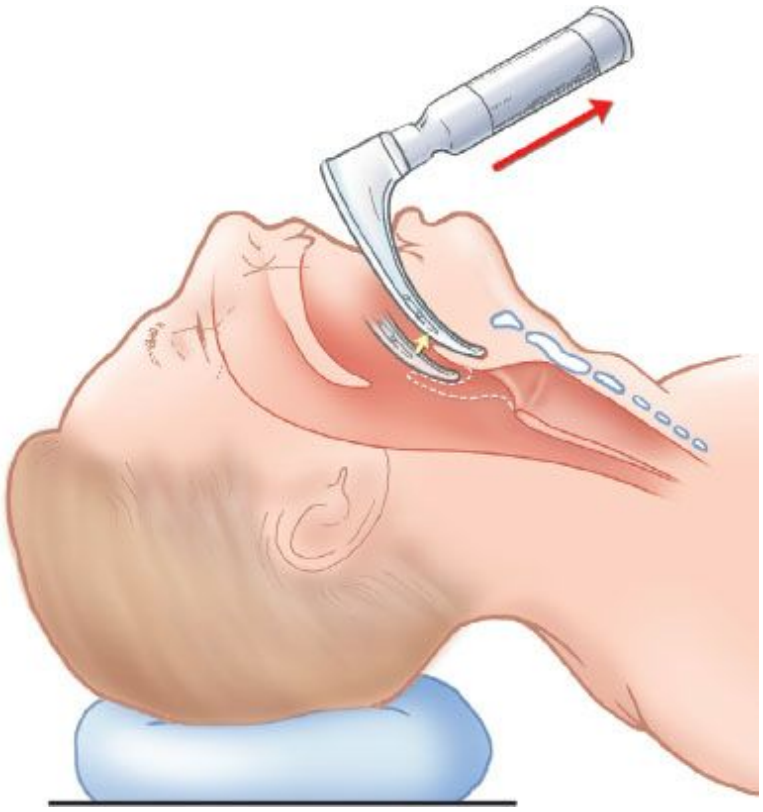

FIGURE 2.5 Intubation with the Macintosh blade. The blade is inserted into the vallecula to elevate the mandible, tongue, and epiglottis as a unit. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

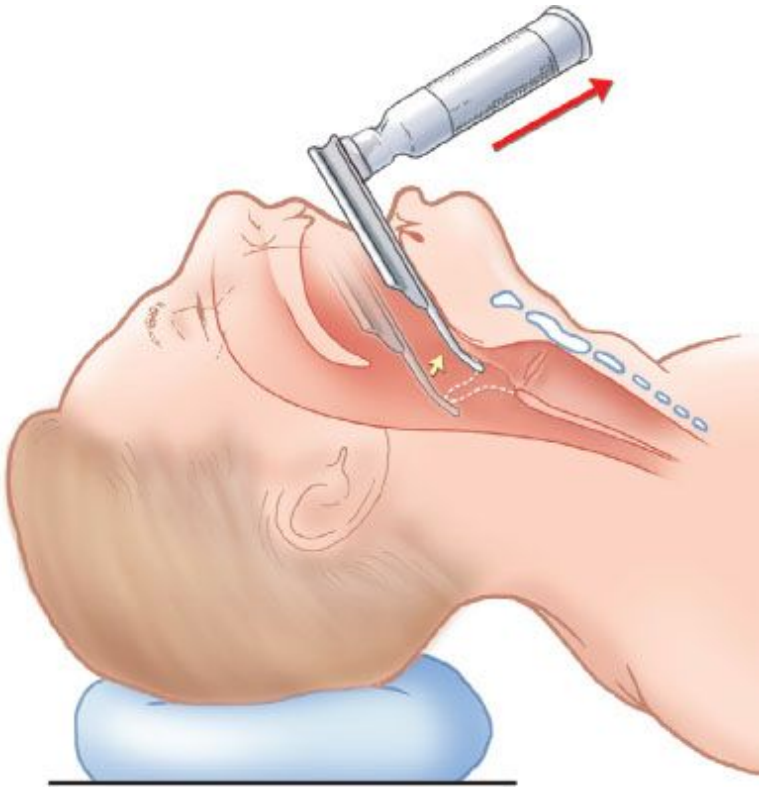

FIGURE 2.6 Intubation with the Miller blade. The blade is inserted into the vallecula to elevate the mandible, tongue, and epiglottis as a unit. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Numerous complications are associated with orotracheal intubation (3). Hypoxia often results from prolonged intubation attempts and misplaced ETTs. Bradycardia can be produced by pharyngeal manipulation. Bradycardia may be especially pronounced in children because of their higher vagal tone. Pretreatment with atropine (0.02 mg/kg, with a minimum dose of 0.15 mg) in children younger than 6 years of age can prevent bradycardia. Increased intracranial pressure that is transient can occur as a result of the direct laryngoscopy. Direct mechanical complications from the laryngoscope include lacerations of the lips, trauma to the pharyngeal wall, broken teeth, or dentures that may be aspirated. Vomiting and aspiration can cause subsequent chemical and bacterial pneumonitis. Prolonged stimulation of the pharynx may cause apnea, bronchospasm, or laryngospasm.

Nasotracheal Intubation

Nasotracheal intubation is an alternative to orotracheal intubation to secure an airway in the spontaneously breathing patient (5). Nasotracheal intubation allows awake intubations while the patient maintains protective airway reflexes and avoids the risks of paralytic agents. It is a fairly simple procedure that should be considered in patients with spontaneous respirations in whom an oral airway is considered difficult and in those with an anticipated short intubation period. Nasotracheal intubation is well tolerated by most patients and produces less reflex salivation than orotracheal intubation, thus leading to fewer attempts of self-extubating.

Nasotracheal intubation is contraindicated in patients with apnea, with severe facial or maxillofacial fractures, with basilar skull fractures, with head injury and an elevated intracranial pressure, with nasal or nasopharyngeal obstruction, receiving thrombolytics, with a coagulopathy, or receiving parenteral anticoagulants. Nasotracheal intubation is also contraindicated in patients with neck injuries, as the procedure may increase morbidity and mortality. Nasotracheal intubation should not be performed in neonates, infants, and young children.

Prepare for the procedure. Apply a topical vasoconstrictor to shrink the nasal mucosa. Apply a topical anesthetic to the nasal mucosa. Dilate the nasal passage with your little finger or a series of increasingly larger size nasopharyngeal airways. Choose an ETT. The proper size tube should be at least 0.5 to 1 mm smaller than the size chosen for orotracheal intubation of the same patient.

Insert the ETT into the nostril with the bevel facing the septum (Fig. 2.7A). Advance the ETT with gentle pressure along the nasal floor to pass it through the nasal cavity (Fig. 2.7B). Continue advancing the ETT as resistance is met while it makes a 90-degree change of direction into the oropharynx. Advance the ETT through the oropharynx and into the laryngopharynx (Fig. 2.7C). Listen for breath sounds through the proximal end of the ETT while advancing it. As soon as an exhalation is heard, the patient will take a breath. Advance the ETT during inhalation. The vocal cords are opened their widest during inspiration, which facilitates passage of the ETT.

Inflate the cuff (Fig. 2.7D), begin ventilation, confirm proper positioning, and secure the ETT.

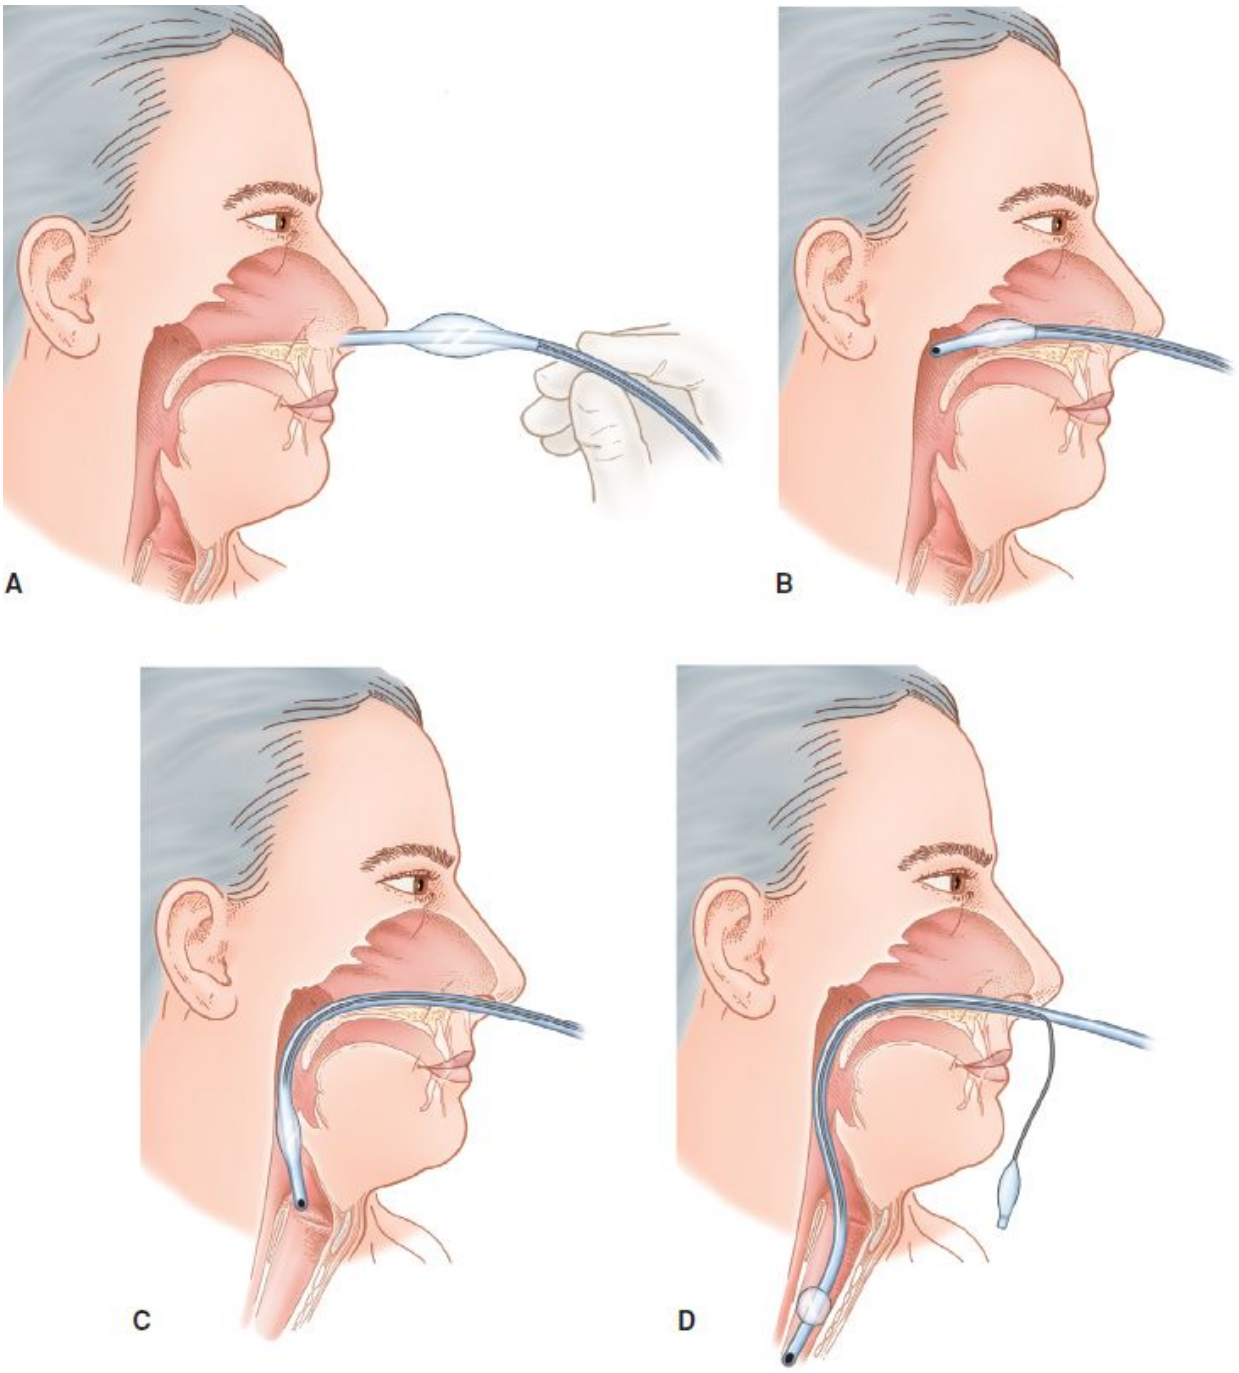

FIGURE 2.7 Nasotracheal intubation. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

The immediate complications of nasotracheal intubation include epistaxis, laryngeal and tracheal trauma, mucosal avulsion, retropharyngeal laceration, turbinate avulsion, intracranial placement, bacteremia, esophageal intubation, and prolonged attempts to place the ETT. Many of these complications can be prevented by choosing the appropriate-size ETT, facilitating nasal mucosal vasoconstriction, and applying lubricant to the ETT. Long-term complications include maxillary sinusitis, retropharyngeal abscess, mediastinitis, nasal mucosal necrosis, and cellulitis.

Digital (Tactile) Orotracheal Intubation

Digital (tactile) intubation is a viable alternative airway management technique with which every practitioner of emergency medicine should be familiar (6). Digital intubation is a rapid and safe method to intubate a patient. It is an ideal method for intubating a comatose or paralyzed patient if the patient's upper airway cannot be visualized because of secretions or blood. Digital intubation also should be considered when intubating the patient with a known or suspected cervical spine fracture as this technique requires minimal head and neck movement. Digital intubation is also a variable method for out-of-hospital intubation. The main danger of this procedure involves the healthcare worker performing the intubation being at risk for having his or her fingers bitten. This technique should only be performed on patients who are paralyzed or unconscious.

Stand to the patient's right side, and face the patient. Insert the right index and middle fingers into the right side of the patient's mouth. Elevate the epiglottis with the index finger (Fig. 2.8). Insert the ETT into the patient's mouth between the two fingers, and advance the tip into the trachea. Advance the ETT an additional 3 to 4 cm. Inflate the cuff, begin ventilation, confirm proper tube placement, and secure the tube.

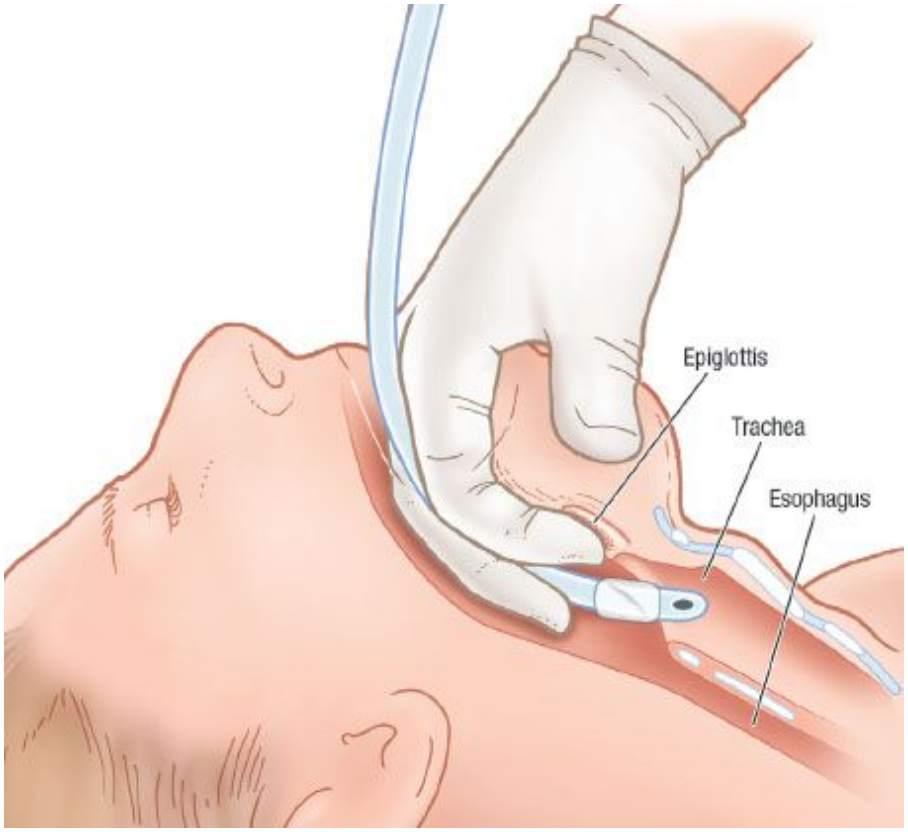

FIGURE 2.8 Digital orotracheal intubation. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Supraglottic Airway Devices

Supraglottic devices all allow positive pressure ventilation with placement of the device above the glottis, and thus they are classified as supraglottic devices. The most commonly used of these devices are the esophageal–tracheal Combitube (ETC) or the laryngeal mask airway (LMA) described later in this chapter. The advantage of a supraglottic device is that it allows ventilation without tracheal placement. The majority of these devices can be inserted blindly and quickly by minimally trained personnel, which makes them ideal for prehospital providers, in hospital arrests where no airway providers are available, or as a rescue device in the setting of a failed intubation. In general, supraglottic devices have a cuff that inflates in the posterior pharynx and obstructs the proximal airway above the distal port, allowing positive pressure ventilation of the lungs.

Laryngeal Mask Airway and Intubating Laryngeal Mask Airway

The LMA is a novel device that fills the gap in airway management between endotracheal intubation and the use of a face mask (7). The LMA was designed primarily as a means of providing ventilatory support while avoiding the fundamental disadvantage of the need to visualize and penetrate the vocal cords with an ETT. The LMA is blindly introduced into the hypopharynx to form a low-pressure seal around the laryngeal inlet and to permit positive pressure ventilation.

Many disadvantages of the standard LMA became apparent with widespread use of the device. The intubating laryngeal mask airway (ILMA) was then developed through the aid of analysis of magnetic resonance images of the human pharynx and laboratory testing of ETTs.

The LMA and ILMA are proprietary devices of a single company (LMA North America, San Diego, CA). Numerous other companies produce similar laryngeal mask devices with a variety of modifications as to not interfere with the LMA and ILMA patents. These other devices are used and inserted similarly to the LMA and ILMA with some minor differences specific to each device.

The indications for the use of the LMA and the ILMA parallel the general indications for active airway management. Either the LMA or the ILMA may be used in the event of a failed endotracheal intubation. These devices have a role in securing the airway preemptively in patients with an “anteriorly” situated larynx. However, there is a conspicuous absence of airway protection from aspiration.

There are no absolute contraindications to the use of either the LMA or the ILMA. However, there are several relative contraindications, including patients at an increased risk of regurgitation or aspiration; with airway obstruction at or below the larynx; with low pulmonary compliance or high airway resistance (e.g., morbidly obese, bronchospasm, pulmonary edema, pulmonary fibrosis or thoracic trauma); and who cannot open their mouth at least 1.5 cm. The LMA and ILMA are relatively contraindicated in

cases of pharyngeal pathology. Pathology includes, but is not limited to, abscesses, hematomas, or tissue disruptions.

The LMA is a disposable unit that conforms to the contours of the hypopharynx with its lumen facing the glottic opening (Fig. 2.9). The unit consists of an airway tube, inflation line, and mask. The technique for inserting the LMA is rather simple (7). Position the patient's head as for endotracheal intubation in the "sniffing" position. Insert and advance the LMA into the oral cavity in one smooth movement following the curvature of the pharynx until it enters the hypopharynx and resistance is felt. Inflate the cuff with the recommended volume of air. When correctly positioned, the tip of the LMA cuff lies at the base of the hypopharynx against the upper esophageal sphincter, the sides lie in the pyriform fossae, and the upper border of the mask lies at the base of the tongue, pushing it forward (Fig. 2.9). Secure the LMA in a fashion similar to that used to secure an ETT.

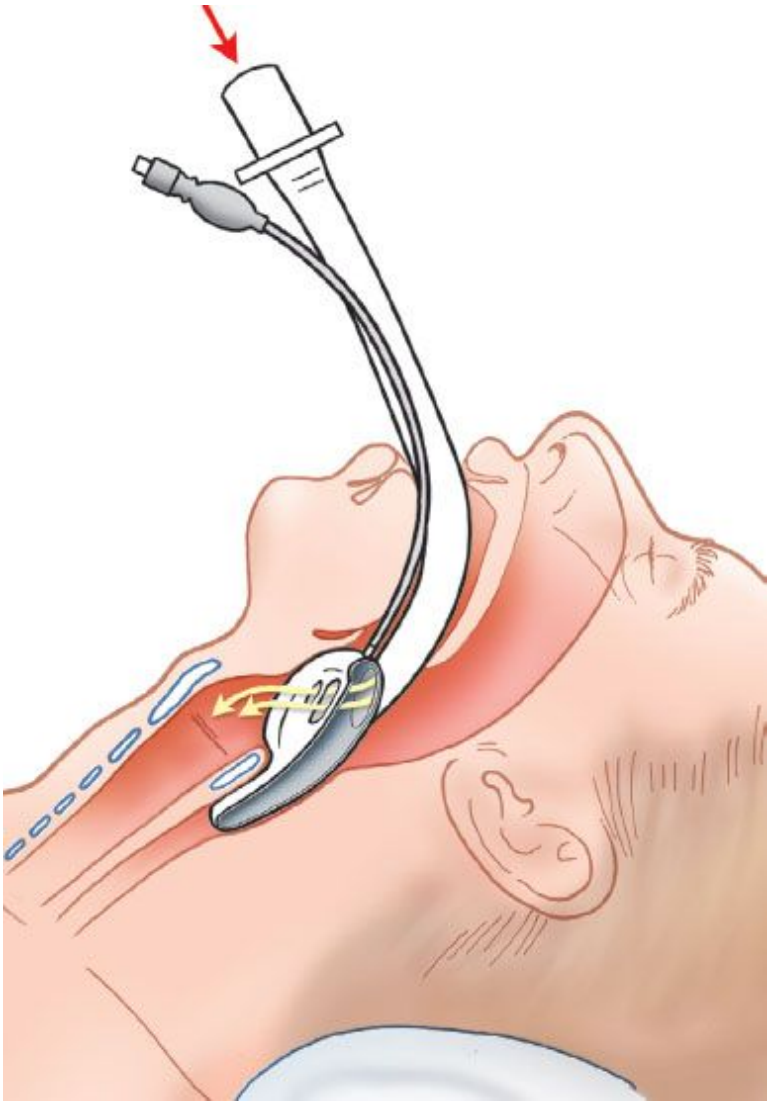

FIGURE 2.9 Sagittal view of the airway demonstrating correct placement of the laryngeal mask airway. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

The form of the ILMA was derived from head and neck sagittal magnetic resonance imaging studies. The ILMA consists of an anatomically curved steel tube connected to the standard LMA cuff. The ILMA has several significant modifications that make it different from the LMA. These modifications include a stainless steel airway tube covered with silicone rubber, a handle fused to the airway tube, and a larger inner diameter (13 mm vs. 9 mm) than the LMA. The

mask of the ILMA is similar to that of the LMA with two major modifications. A ramp inside the distal airway tube directs an ETT into the center of the aperture and into the patient's airway. The ILMA has a large, single, and stiff epiglottic-elevating bar designed to lift the epiglottis away from the path of the advancing ETT.

The insertion of the ILMA is not too dissimilar from the standard LMA (7). Confirm proper placement of the ILMA with a bag-valve device attached to the proximal end of the airway tube, and ventilate the patient. The ILMA may be left in this placement (Fig. 2.10A). Alternatively, an ETT can be inserted through the ILMA and into the trachea (Fig. 2.10B).

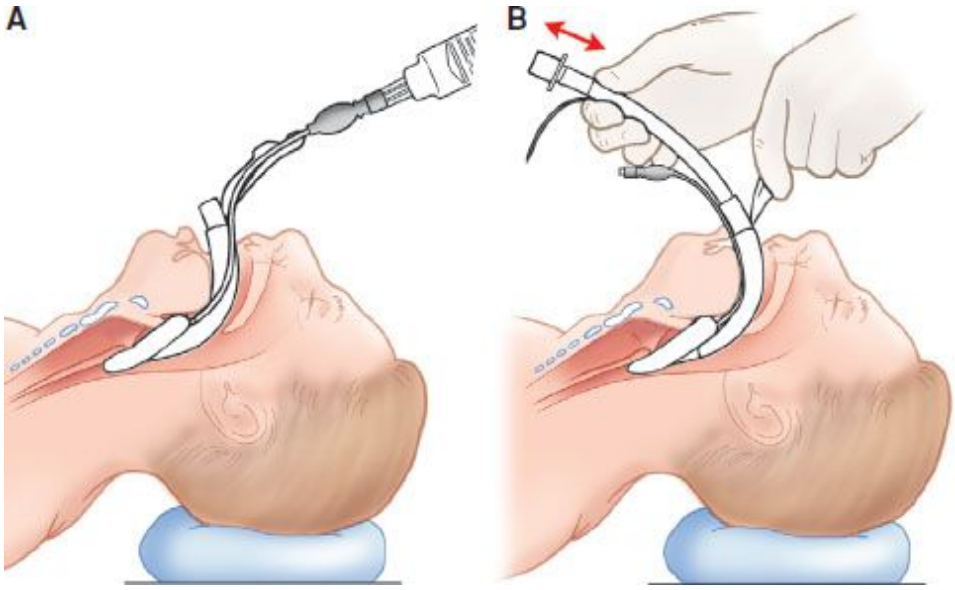

FIGURE 2.10 Insertion of the intubating laryngeal mask airway. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

There are numerous documented complications associated with the use of the LMA and ILMA. An obvious complication, and potentially the most devastating, is the failure to successfully place the device or to attain a satisfactory laryngeal seal. The incidence of failure to attain satisfactory ventilation is quite low. Other complications include aspiration, cuff herniation, contusions, lingual nerve injury, tongue numbness, parotid gland swelling, hypoglossal nerve palsy,

unilateral vocal cord paralysis, dental trauma, laryngospasm, bronchospasm, and cardiac arrhythmias.

Double Lumen Airway Tube Intubation

The ETC (Kendall Sheridan, Mansfield, MA) and the EasyTube (EzT; Teleflex Medical, Kernen, Germany) are double-lumen, double-tubed, and double-cuffed airway devices that can be blindly inserted into the unconscious and unresponsive patient (8). The ETC and EzT are most often used in the prehospital setting by emergency medical technicians not trained in standard orotracheal intubation and by paramedic-level rescuers as an alternative when standard orotracheal intubation fails.

These devices are inserted blindly into a patient's airway. If the distal tip enters the trachea, the patient is ventilated through the shorter tube, and the distal cuff prevents aspiration of gastric contents into the trachea. If the distal tip enters the esophagus, the patient is ventilated through the longer tube whose proximal ports lie in the hypopharynx while the distal cuff will occlude the esophagus.

Certain contraindications should be mentioned. The ETC and EzT should not be used on patients with an intact gag reflex. The size limits of the standard ETC prevent its use in patients shorter than 5 ft in height. The smaller SA model can be used in shorter adults and adolescent patients from 4 to 5.5 ft in height. Neither model can be used in people shorter than 4 ft in height. The ETC and EzT are contraindicated if the patient has known esophageal disease or an airway obstruction.

Insert the ETC or EzT into the midline of the patient's open mouth (Fig. 2.11A). Advance the device in a downward curved motion until the patient's teeth or alveolar ridge lie between the two printed bands (Fig. 2.11B). Inflate the pharyngeal cuff with air. The device will slightly withdraw from the patient's mouth. Inflate the distal cuff with air.

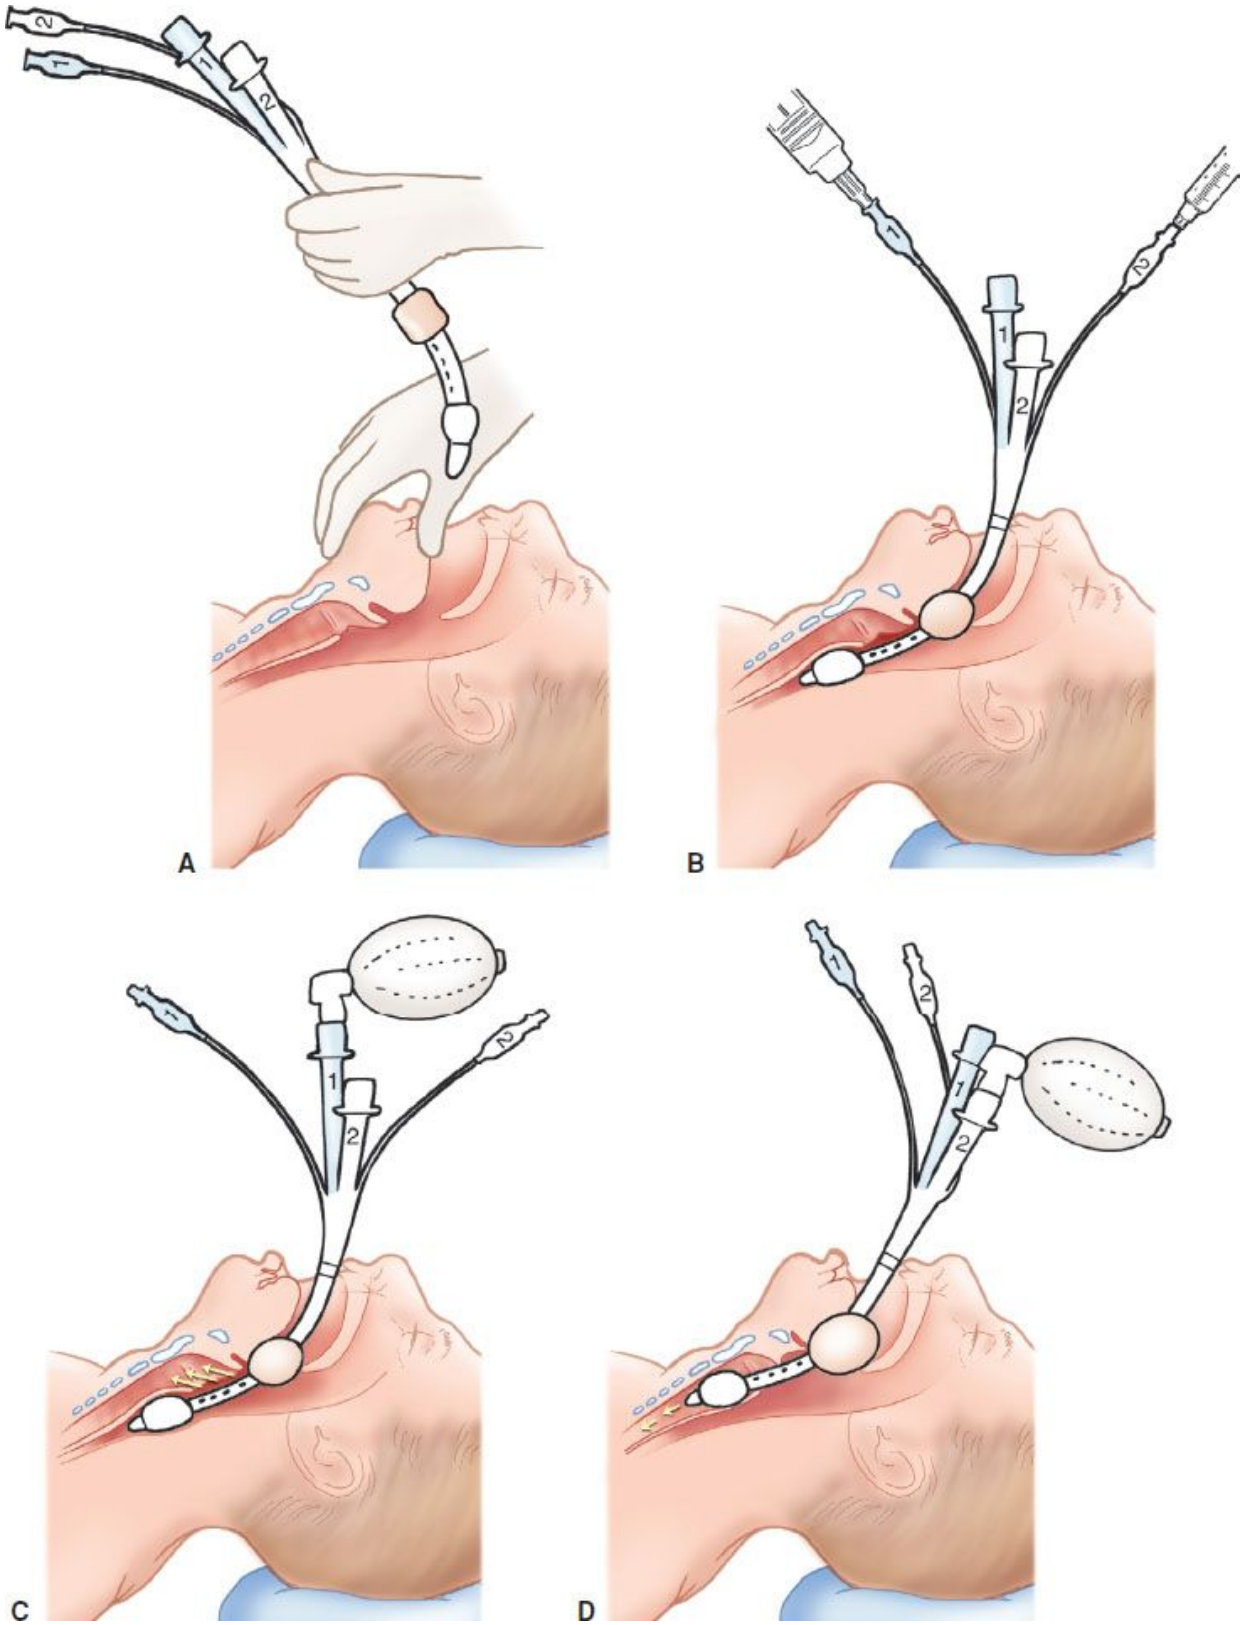

FIGURE 2.11 Intubation with the esophageal–tracheal Combitube. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New

York, NY: McGraw-Hill; 2013, with permission.)

Because most intubations are esophageal, begin ventilation through the longer blue tube labeled No. 1 (Fig. 2.11C). Auscultation of breath sounds, symmetric rise of the chest, fogging in the tube for more than six breaths, and lack of gastric insufflation confirm placement within the esophagus and ventilation through the proximal ports (Fig. 2.11C). If no breath sounds are auscultated and gastric insufflation occurs, the trachea is intubated (Fig. 2.11D). Begin ventilation through the shorter clear tube and verify by auscultation the presence of breath sounds. Secure the device using the standard method of taping or a commercially available ETT holder.

Despite the potential utility of the ETC or EzT in acute situations, several disadvantages must be kept in mind (8), including its high cost and bulky packaging. A rigid cervical collar might cause great difficulties in the proper placement of this device. There is a risk of esophageal injury. There is no way to suction the trachea with the open distal port in the esophagus. It is important to note that resuscitation drugs that can be routinely given through an ETT cannot be given through the device positioned with the tip in the esophagus. Significant soft tissue injury can occur as a consequence of the tip of the device or the balloons containing too much air.

Laryngeal Tube

The laryngeal tube (LT; King Systems, Noblesville, IN) is available in a variety of styles and is a device similar to the ETC and EzT. The LT has a single port placed between an oropharyngeal cuff and an esophageal cuff. The LT lacks a distal port. The device is designed to be placed in the same way as the ETC and EzT. Insert the LT blindly in the midline until significant resistance is felt. Inflate both cuffs, and begin ventilation through the port in the glottis. Adequate ventilation is confirmed by auscultation, chest rise, and end-tidal CO_2 measurements. The most significant difference as compared to the ETC and EzT is the single port opening in the hypopharynx. The distal tip is designed to be placed in the esophagus. The LTD models

have no distal port to allow for esophageal and gastric suctioning. The LTS-D models have a distal port to allow for esophageal and gastric suctioning.

Advanced Airway Devices

Intubating Introducers

Intubating introducers were first described by Dr. Robert Macintosh when a gum rubber urologic stylet was used as a device to aid in intubation (9). The device was inserted into the trachea, and an ETT advanced over the stylet. This "Seldinger-type" intubation did not gain widespread use until much later. Intubating introducers are now often considered standard equipment in the management of difficult airways.

Multiple intubating introducers are currently available (10). Two of the most common are the Eschmann (Eschmann Tracheal Tube Introducer, SIMS Portex, Inc., Keene, NH) and the Frova (Cook Medical Inc., Bloomington, IN). Both of these devices have a 30-degree bend at the tip and are rigid enough to hold an additional bend placed in the shaft of the introducer by the physician. There are differences between the two devices. The Frova is a single-use item, and the Eschmann is designed for multiple uses. The Frova has a central port that can provide limited ventilation, and the Eschmann is a solid introducer. The Eschmann is more flexible and may potentially decrease the forces transmitted to the airway and decrease airway trauma.

Although there are slight differences between the two devices, they are used in a similar manner (Fig. 2.12). Perform direct laryngoscopy in the standard fashion. An intubation introducer can be used if a limited view is obtained or a difficult airway is predicted. The vocal cords or epiglottis should be visualized to use the introducer effectively. Insert the introducer with the 30-degree bend at the tip and the introducer distance markings aimed anteriorly (Fig. 2.12A). Advance the stylet under the epiglottis (Fig. 2.12B). If the vocal cords are visualized, continue to advance the stylet through the cords. If only the epiglottis is visualized, gently

advance the stylet “blindly” while relying on the 30-degree bend to direct it into the trachea (Fig. 2.12C). Continue to advance the stylet until the 25-cm mark is positioned at the patient’s lips. This motion should place the tip of the stylet in the midtrachea and should avoid entering either the left or right mainstem bronchus (Fig. 2.12D).

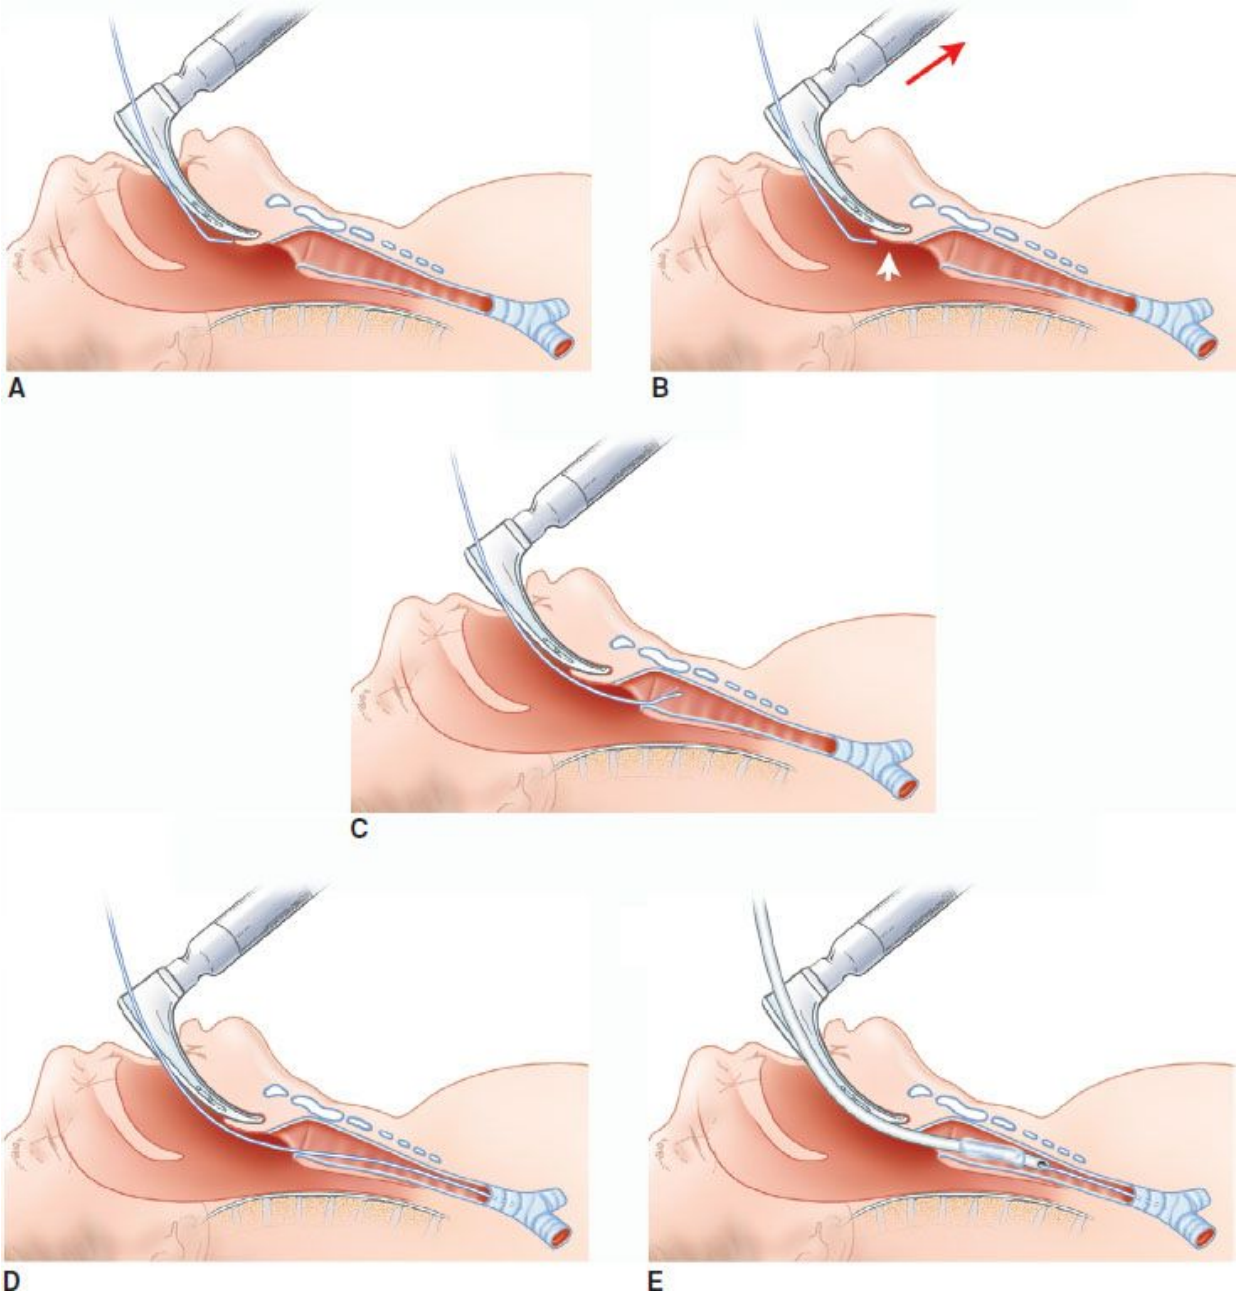

FIGURE 2.12 Intubation using a bougie or intubating introducer. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Tracheal placement of the stylet is identified by one of four methods. The most reliable method is direct visualization of the stylet passing through the vocal cords. The second method is feeling the transmission of vibratory clicks as the advancing stylet tip contacts the tracheal rings. Absence of this sensation does not confirm esophageal placement. The third method is noting the presence of a cough in a patient who is sedated but not paralyzed. The final method is advancement of the introducer until there is distal holdup or blockage of advancement as the introducer enters the distal airways. This advancement is potentially the most dangerous of the methods and should not be used if any other method can confirm placement.

Advance the ETT over the introducer while maintaining direct laryngoscopy (Fig. 2.12E). This method allows easier placement of the ETT by minimizing curvature of the airway. Advance the ETT to the appropriate depth. If there is difficulty in advancing the ETT, it can be gently rotated 90 degrees to the right and left to promote passage through the vocal cords. Remove the introducer while firmly holding the ETT so it does not change position. Confirm proper ETT placement, and secure it in position.

The complications for this procedure are similar to direct laryngoscopy with the additional risk of airway trauma from the intubating introducer. The use of intubating introducers and bougies is an easily learned technique to improve endotracheal intubation when an anticipated or actual difficult airway is encountered.

Video Laryngoscopy

Video laryngoscopy is a relatively new method of indirect laryngoscopy. Video laryngoscopy involves a laryngoscope blade with a camera or another optical device attached to the end of the blade. The laryngoscope is then attached to a view screen. These devices are different from fiberoptic devices in that they require viewing on a screen, as there is no optical port on the device. Two more commonly available devices are multiple versions of the GlideScope (Verathon Inc., Bothell, WA) and the C-MAC Video Laryngoscope (Karl Storz Endoscopy Ltd., Tuttlingen, Germany).

Video laryngoscopy allows for indirect viewing of the epiglottis and vocal cords, and hence indirect orotracheal intubation (11). The indirect view can be obtained with minimal force and less manipulation of the airway. This may lead to decreased movement of the cervical spine as compared to other techniques. Video laryngoscopy can also provide for a better view of the epiglottis and vocal cords when compared to direct laryngoscopy. Video laryngoscopy may be easier to learn than either direct laryngoscopy or other methods of indirect laryngoscopy. Viewing images on a screen can be used as a teaching adjunct either during the intubation or can be recorded and reviewed at a later time.

Video laryngoscopy can be used for both routine and difficult intubations. This technique may be of additional benefit in patients with predicted difficult airways, limited laryngoscopic views during direct laryngoscopy, or restricted cervical spine movement. Video laryngoscopy is contraindicated when there is a proximal obstruction preventing passage of an ETT. The camera placement midway on the blade decreases the risk of occlusion of the camera with secretions, but occlusion is still a possibility.

The GlideScope consists of a 60-degree curved laryngoscope blade and handle combination with a camera embedded in the blade midway on the device. There are light emitting diode (LED) lights mounted adjacent to the camera. The device is attached to a color liquid crystal display (LCD) screen for image viewing. The GlideScope is available in three sizes (small, medium, and large). The small size is similar to a Macintosh size 0 blade, the medium is similar to a Macintosh size 2 blade, and the large is similar to a Macintosh size 3 blade. The benefit of this design is the camera mounted at the midpoint of the blade that allows for a wider view and less obstruction of the view with debris and secretions in the airway. The similarity to a standard Macintosh blade helps facilitate the GlideScope use with providers skilled in direct laryngoscopy.

To orotracheal intubate with a GlideScope, the first step is preparation. Turn on the device, and position the screen for the intubator to view. Prepare an ETT containing a stylet curved to a 60-degree or 90-degree angle. Open the patient’s mouth with the right

hand while the GlideScope is advanced with the left hand in the midline and posteriorly. When the blade enters the oropharynx, the physician views the screen. Continue to advance the blade in the midline until the epiglottis is seen. The blade is either in the vallecula or underneath the uvula. Apply slight upward pressure in a tilting motion to visualize the vocal cords. Once the vocal cords are visualized, advance the ETT until it is viewed on the screen. Continue to advance the ETT through the vocal cords. The ETT can be used without the stylet to decrease the angle of the posterior portion of the tube if there is difficulty in passing the ETT. The GlideScope can be manipulated while viewing on the screen to decrease the laryngeal angle and help in ETT placement.

The C-MAC Video Laryngoscope is a similar device to the GlideScope. This device consists of a Macintosh blade with a camera at the distal aspect of the blade. The C-MAC is used in a similar method to the GlideScope and standard Macintosh blade. The C-MAC improves laryngoscopic views of the epiglottis and vocal cords.

The complications associated with the different video laryngoscopes are not yet well studied. It can be anticipated that the complications are similar to those of direct laryngoscopy and fiberoptic devices.

Overall, video laryngoscopy is a useful device for the management of both uncomplicated and complicated airways. Video laryngoscopy improves views of the epiglottis and vocal cords. It requires less force than direct laryngoscopy, which may cause less airway trauma, less cervical spine movement, and decreased hemodynamic response to intubation. Lastly, video laryngoscopy is a strong educational tool for teaching airway management.

Rigid and Semirigid Fiberoptic Devices

This category of devices is one of the most rapidly growing areas of difficult airway management. Fiberoptic devices allow for indirect visualization of the larynx, similar to the flexible fiberoptic scopes and rigid fiberoptic scope blade combinations. This device allows for airway management without the force and movement of the airway inherent to direct laryngoscopy. The benefit is decreased cervical

spine motion during laryngoscopy (12,13). These devices demonstrate improved views of the larynx, allowing for increased endotracheal intubation rates in difficult airways.

There are numerous advantages to the rigid and semirigid devices when compared to flexible fiberoptic scopes. These devices are often easier to learn and master when compared to flexible fiberoptic scopes. The rigid and semirigid devices are designed to function similar to or in conjunction with direct laryngoscopy. Their rigidity and shape conforms to the airway. This allows easier passage through the pharynx and past the tongue. These devices are often less expensive and more durable than flexible fiberoptic scopes.

The indications for the use of rigid and semirigid devices are the same as for direct laryngoscopy. They can be used as a primary device in uncomplicated airways, in potentially difficult airways, or as a secondary device after a failed intubation attempt. Rigid and semirigid devices are contraindicated, as are other fiberoptic devices, if there is a proximal airway obstruction and relatively contraindicated when the airway contains vomitus, blood, or copious secretions that may obstruct the optical port.

These devices can be used either as an adjunct to direct laryngoscopy or as a single instrument for endotracheal intubation. Most rigid and semirigid devices have a site for attachment of a viewer or can be connected to a monitor for viewing. These devices represent a useful adjunct in the management of the difficult airway. Rigid and semirigid devices often require less training to master than flexible fiberoptic scopes. Although there is still limited evidence of their use in the emergency department, it is likely these devices will become commonly used in airway management.

There are multiple rigid and semirigid devices on the market including the Bonfils Retromolar Intubation Fiberscope (Karl Storz Endoscopy Ltd., Tuttlingen, Germany), the Levitan FPS (Clarus Medical, Minneapolis, MN), the Video Optical Intubating Stylet (VOIS, VOLPI AG, Schlieren, Switzerland), and the TrachView Intubating Videoscope (Parker Medical, Englewood, CO). Although there is evidence that the use of these devices improves laryngeal views in the difficult airway, there is little evidence comparing these

devices to each other. Preference for a device is often user and institution specific.

Fiberoptic Endoscopic Intubation

The flexible fiberoptic bronchoscope has become a popular and useful instrument for placing ETTs in awake and nonparalyzed patients. This bronchoscope is unique because its flexible cord allows it to conform to the patient's anatomy, making intubation possible in a variety of clinical situations when direct laryngoscopy is likely to be difficult or impossible. When performed properly, awake fiberoptic tracheal intubation is more accepted by patients and is associated with fewer hemodynamic changes than awake laryngoscopy. Fiberoptic intubation may be used to orally or nasally intubate a patient (14). It provides excellent visualization of the airway.

A fiberoptic intubation is indicated when it is anticipated that a direct laryngoscopy might be difficult to perform such as in morbidly obese patients; in patients with a limited mandibular opening, an unstable or immobile cervical spine, macroglossia, or micrognathia; in patients who appear to have pathologic airway anatomy (e.g., tracheal deviation, stenosis, tumors, trauma); and in patients who appear to be at increased risk for dental damage.

Proficiency in the skills required for fiberoptic intubation requires both instruction and practice. In most instances, it is a lack of expertise with the fiberoptic bronchoscope that results in technical problems, inadequate patient preparation, and prevents the successful completion of fiberoptic intubation. Successful intubation is also prevented by blood or secretions obstructing the fiberoptic port. Patients who are hypoxic or require assisted ventilation by mask are poor candidates. Contraindications specific to nasal fiberoptic intubation include coagulopathy, significant midface trauma, severe intranasal pathology, cribriform plate fracture, and cerebrospinal fluid leak.

Prepare the fiberoptic bronchoscope. Apply antifog solution to the insertion cord tip, or place the tip in warm water. Apply a thin film

of silicone spray or water-soluble lubricant onto the flexible insertion cord. Insert the flexible insertion cord completely through the ETT.

Insert and navigate the insertion cord tip through the nose or mouth until the glottic opening comes into view. Advance the insertion cord tip toward and past the vocal cords. Advance the insertion cord tip further to bring the bifurcation of the trachea at the carina into view. Advance the ETT over the insertion cord and into the trachea. Securely hold the ETT, and remove the insertion cord. Inflate the ETT cuff, begin ventilation, confirm proper tube placement, and secure the tube.

Although the fiberscope is passed through the glottis and into the trachea with direct vision, the ETT is passed blindly over the fiberoptic bronchoscope. It is possible to cause injury to the arytenoids. The ETT may also be blocked in the nasal cavity or larynx, resulting in epistaxis, nasal turbinate fracture, and tearing of the tracheal tube cuff.

Rigid Fiberoptic Scopes and Blades

The Bullard laryngoscope is the most well-known of the rigid fiberoptic scopes. Other commonly used devices include the Airtraq (King Systems Corp., Noblesville, IA), the Upsherscope (Mercury Medical, Clearwater, FL), and the WuScope (Achi Corporation, Fremont, CA). These devices are all rigid devices with a built-in optical and light system, a rigid blade, and a channel for the ETT. The most significant difference among these devices is the Airtraq, is a single-use disposable device and the others are reusable.

These devices have waned in popularity as flexible and semirigid fiberoptic scopes have become more prevalent and simpler to use. The major limitation of these devices is their complex design and difficulty in ETT advancement after visualization of the vocal cords. Two of them require multiple pieces to be assembled before use—not a desirable characteristic when a device is required in an emergency or as a rescue technique after a failed airway by direct laryngoscopy. The Airtraq, a single-piece disposable device, may overcome some of these limitations, but the evidence to support its use in the emergency department is limited.

Surgical Airways

Cricothyroidotomy

Cricothyroidotomy is a technique that has been in use since the early 1900s. This technique has evolved into the surgical airway of choice for emergent situations in which other less-invasive intubation methods have failed or are contraindicated (15). There are numerous advantages to performing a cricothyroidotomy instead of a tracheostomy. A cricothyroidotomy is easier, faster, and safer to perform. It can be performed in less than 2 minutes. A cricothyroidotomy can be performed by those with little to no surgical training. It does not require the support of an operating room and a large amount of equipment. The anatomic landmarks are superficial, easily seen, and easy to palpate. Cricothyroidotomy does not require a deep dissection. The cricothyroid membrane is not covered by any structures that would interfere with the procedure. A cricothyroidotomy can be performed with the neck in a neutral position. The procedure has fewer associated complications than a tracheostomy.

There are a few absolute contraindications to performing a cricothyroidotomy. The most important contraindication is when the patient can be endotracheally intubated by less-invasive methods. Partial or complete transection of the airway is a contraindication to a cricothyroidotomy. In these cases, a tracheostomy is the preferred method to secure the airway. Finally, a cricothyroidotomy should not be performed in cases of significant injury or fracture of the cricoid cartilage, larynx, and/or thyroid cartilage. Relative contraindications to performing a cricothyroidotomy are the presence of a coagulopathy, massive neck swelling, or a hematoma in the neck; all of which increase the risk of bleeding and distortion of the anatomy.

Stabilize the large thyroid cartilage. The immobilization of the larynx cannot be overemphasized. If the larynx is not secure and the landmarks are lost, the procedure will fail. Identify the anatomic landmarks necessary to perform this procedure. This identification is critical to the performance of a cricothyroidotomy.

There are numerous techniques to perform a cricothyroidotomy (15). The surgical techniques require a skin incision carried down through the cricothyroid membrane (Fig. 2.13A). This is followed by grasping the thyroid cartilage with a tracheal hook to control the airway (Fig. 2.13B). The tract is dilated (Fig. 2.13C), and a tracheostomy tube or ETT is inserted into the trachea (Fig. 2.13D). A percutaneous kit is available and uses a modified Seldinger technique to perform a cricothyroidotomy. A needle cricothyroidotomy is performed in children, instead of the surgical approach.

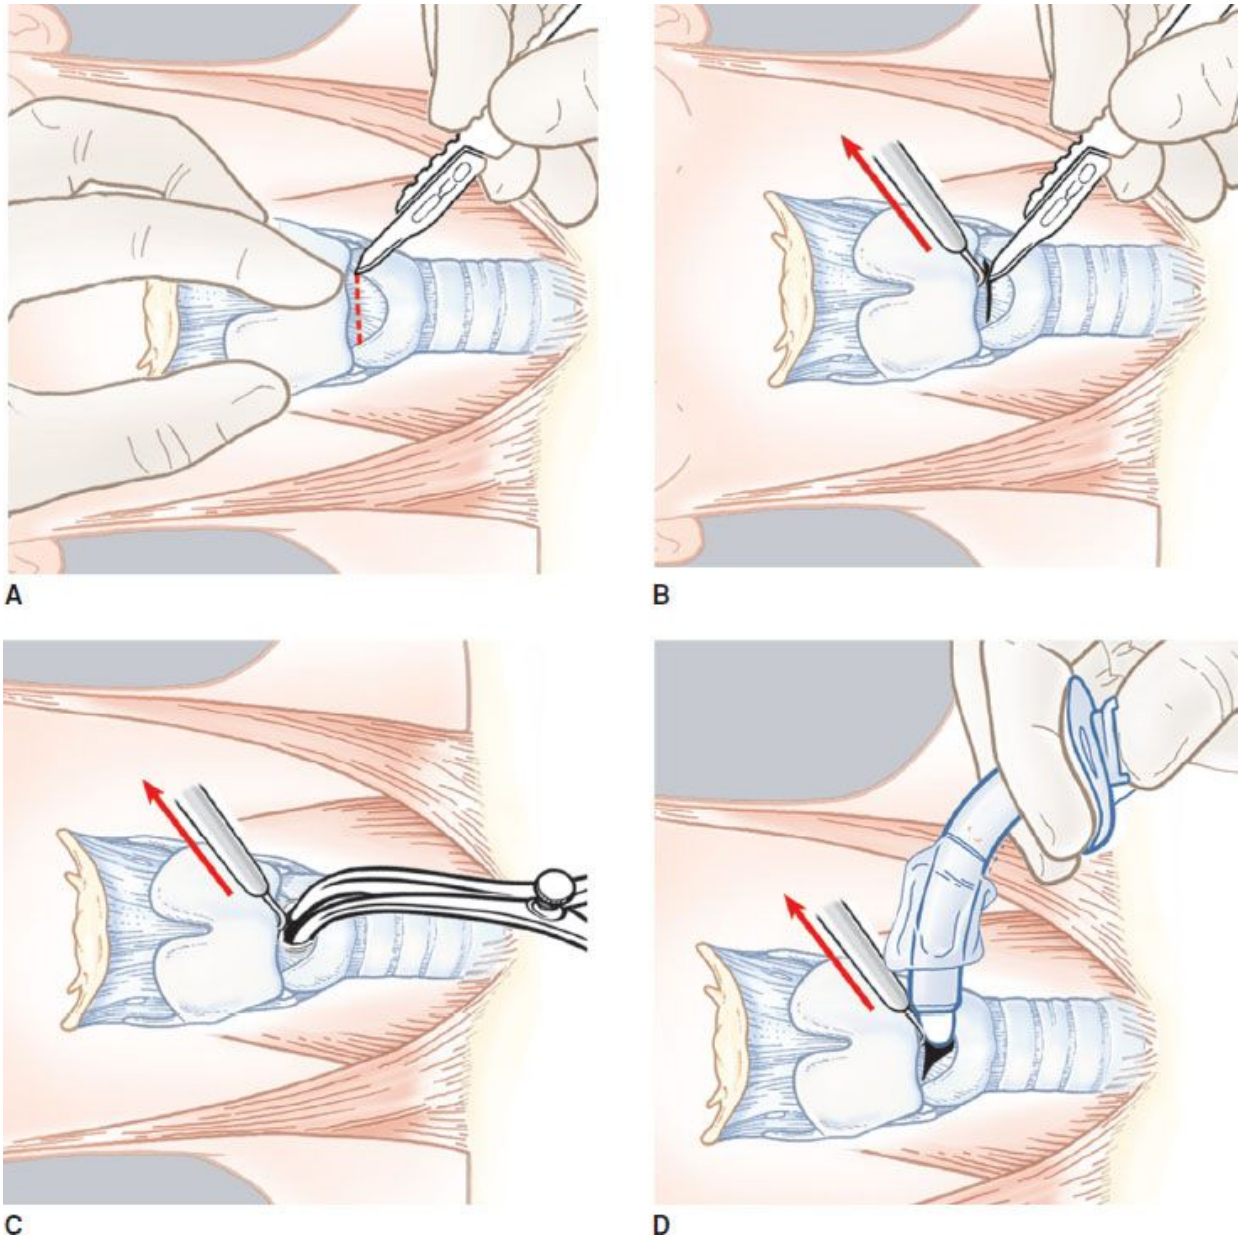

FIGURE 2.13 Cricothyroidotomy. (From Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013, with permission.)

Complications following a cricothyroidotomy can be classified as early or late based on when they occur. Early complications will be recognized either immediately after insertion of the tracheostomy tube or within a few hours. These complications include tube malposition, laryngeal injury, bleeding, and infection. Late complications may not be apparent for weeks to months following the procedure. These complications include progressive airway obstruction and chronic voice changes.

A cricothyroidotomy is a potentially life-saving technique. It is an important procedure for the emergency physician to be skilled in as it may represent the only access to the patient's airway. Cricothyroidotomy can be used to provide oxygenation and ventilation to a patient when other less-invasive airway control methods have failed or are contraindicated. It is a relatively safe, simple, and reliable procedure that can be performed within a few minutes. Knowledge of the anatomy of the anterior neck is essential to minimize early complications.

Tracheostomy

A tracheostomy is an ancient and time-honored technique for securing and maintaining an artificial airway. Modern emergency physicians have many options for airway management. They are skilled in a variety of invasive, noninvasive, and surgical procedures to optimize the management of a patient's airway. The role of tracheostomy for emergent airway access has diminished as newer, safer, and equally effective techniques have evolved. Familiarity with the methods for tracheostomy is still valuable (16). Knowledge of proper techniques, possible indications, limitations, and likely complications will guide one's judgment in critical moments when it most counts. Understanding the procedure for a tracheostomy allows emergency physicians to properly care for a problem or complication

when a patient with a tracheostomy tube presents to the emergency department.

When performed under emergency circumstances, a tracheostomy is fraught with danger. There are only three clinical settings in which an emergency tracheostomy should be considered (16). The first is laryngotracheal injuries with airway disruption. The second is the need for a surgical airway in an infant or a small child where a cricothyroidotomy is contraindicated. The third is the need for an airway when all other methods have failed.

A cricothyroidotomy is the procedure of choice when an invasive approach to the airway is needed. Compared with a tracheostomy, the cricothyroidotomy is faster, is more direct, relies predominantly on external landmarks, requires only a single operator, can be done with ambient lighting, and requires a limited amount of equipment. In contrast, a tracheostomy is a procedure requiring multiple steps. The procedure involves direct visualization to dissect through vascular structures and requires better light than is commonly present at the bedside. It is easier, and thus faster, if one has an assistant, proper suctioning equipment, and electrocautery. Without these advantages, the technique is difficult and likely to be complicated. The average time to establish an airway by tracheostomy is too long for the true emergency in a patient who lacks an airway.

Tracheal Confirmation Devices

Confirmation of ETT placement within the trachea is one of the most important steps of endotracheal intubation. If the ETT is placed within the esophagus or pharynx, it must be quickly recognized, and tracheal intubation or effective ventilation promptly performed. This necessity has led to a vast array of techniques to confirm correct ETT position.

One of the most sensitive and specific tests for correct ETT placement is direct visualization of the ETT passing through the vocal cords and into the trachea. This can be done by direct laryngoscopy or a fiberoptic device. When the ETT is visualized passing through the vocal cords, tracheal placement is confirmed;

however, this cannot be done in all cases. Because of the life-threatening complications of a misplaced ETT, correct placement must be confirmed by multiple methods.

Methods of tracheal confirmation can be separated into three categories: Clinical examination, tests based on anatomic differences between the trachea and esophagus, and tests based on physiologic differences (17). The clinical examination findings of tracheal intubation are symmetric chest rise, absence of sounds over the epigastrium, bilateral breath sounds in the axilla, condensation in the ETT with ventilation, and direct visualization of the ETT passing through the cords. Although all of these findings can have false positives and negatives, in combination, these findings are sensitive and specific indicators of tracheal intubation.

Tests for tracheal intubation that rely on anatomic differences include esophageal detector devices (EDDs), transtracheal illumination, and transtracheal ultrasound. These tests rely on the structural difference of the esophagus and trachea, as well as their relative position in the neck. EDDs rely on the flexible esophagus collapsing when negative pressure is applied while the cartilaginous trachea is unaffected by negative pressure. The negative pressure is applied by either a syringe-like device or self-inflating bulb attached to the ETT. When the syringe-like device is used, an ETT in the trachea results in no resistance or rebound of the plunger during aspiration of 40 to 60 mL of air into the syringe. If the ETT is placed within the esophagus, the esophagus will collapse around the ETT, preventing large-volume aspiration and causing rebound of the plunger.

Self-inflating bulbs work in a similar method to the syringe-like devices. Deflate the bulb, and attach it to the end of an ETT. The bulb is then allowed to inflate passively. Inflation should take less than 4 seconds if the ETT is within the trachea. Reinflation of the bulb may be prolonged or not occur if the ETT is within the esophagus.

In the transtracheal illumination technique, alighted stylet is placed through the ETT and illuminated. If the ETT and stylet are within the trachea there should be a discreet glow seen on the

anterior neck. If the ETT is placed within the esophagus, the posterior position of this structure, as well as its muscular wall and soft tissue will cause a diffuse dull light in the neck. This method is best used when the physician is comfortable with lighted stylet intubation.

Transtracheal ultrasound relies on ultrasonographic images to confirm correct ETT position. This can be done by either the dynamic or the static method. In the dynamic method, the trachea is visualized with a high-frequency linear transducer. The ETT is then visualized entering the trachea, and position is confirmed. The static method uses ultrasound to confirm tracheal placement after the ETT has been placed. Although there is limited evidence to support its use at this time, ultrasound may become a commonly used method for ETT confirmation in the emergency department (18,19).

The tests for tracheal intubation that rely on physiologic differences include capnometry, the Beck Airway Airflow Monitor (BAAM, Great Plains Ballistics, Lubbock, TX), and pulse oximetry. Capnometry relies on detection of CO_2 in exhalation. In a healthy preoperative patient, capnometry is a highly sensitive and specific test for tracheal intubation. In the emergency setting, capnometry can be limited by CO_2 in the gastrointestinal tract and in situations where respiration is limited or absent, such as cardiac arrest and severe pulmonary edema. There are two commonly used methods of capnometry in the emergency department: colorimetric and quantitative capnometry or capnography. Colorimetric capnometry uses a device that contains purple-colored pH paper that releases hydrogen ions when in contact with CO_2, turning the paper yellow. The device is attached to the end of the ETT between the bag-valve-mask device and the respiratory adapter. Ventilate the patient, and check the colored indicator paper after five to six breaths to allow for washout of residual carbon dioxide.

Capnography samples the exhaled gasses and calculates end tidal CO_2, which is displayed as a number or a graph on a physiologic monitor. The advantage of capnography instead of colorimetric capnometry is a continuous reading of end tidal CO_2. This reading

allows for both continuous monitoring of ETT position and continuous monitoring of respiration. In the noncardiac arrest patient, capnography is a very useful tool in confirming ETT placement (19).

The BAAM is a novel device that contains a whistle that attaches to the respiratory connector of an ETT. Air exiting the proximal end of an ETT results in a whistle. In a spontaneously breathing patient this device works well to confirm tracheal placement. This device is best used in a nasotracheal intubation of an awake (sedated) intubation. In an apneic patient, the chest can be compressed, and the forced exhalation of air can cause the whistle. If the tube is placed in the esophagus, there should be no air movement with respiration or chest compression. There is very limited evidence to support the use of the BAAM.

Pulse oximetry is a commonly used device that is a poor predictor of esophageal intubation. In a preoxygenated patient, it can take several minutes for hypoxia to present, regardless of esophageal or tracheal intubation. If the ETT is misplaced, confirmation is desired before hypoxia ensues. Although pulse oximetry is a useful adjunct for monitoring for intubation, it is not an ideal agent for confirmation of tracheal intubation.

The last method for confirming ETT position is the chest radiograph. Although chest radiographs are taken after almost every endotracheal intubation, it is difficult to determine endotracheal or esophageal position in a single anteroposterior (AP) view. Indications of esophageal placement include ETT visualized outside the tracheal shadow or an ETT in the midline below the carina. A chest radiograph is best utilized to determine tracheal position of a confirmed tracheal intubation.

The clinical examination, in addition to capnometry or EDDs, are the best methods for determination of tracheal intubation. In the nonarrest patient, either colorimetric or continuous capnography is very sensitive and specific. In the postarrest patient, capnometry can be difficult to interpret, and the clinical examination and EDDs are the best methods to confirm the tracheal tube position (20).

CRITICAL INTERVENTIONS

- Properly position the patient's head to optimize the view of the vocal cords during orotracheal intubation.
- Prepare sequential airway securing techniques when faced with a potentially difficult airway.
- Video-assisted intubation devices should be considered as a primary intubation device as well as for failed direct laryngoscopy.
- Confirm proper position of ETT after intubation.

DISPOSITION

Almost all patients who require the airway management techniques as described in this chapter will be admitted to an intensive care setting. The patient who is intoxicated, has taken too much medication, or used illicit substances may be the exception to admission.

Common Pitfalls

- Proper patient positioning is very basic but often overlooked.
- Simple maneuvers using the jaw thrust, chin lift, nasopharyngeal airway, or oral airway can prevent hypoxia and hypercarbia in the apneic patient.
- Orotracheal intubation is the airway of choice.
- The emergency physician must know several alternative techniques for airway management when orotracheal intubation fails or is contraindicated.
- The cricothyroidotomy is the preferred surgical airway in an emergency.

CHAPTER 3 Cardiopulmonary Arrest

Christopher Ross and Theresa M. Schwab

Sudden cardiopulmonary arrest (SCA) and sudden cardiac death (SCD) typically result due to ventricular dysrhythmias resulting in hemodynamic collapse due to the sudden cessation of cardiac activity. The triad of unconsciousness, apnea, and pulselessness defines cardiopulmonary arrest. Cardiovascular disease causes about a third of all worldwide mortality with half of this caused by SCD (1). SCD is defined as an unexpected natural death from a cardiac cause that occurs instantaneously or within 1 hour from the onset of an abrupt change in clinical status in a person without a prior condition that would appear to be fatal. The term SCD is used to describe cardiac arrest whether or not resuscitation occurs. The term can be misleading because not all affected individuals die. Patients who do not die after cardiac arrest have “aborted SCD.” By convention, the term describes both fatal and nonfatal cardiac arrest (2).

Resuscitation was described more than 100 years ago. It was only in the late 1950s that closed-chest cardiac massage, mouth-to-mouth ventilation, and electrical defibrillation were incorporated into practice guidelines in an attempt to improve survival. Although advances in emergency medical services (EMSs) and in the field of resuscitation have occurred, the rate of survival of cardiac arrest victims who are neurologically intact remains dismally poor (3). Although survival assessments have reached widely disparate conclusions based on study populations in the out-of-hospital setting, survival rates range from 4% to 15% (4). Survival to hospital discharge has been reported to increase in those treated with

bystander cardiopulmonary resuscitation (CPR), EMS, and when the underlying rhythm was ventricular fibrillation (VF) (2). In-hospital survival of SCD has been reported to be 22% survival to hospital discharge (5). The concept of extending treatment into the community is a fairly new phenomenon. In the 1970s, it was demonstrated that advanced cardiac life support (ACLS) by trained paramedics could significantly improve resuscitation and survival in patients suffering cardiac arrest. Training laypersons in the community to deliver CPR has been shown to increase survival of SCD. The availability of automatic external defibrillators to trained persons such as police and flight attendants and their use by these people prior to EMS intervention also increases survival (2).

The epidemiology of SCD parallels that of ischemic heart disease with up to 70% of patients with known coronary artery disease (CAD) succumbing to SCD. The incidence increases with age and cardiac risk factors such as smoking, diabetes, left ventricular hypertrophy, and hypercholesterolemia. The biggest risk factor for SCD is previous CAD, especially if there is associated left ventricular dysfunction (6). The more cardiac risk factors and electrocardiogram (ECG) abnormalities present, the higher the risk of SCD.

The effect of race on SCD is controversial as it is difficult to separate socioeconomic influences from a true genetic predisposition. That being said, black patients appear more likely than whites to experience SCD at a younger age and with lower survivability. Black patients are also more likely to have an unwitnessed arrest and have their initial rhythm being a less favorable one for resuscitation (7). Men are three to four times more likely than women to experience SCD. This difference can be explained by the difference in the incidence of CAD and the hormonal protection women have before menopause. Recent major life changes, women who are not married or who have no children or few children, high-stress lifestyle, and type A personality are all factors that increase the risk for SCD, although the validity of some of these claims remains controversial. There may be both seasonal and circadian patterns for risk assessment in SCD because SCD is more likely to occur in the winter months. SCD, like acute myocardial infarction (AMI), is most likely

to occur in the first few hours after awakening from sleep as a consequence of increased sympathetic stimulation (7). Modifiable risk factors play a role in risk of SCD. There was a 92% reduction in SCD in female patients who did not smoke, had an appropriate weight, exercised, and ate an appropriate diet (8).

The ECG can identify patients at an increased risk for SCD. ECG findings consistent with previous or current ischemic disease such as old myocardial infarction (MI), left ventricular hypertrophy, interventricular conduction delay, repolarization abnormality, or any current of injury pattern are significant predictors of SCD. Some studies report that a powerful predictor of SCD is three or more premature ventricular contractions (PVCs). Other studies state that high-risk forms of PVCs such as multifocal, bigeminy, short coupling with R-on-T phenomenon, and three or more consecutive ectopic beats are more predictive. There are also specific ECG findings such as interventricular conduction delays, QT prolongation, delta waves, and an increase in resting heart rate of more than 90 beats per minute that place patients at a higher risk.

Multiple factors trigger SCD in a susceptible myocardium, but the final mechanisms for triggering the fatal ventricular dysrhythmias is unclear. Significant coronary stenosis is the most common abnormality found in SCD patients, although more than half of SCD patients have no previous history of CAD. Fewer than half of all SCDs occur during an AMI. In fact, cardiac arrest during AMI is associated with an improved outcome when compared to cases not occurring in this setting. Other factors involved include other structural abnormalities and transient electrophysiologic disturbances (Table 3.1). In the majority of cases, the terminal rhythm of VF has occurred from the initiating event of a ventricular tachydyrhythmia (7).

TABLE 3.1
Risks Associated with Sudden Cardiac Death

Structural Abnormalities

- Coronary artery disease and acute myocardial infarction
- Hypertrophic cardiomyopathy
- Valvular heart disease
- Dilated cardiomyopathy
- Inflammatory and infiltrative disorders

Primary Electrophysiologic Abnormalities

- Congenital long QT syndrome
  - Jervell and Lange-Nielsen
  - Romano-Ward
- Acquired long QT syndrome
  - Antidysrhythmics (class IA, class III)
  - Antihistamines (terfenadine, astemizole)
  - Antimicrobials (erythromycin, clarithromycin, azithromycin, ketoconazole, chloroquine)
  - Antipsychotics (phenothiazine, haloperidol, risperidone)
  - Antidepressants (tricyclic antidepressants, ketanserin, zindeline)
  - Antimotility (cisapride)
  - Electrolytes (hypokalemia, hyponatremia, hypocalcemia, hypomagnesemia)
  - Organophosphates
  - Intracranial hemorrhage and trauma
  - Bradydysrhythmias
  - Dietary (anorexia nervosa, liquid protein diets)
- Wolff–Parkinson–White syndrome
- Brugada syndrome
- Idiopathic ventricular tachycardia
- Specialized conduction system abnormalities
  - Lenègre disease
  - Lev disease

Prolongation of the QT interval on the ECG increases the risk of SCD as a consequence of the increased risk of polymorphic ventricular tachycardia (VT). This prolongation predisposes myocardium to re-entry phenomenon. Re-entry is the major mechanism by which a dysrhythmia is created and maintained, although triggered activity and increased automaticity are also important. A minority of cases of SCD begins with a bradydysrhythmia or an organized rhythm without a pulse (pulseless

electrical activity [PEA]). VF usually begins with a run of sustained or nonsustained VT that degenerates to VF.

The net result of the dysrhythmia is global cessation of blood flow and corresponding ischemic injury to various organs. Resultant hypoxia and hypotension cause cessation of aerobic metabolism within seconds. Anaerobic metabolism occurs that cannot meet the metabolic demands of the tissues, and subsequent cell death ensues if spontaneous circulation is not resumed. The time before irreversible cell death is dependent on the metabolic rate of the organ system. Both the heart and brain have high metabolic rate and are very sensitive to ischemic insults. Thus the probability of achieving successful resuscitation from cardiac arrest is related to the interval from onset to institution of resuscitative efforts, the setting in which the event occurs, the mechanism (VF, VT, PEA, or asystole), and the clinical status of the patient prior to the cardiac arrest.

Although estimates vary widely, VF and pulseless VT are responsible for 25% to 35% of all out-of-hospital episodes of SCD. PEA accounts for as much as 25%. The acute management of patients with SCD is based upon the underlying electrocardiographic rhythm. During the course of resuscitation, patients may manifest many different rhythms, and therapy is modified based on these changes.

CLINICAL PRESENTATION

Patients suffering from SCD do not have any more specific complaints than those suffering any major cardiac or pulmonary event. Often, symptoms such as increasing angina, dyspnea, palpitations, easy fatigability, and other nonspecific complaints are experienced by these patients in the preceding days to months of the event. However, the onset of the terminal event of SCD, if instantaneous or abrupt, is cardiac in origin in more than 95% of patients. Dysrhythmic events, characterized by a high likelihood of patients being awake and active immediately prior to the event, are dominated by VF as the electrical mechanism, and have a short duration of terminal illness. Patients who have circulatory failure deaths tend to have more systemic medical problems and present with a higher incidence of asystole and PEA. A cardiac arrest may be

characterized by symptoms such as prolonged angina or the pain of an MI, acute shortness of breath, palpitations, and lightheadedness. The complete loss of consciousness in this setting is the *sine qua non* in cardiac arrest. The natural history of cardiac arrest is to progress to death within minutes unless expedient interventions are undertaken.

Phases of Resuscitation

Many researchers now consider there to be three distinct time-sensitive phases of cardiac arrest: electrical, circulatory or hemodynamic, and metabolic. Treatment emphasis varies according to the phase (9).

The electrical phase occurs during the first 4 minutes of arrest caused by VF. This is the period when immediate defibrillation is likely to be successful. As ischemia progresses, the success of attempted defibrillation diminishes without CPR. The hemodynamic or circulatory phase occurs during the period of 4 to 10 minutes after sudden cardiac arrest. This phase is characterized by transition to slow VF wavelets as ischemic metabolites accumulate in the myocardium. The patient may remain in VF. Although early defibrillation has traditionally been advocated for all patients found in VF, there is evidence that patients with time-sensitive phases caused by prolonged pulselessness may benefit from well-performed CPR to generate adequate cerebral and coronary perfusion prior to the initial attempts at defibrillation. There is insufficient evidence to determine if the 1½ to 3 minutes of CPR should be provided prior to defibrillation (10). CPR should be performed while a defibrillator is being readied for use. Treatment of the metabolic phase, which is defined as occurring after >10 minutes of pulselessness, stresses postresuscitation measures including hypothermia therapy. In the absence of conversion into a perfusing rhythm, patients who have reached this phase generally do not survive.

ED EVALUATION AND MANAGEMENT

Many of the recommendations stated in this chapter are taken from the guidelines for CPR introduced in 2010 by the American Heart Association. The new CPR guidelines evolved from emerging evidence-based resuscitation studies (Table 3.2). Based on their extensive review, the AHA and European Resuscitation Council (ERC), in collaboration with the International Liaison Committee on Resuscitation (ILCOR), published updated guidelines for BLS and ACLS.

TABLE 3.2
Levels of Evidence for Interventions

Class I	Definitely helpful
Class IIA	Acceptable, probably helpful
Class IIB	Acceptable, possibly helpful
Class III	Not indicated, may be harmful
Class indeterminate	No recommendation until further evidence available

Return of spontaneous circulations (ROSCs) is dependent on restoration of adequate cardiac function. Restoration of normal brain function is the defining factor of a successful resuscitation. The likelihood of attainment of both of these goals decreases with each passing minute of the cardiac arrest. Healthcare providers need to orchestrate simultaneous assessment and management of a cardiac arrest victim.

Patients require airway and ventilatory support, control of cardiac dysrhythmias, and cardiac output stabilized to restore organ perfusion. Emphasis is on immediate, uninterrupted, high-quality CPR and early defibrillation. These procedures along with advanced life support measures such as endotracheal intubation, pacing, pressor agents, and insertion of an intravenous (IV) line carry out these goals in resuscitation. The final goal is to restore ROSC before irreversible neurologic damage occurs. If the patient is resuscitated, rapid diagnosis and proper management of the pathologic condition that precipitated and resulted from the arrest are essential for optimal outcome. Treatment with mild hypothermia also improves cerebral resuscitation in these patients.

Basic Cardiopulmonary Resuscitation

Americans spend about a billion dollars a year on some form of CPR training or retraining. Yet the utility of this training is limited in the field because of the poor outcome of community cardiac arrests. CPR alone is of little value for restoring effective circulation and preventing brain death. The survival from SCD is dependent on a series of actions represented by the AHA Chain of Survival: early access to 911, early CPR, early defibrillation, and early advanced care.

An algorithmic approach to the unresponsive victim is used. Once a victim is found unresponsive, activation of the EMS system should occur. The activation of the EMS system to allow rapid initiation of ACLS protocols is the first step in the graduated response to care. If the lay rescuer finds an unresponsive victim who is breathing abnormally or not at all, CPR should be initiated. Trained healthcare providers should take no longer than 10 seconds to check a pulse before CPR is initiated. For lay person/untrained personnel, chest compression only CPR (no intervening breaths) is recommended (11). For trained personnel, compressions should be performed prior to rescue breaths in a ratio of 30:2 with a rate of 100 compressions per minute. The patient's airway can then be opened, followed by two breaths that should make the chest rise. Healthcare providers can then check for a pulse and, if it is absent, can initiate CPR in cycles of 30 compressions to two breaths. The function of basic CPR is to provide some blood flow to vital organs until more definitive treatment, such as defibrillation, can be initiated. Once a defibrillator arrives, the electrical rhythm of the heart can be ascertained, and, if a shockable rhythm is present, defibrillation can occur.

Most studies show a benefit of layperson CPR in the resuscitation of victims of cardiac arrest, especially when initiated early. "Hands only" CPR is a potentially lifesaving technique involving no mouth-to-mouth contact and has been the focus of the American Heart Association media blitz to educate the public that patients who get immediate CPR have twice the survival of those who do not. The earlier the CPR is applied the better the outcome becomes. Cardiac

output generated by standard chest compressions is <10% to 30% of baseline and decreases precipitously with both time to initiation and duration of chest compressions. Endogenous mechanisms direct blood flow preferentially to the heart and brain during the early minutes of resuscitation. This distribution of blood flow is ideal during CPR because the goal is to generate myocardial perfusion adequate to restore organized electrical activity and effective mechanical function of the heart while minimizing ischemic brain injury. This response becomes ineffective within minutes of circulatory arrest; so early intervention is the key to survival.

The mechanism of blood flow during closed-chest compressions has been continuously debated. The major theories include (a) the direct cardiac compression model in which CPR squeezes the heart between the sternum and the thoracic spine, creating a pressure gradient between the ventricles and the great arteries and (b) the thoracic pump mechanism in which the thorax acts as a pump when the chest is compressed, generating pressure gradients between intrathoracic and extrathoracic structures. In either method, the valve system in the heart allows forward, rather than retrograde, blood flow (12) (See Figure 3.1. The boxes bordered with dotted lines indicate actions or steps performed by the healthcare provider but not the lay rescuer.)

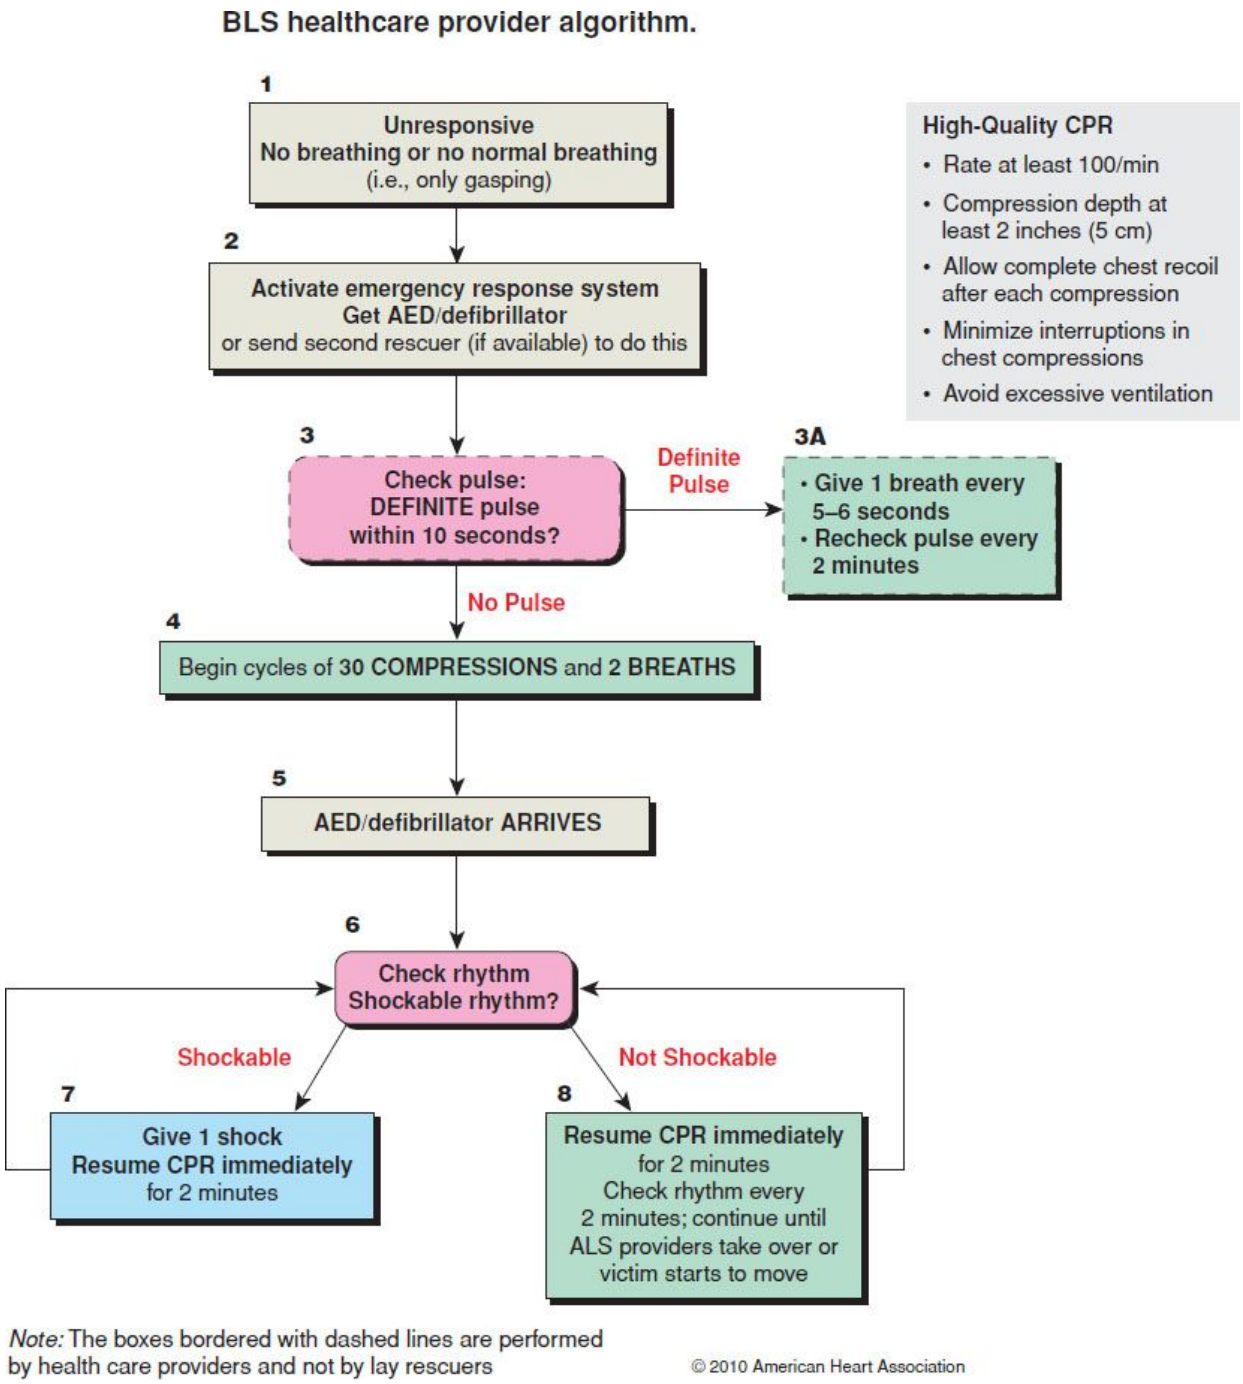

FIGURE 3.1 Adult basic life support healthcare provider algorithm. (From Berg RA, Hemphill R, Abella BS, et al. Part 5: Adult basic life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation*. 2010;122: S685–S705.)

The mechanism used to stimulate blood flow back to the heart is controversial. It was recently recognized that a small vacuum occurs in the thorax after each chest compression. New devices have been developed to increase this vacuum effect, such as the vest approach, active compression–decompression, and an impedance threshold valve. Using these adjuncts for resuscitation in this manner has been tried, but clinical results have proven disappointing for many reasons, including an inability to implement the mechanism and an inability to overcome the standard CPR mindset. Thus, CPR has changed very little in the past 20 years.

CPR has now taken a more central role in the provision of BLS. The current focus is on high-quality CPR. Poor performance of CPR is one factor contributing to poor outcomes. Multiple studies assessing both in-hospital and prehospital CPR performance have shown that trained healthcare providers consistently fail to meet BLS guidelines. Outcomes from sudden death are dependent on the effectiveness of chest compression, and chest compressions are thought to be the most important element of CPR. When performed at a rate of 100 compressions per minute, with a downstroke of at least 38 mm and allowing the chest to recoil fully between each downstroke, coronary perfusion pressures are optimized, and ROSC is maximized. Most importantly, interruptions in compressions, regardless of how brief, result in a decline in coronary perfusion pressure and result in worse outcomes (13). Clinicians must strive to minimize interruptions of compressions, because interruptions that exceed 15 seconds appear to significantly reduce the success of resuscitation, increase myocardial dysfunction, and significantly reduce survival. The new guidelines mandate that for routine resuscitation, only a single shock, rather than a sequence of three shocks, be delivered so that there is minimal interruption of compressions. Another mandate is to immediately resume chest compressions after defibrillation, decreasing the delay that occurs for a visual confirmation of rhythm. If there is a delay in recognizing that a perfusing rhythm has occurred, continuing chest compressions is not likely to be damaging. The 2010 ACLS protocols stress initiating advanced

procedures (advance airway, medication, and reassessments) in a way that does not interrupt CPR (14).

The precordial thump was originally advocated for use in a witnessed cardiac arrest scenario. A forceful precordial thump can convert patients from VF or pulseless VT into a perfusing rhythm. However, patients can also be converted from coordinated cardiac activity to VF, pulseless VT, or asystole. There is little recent literature in the form of peer-reviewed studies, but there are numerous case reports of both benefit and risk (15). The precordial thump should not be used for unwitnessed out-of-hospital cardiac arrest. The precordial thumb may be considered for patients with witnessed, monitored, unstable VT including pulseless VT if a defibrillator is not immediately available, but this should never delay CPR and shock delivery (13).

Airway

After assessing a cardiac arrest victim's unresponsiveness and activating the response system (in the community, the EMS system and the code team in a hospital are activated), the next step is airway management if there is no immediate access to a defibrillator. In a cardiac arrest victim, the most common reason for airway obstruction is from the tongue falling back in the oropharynx. The airway can be opened by performing either a jaw-thrust or head-tilt–chin-lift maneuver (see Chapter 2). The jaw thrust is the better maneuver if any trauma is suspected or if cervical spine immobilization is required (16).

If the airway is still obstructed after these maneuvers, one must be concerned about an obstructed airway from another cause. The Heimlich maneuver, or subdiaphragmatic abdominal thrust, is the recommended procedure for clearing the obstructed airway of a foreign body. The rescuer's hand is positioned between the patient's xiphoid and navel, and several quick thrusts are administered in an attempt to relieve the foreign body obstruction. If the victim is unconscious, like a victim of SCD, the abdominal thrust maneuver may be accompanied by attempts to visualize the foreign body in the pharynx and by finger sweeps to remove the foreign body.

Breathing

The 2010 AHA Guidelines for CPR and Emergency Cardiovascular Care (ECC) recommend the initiation of compressions before ventilations. Blood flow depends on chest compression and delays in, and interruptions of, chest compressions reduce chance of survival. Beginning CPR with 30 compressions rather than two ventilations leads to a shorter delay to first compression. Once chest compressions have been initiated, a trained rescuer should deliver rescue breaths by mouth-to-mouth or bag mask to provide oxygenation and ventilation. The compression to ventilation ratio of 30 chest compressions to 2 ventilations should be followed. During the initial phase of cardiac arrest, the pulmonary vessels and the heart are likely to contain sufficient oxygenated blood to meet markedly reduced demands, and here the importance of compressions supersedes that of ventilations (16). As pulselessness persists, properly performed ventilations become more important, but clinicians must continue to ensure that ventilations do not interfere with the continuity of chest compressions. In the patient with an advanced airway, one asynchronous ventilation (not necessarily coordinated with chest compression) should be given 8 to 10 times per minute and should be delivered in as short a period as possible, while avoiding excessive ventilatory force. Only enough tidal volume should be given to obtain a chest rise. Multiple studies have shown that hyperventilation during resuscitation is routine either through higher rates or increased volumes. Hyperventilation raises intrathoracic pressure, which decreases venous return, pulmonary perfusion, cardiac output, and cerebral and coronary perfusion pressures. This hyperventilation reduces the success of defibrillation and decreases overall survival (16).

Bag mask ventilation is the first choice for BLS ventilation but should give way to alternative airway ventilation methods once ACLS providers are available. Tracheal intubation remains the procedure of choice for the unconscious, apneic patient, although there is no study directly addressing the timing of advanced airway placement during ACLS. This skill is not without significant challenges, and ACLS guidelines recommend intubation be

performed by those experienced in the procedure. Physical examination, an end-tidal carbon dioxide detector, or an esophageal detection device can confirm correct tube placement in the trachea. Continuous quantitative waveform capnography is recommended for confirmation and monitoring of endotracheal tube placement, CPR quality, and to aid in the detection of ROSC.

Other airway maneuvers recommended instead of bag valve masking are the laryngeal mask airway or the esophageal–tracheal Combitube (see Chapter 2). Once definitive airway management has occurred, the ventilations are administered independent of the chest compressions at a rate of 8 to 10 per minute.

Circulation

Lay rescuers and healthcare providers have difficulty detecting a pulse in unresponsive patients. Healthcare providers also often take too long trying to feel for a pulse. Lay rescuers should not check for a pulse and healthcare providers should spend no longer than 10 seconds feeling for a pulse. If a pulse check is undertaken, the carotid pulse should be checked because it is the most reliable pulse to check in low-flow states. If no pulse is detected, chest compressions should be instituted. The victim needs to be placed on a firm surface or backboard to assist mechanically with the compressions. The heel of the hand is placed on the lower half of the sternum and depressed 1.5 to 2 in in the adult. In children, the compression depth should be 1 to 1.5 in, and in neonates, it should be 0.5 to 1 in. The recommended compression rate is 100 times per minute in adults (ratio of 30:2 until an advanced airway is placed). Rescuers should push hard and push fast, allow complete chest recoil between compressions, and minimize interruptions in compressions for all victims (13).

Advanced Life Support

Defibrillation

The passage of current through the heart causes defibrillation with the goal of restoring a perfusing cardiac rhythm. If energy and current are too low, the delivered shock will not terminate the

dysrhythmia; if energy and current are too high, myocardial damage may result. Because of ischemia, acidosis, and electrophysiologic deterioration, a longer duration of VF correlates with a higher defibrillation threshold (17).

Modern day defibrillators deliver electrical shocks in one of two ways. Monophasic waveforms deliver current in one direction through the heart. Biphasic waveforms are used to deliver current through the heart, reverse polarity, and return through the myocardium. As a result, the energy needed for successful conversion of tachydysrhythmias with biphasic technology is often significantly less than that required with monophasic waveforms. The latest defibrillators and automated external defibrillators (AEDs) use biphasic waveform technology. If a biphasic defibrillator is available, providers should use the manufacturer's recommended energy dose for terminating VF (usually 120 to 200 J). If the provider is unaware of the effective dose range, the provider may use the maximal dose. Second and subsequent energy levels should be at least equivalent, and higher energy levels may be considered if available (14).

Current is directly related to the energy set on the defibrillator and inversely related to the transthoracic impedance. The transthoracic impedance can be minimized by attention to several factors, including position of the defibrillation paddles, the amount of energy selected on the defibrillator, firm pressure on the paddles, the use of conductive material between the skin and paddles, employment of sets of shocks, and the coordination of the shock with the end-expiratory phase of ventilation.

Defibrillation should be used quickly because delay will reduce the effectiveness of the resuscitation. If VF is corrected within 1 minute, there is a survival rate of $>90\%$; however, the survival rate falls by 10% per minute following the initiating event. In this fashion, public access defibrillation (PAD) has the potential to be one of the greatest advances in the treatment of SCD since the development of CPR. The mechanism for PAD is in the form of an AED. AEDs are computerized devices that are simple and reliable to operate; they allow lay rescuers with minimal training to administer this life-saving intervention. Self-adhesive electrode pads are provided with

application diagrams; voice and text prompts guide the rescuer through a few simple steps. A dysrhythmia analysis algorithm automatically interprets the rhythm and either recommends countershock, to be given by the push of a button, or no countershock. After the shock, the device immediately re-evaluates the rhythm and determines whether to recommend an additional shock. Flight attendants, security personnel, sports trainers, police officers, firefighters, lifeguards, family members, and many other trained laypersons have used AEDs successfully in the field.

In the past several years there have been significant changes in our understanding of the physiology of cardiac arrest and the technology used for defibrillation. Biphasic defibrillators, which measure impedance between the electrodes placed on the patient and adjust the energy delivered accordingly, successfully defibrillate approximately 85% of patients with the first shock. The 2010 guidelines restrict the recommended energy delivery to 360 J when using a monophasic defibrillator. With a biphasic defibrillator the suggested energy level is 200 J. The single major change regarding shock delivery in the most recent guidelines is to no longer recommend three-stacked shocks. The single shock should be followed by 2 minutes of CPR with no pulse check. Although there are no randomized controlled trials comparing the one-shock strategy to the three-shock strategy, the evidence for a reduction of coronary perfusion pressure with the interruption of chest compressions was felt to be compelling enough to recommend the one-shock strategy. Early after cardiac arrest, immediate defibrillation is likely successful. The question of intentionally delaying defibrillation to perform CPR is controversial with differing results in out-of-hospital studies. If a defibrillator is immediately available and VF or pulseless VT is evident, a 120-J biphasic shock should be delivered preceding airway management and IV line placement. If VF or pulseless VT is sustained after the initial 120-J shock, higher energies of 200 J are tried later in the resuscitation.

There is a wide variation in the ability of rescuers to determine pulselessness. The AHA 2010 BLS guidelines recommend that CPR performed by the lay rescuer be initiated immediately without a

pulse check upon determining unconsciousness in a patient without signs of respiratory effort. Healthcare providers must not spend >10 seconds checking for a pulse and should start CPR immediately if no pulse is felt. Agonal or gasping breaths should not be taken as evidence that organized respiratory effort is present. Further, the guidelines recommend that CPR be resumed for 2 minutes without a pulse check after defibrillation, regardless of the resulting rhythm. Data suggest that after defibrillation the myocardium does not provide effective cardiac output and that CPR may improve postdefibrillation perfusion (14).

Pharmacologic Therapy

Pressor Agents

Historically, catecholamine-induced adrenergic receptor stimulation is the therapy most commonly used in cardiac arrest, with epinephrine being the drug used most often. Epinephrine stimulates α_1 and α_2 receptors almost equally, and β_1 and β_2 receptors in a ratio of 1:4. We now realize that trials validating the use of epinephrine in cardiac arrest are not well defined because there are no prospective clinical trials. Although some study results have raised doubts about the benefit of epinephrine, including a large prospective study published in 2012, pending more conclusive data or a formal change in ACLS protocols, epinephrine is still recommended in accordance with ACLS guidelines (18). “High-dose” epinephrine was endorsed in cardiac arrest if regular-dose epinephrine was unsuccessful in resuscitation, only to have the endorsement rescinded by the AHA when larger numbers revealed no benefit and potential harm with such administration. Some studies found that patients may have a higher incidence of ROSC with high-dose epinephrine but no improvement in neurologic outcome. Patients with irreparable central nervous system (CNS) injury may result in significant burden on families and healthcare resources. At present, meta-analyses have not determined if high-dose epinephrine is better, worse, or the same as standard dose. The current recommended dose is epinephrine 1 mg initially

intravenously/intraosseously, with repeated doses every 3 to 5 minutes, but the optimal dose has not been established (19).

Vasopressin, also termed antidiuretic hormone, is also part of the treatment armamentarium for the cardiac arrest victim who has VF or pulseless VT. Vasopressin produces the same positive effects as epinephrine in terms of vasoconstriction and increasing the blood flow to the brain and heart during CPR. Vasopressin may not have the adverse effects on the heart that epinephrine does, such as increased ischemia and irritability and, paradoxically, the propensity for VF. Circulating endogenous vasopressin concentrations were high in patients undergoing CPR, and levels in successfully resuscitated patients are significantly higher than in patients who died. Meta-analysis of trials comparing vasopressin with epinephrine for cardiac arrest found no evidence of improved overall outcome or in any subgroup associated with vasopressin therapy (19). Vasopressin is given as a single one-time dose (40 U IV/IO) because of the much longer half-life of 10 to 20 minutes. Vasopressin can be administered as an alternative to the first or second dose of epinephrine.

There is limited experience with vasopressin in PEA or asystole, so epinephrine remains the pressor of choice empirically.

Antidysrhythmic Agents

The role of antidysrhythmic drugs is to suppress premature ectopic complexes and improve symptoms related to palpitations. Most of the antidysrhythmic agents raise the fibrillation threshold and are thus useful for preventing recurrent VF in patients who have been successfully defibrillated.

Amiodarone is categorized as a class III antidysrhythmic but contains characteristics of all four Vaughan Williams classes. Amiodarone can be considered for VF/pulseless VT that is refractory to CPR and vasopressor therapy. In blinded randomized controlled trials in adults with refractory VT/VF in the out-of-hospital setting, paramedic administration of amiodarone (300 mg or 5 mg/kg) improved survival to hospital admission rates when compared with administration of placebo or 1.5 mg/kg or lidocaine (20). This study demonstrated no difference between the amiodarone and placebo

groups in hospital discharge of patients with good neurologic functioning, although the study was underpowered for these observations. Additional studies documented consistent improvement in defibrillation response when amiodarone was given to humans or animals with VF or hemodynamically unstable VT. In the ALIVE trial of patients with persistent or recurrent VF despite defibrillation and epinephrine, the number of patients surviving to hospital admission was higher with amiodarone. The ARREST trial in patients with resistant VF/VT again showed increased survival to hospital admission in the amiodarone group. Time to therapy with amiodarone was an independent predictor of survival (21). No study has shown or been powered to show differences in survival to hospital discharge when comparing amiodarone to lidocaine. Amiodarone has been associated with more treatment requiring adverse effects including hypotension and bradycardia when compared to lidocaine but this has been attributed to the vasoactive solvents, as when these products were removed, there was no more hypotension that associated with lidocaine administration (22). The dosage of amiodarone in VF/pulseless VT arrests is 300 mg IV push.

Lidocaine has been used to treat VF/pulseless VT but with little evidence to support its use. The only evidence for lidocaine's use is from a large historical trial in which receipt of the drug was associated with improved resuscitation and admission alive to hospital. This study had nursing staff present only for the lidocaine cohort, which could explain the difference in survival alone (23). Lidocaine has thus taken an indeterminate role in ACLS and is primarily used if amiodarone is unavailable. The initial recommended dosage of lidocaine is 1 to 1.5 mg/kg IV/IO push. This dose can be followed with 0.5 to 0.75 mg/kg every 5 to 10 minutes for refractory VF to a maximum of 3 mg/kg.

Procainamide is no longer considered an antiarrhythmic option if amiodarone or lidocaine is unsuccessful in breaking VT/VF, given the time required for infusion of an effective dose of procainamide. Procainamide is an effective agent for suppressing ectopic ventricular complexes and VT, as well as other perfusing ventricular dysrhythmias. Procainamide has a limited use in cardiac arrest

because of the slow loading to therapeutic doses. Procainamide is administered in an infusion of up to 50 mg/min to a total maximum of 17 mg/kg. The previous use of procainamide in cardiac arrest was supported by only one retrospective comparison study of 20 patients (24).

Magnesium has an unclear mechanism of action in treatment of dysrhythmias. Magnesium's primary use is in the management of *torsades de pointes,* although this indication has not had formalized trials. There have been studies that show a correlation between normal magnesium levels and successful resuscitation, but the administration of supplemental magnesium to patients in arrest has not been studied. Three randomized controlled trials have not shown a benefit of magnesium administration in VF arrest in out-of-hospital and in-hospital settings. Its routine use is not recommended in cardiac arrest. The dosage of magnesium is 1 to 2 g IV push in this specific subset of torsades patients.

Guidelines for Cardiac Arrest

The AHA developed guidelines for treatment of patients in cardiac arrest. Every few years the protocols are updated to include the latest in cardiovascular literature, so clinicians should be aware of the most recent version. Although the ACLS treatment for patients in cardiac arrest is based on the ECG monitor rhythm, the clinician must always consider the etiology of the arrest in developing a treatment plan. Cardiac arrest is an endpoint of a physiologic process that results in the loss of circulation and ventilation. Treatable causes of cardiac arrest should always be thought of during resuscitation (Table 3.3).

TABLE 3.3
Most Frequent Causes of Asystole and Pulseless Electrical Activity

Hypovolemia	Tension pneumothorax
Hypoxia	Tamponade (cardiac)
Hydrogen ion (acidosis)	Thrombosis (cardiac)
Hyperkalemia/hypokalemia	Thrombosis (pulmonary)
Hypothermia	Toxins (β blockers, Ca^{++} channel blockers, digoxin)

Ventricular Fibrillation and Pulseless Ventricular Tachycardia

The key to the treatment of patient with VF or pulseless VT (Fig. 3.2) is to remember that successful resuscitation depends on electrical defibrillation. All other treatments, including CPR, intubation, and drugs, are merely attempts to prepare the patient for successful defibrillation. Defibrillation should be attempted as soon as the diagnosis is made.

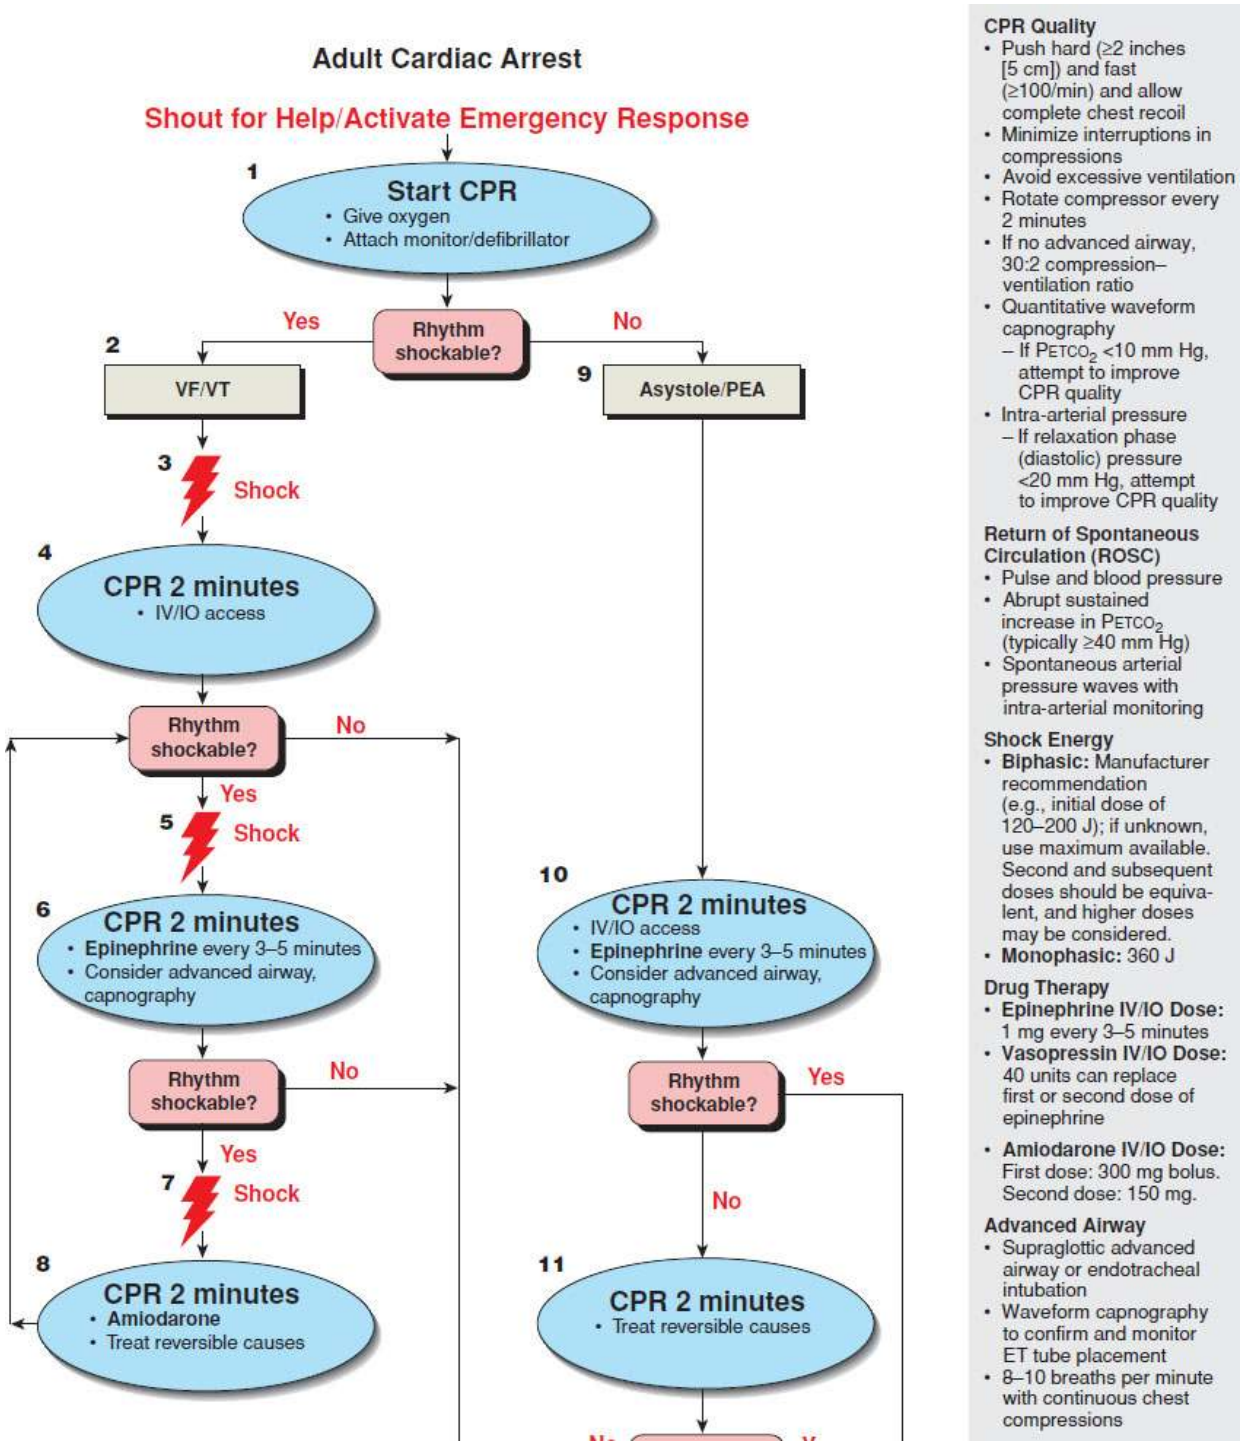

FIGURE 3.2 Advanced cardiac life support pulseless algorithm. (Neumar RW, Otto CW, Link MS, et al. Part 8: Adult advanced cardiovascular life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency

Cardiovascular Care. *Circulation*. 2010;122: S729–S767.)

If defibrillation is unsuccessful, CPR is initiated, the trachea is intubated, and an IV line is placed as soon as possible. Epinephrine or the more recently endorsed vasopressin is the first recommended pharmacologic agent. After administration of the drug, attempts at defibrillation should occur. Antidysrhythmic drugs may be useful in preventing refibrillation once the patient has been electrically defibrillated. Amiodarone is recommended as the first antiarrhythmic agent. Subsequent treatment with magnesium, procainamide, or lidocaine may be used if first-line medications are ineffective. Treatment with sodium bicarbonate should be initiated if there is clinical suspicion of hyperkalemia, tricyclic antidepressants, or pre-existing acidosis. Shock-resistant VF develops in only 10% to 25% of all cardiac arrests, yet 87% to 98% of these patients die.

Asystole

Asystole (Fig. 3.2) is a cardiac arrest rhythm associated with no discernible electrical activity on the ECG. The patient with primary asystole has a poor prognosis for resuscitation. The single most important therapy for asystole is to search for, identify, and reverse any treatable cause. Asystole is often a secondary event, resulting from VF that has been present for several minutes or longer that then has led to the loss of all electrical activity as a result of hypoxia, acidosis, and death of myocardial tissue. The asystolic patient may actually be in fine VF when using confirmation in another lead on the monitor. The diagnosis of asystole should thus be confirmed by checking a straight-line rhythm on three leads. If there is any suspicion of fine VF masking as asystole, the clinician should proceed to immediate defibrillation. As in VF, the clinician must consider the underlying process that precipitated asystole and focus treatment in this specific area while following ACLS protocols (Table 3.3). These conditions cause only the clinical deterioration of these conditions; they do not cause the rhythm.

An important minority of SCD events begins with a bradydysrhythmia that degenerates to asystole. Bradyasystole occurs when there is an intrinsic failure of the heart's electrical system. This failure can be in the form of failure to generate or propagate an adequate number of ventricular depolarizations per minute to sustain consciousness and other vital functions. It is unclear why bradyasystole, which uses very little myocardial oxygen and should have enough high-energy phosphate stores to initiate an ROSC, has such a dismal outcome in the majority of cases. Certainly, the underlying myocardial and valvular dysfunctions in conjunction with systemic insults are entwined in this process. Several studies that used cardiac pacing in this setting showed poor outcomes. To be effective, pacing must be initiated in the first few minutes after arrest. Pharmacologic treatment of asystole involves the use of epinephrine to improve myocardial and cerebral blood flow during CPR. There is conflicting evidence of the benefit of atropine in cardiac arrest. The latest guidelines suggest that routine use of atropine during PEA or asystole is unlikely to have a therapeutic benefit. For this reason atropine has been removed from the cardiac arrest algorithm (14).

Pulseless Electric Activity

PEA (Fig. 3.2) is coordinated electrical activity of the heart (other than VT or VF) without a palpable pulse. In this scenario, either the heart cannot pump at all (true electrical–mechanical dissociation [EMD]) or myocardial contractions do occur but without a palpable pulse (pseudo-EMD). PEA is the term used to describe both true and pseudo-EMD. Primary PEA, like asystole, has a very poor prognosis. The differential of causes of PEA is the same as for asystole.

PEA is the result of a primary disorder of electromechanical coupling in myocardial cells. PEA is most often associated with global myocardial-energy depletion and acidosis resulting from ischemia or hypoxia. Pseudo-EMD is a transient state in the progression to EMD and has the same etiology. In these cases of severely decreased flow, patients must be evaluated for cardiac and extracardiac causes of severe shock.

Intubation and ventilation with 100% oxygen plus an IV fluid bolus can begin the resuscitation. Careful consideration of the common causes of PEA should dictate subsequent interventions. Bedside ultrasonography might allow the treating physician to determine whether or not the heart is beating and whether or not pericardial fluid is present. Alternatively, the placement of an arterial line can be used to differentiate severe shock states from true EMD. In cases where these modalities are unavailable, the clinician must consider the differential and decide whether or not needle thoracostomy and pericardiocentesis are indicated. Once extracardiac causes of EMD are excluded, treatment recommendations include epinephrine to improve myocardial and cerebral blood flow during cardiac arrest and atropine if the ECG shows bradycardia.

As per the above section, atropine is no longer recommended for PEA arrests.

The absence of proven efficacy of sodium bicarbonate and the numerous adverse effects associated with its use have led to the recommendation that it not be routinely used during CPR. It can create extracellular alkalosis that will shift the oxyhemoglobin saturation curve and inhibit oxygen release. It can produce hypernatremia and therefore hyperosmolarity. It produces excess CO_2, which freely diffuses into myocardial and cerebral cells and may paradoxically contribute to intracellular acidosis (14). Sodium bicarbonate may have a role in the treatment of PEA when there is a specific cause such as known hyperkalemia, pre-existing bicarbonate-responsive acidosis, or a tricyclic antidepressant overdose or when alkalinization of the urine is indicated (as in aspirin or other drug overdoses). The classic dose of sodium bicarbonate is 1 mEq/kg.

Therapeutic Mild Hypothermia

Therapeutic hypothermia following hypoxic–ischemic insults has long been thought to offer nonspecific cellular protection. Neurologic injury is the most common cause of death in patients with out-of-hospital cardiac arrest and contributes to the mortality of in-patients with cardiac areas. By lowering the core temperature even a few

degrees reduces the risk of neurologic injury. A large body of evidence now suggests that the protective effects of cooling are much greater than can be explained by the reduction in oxygen and glucose. In animal models, hypothermia has been shown to foster neuroprotection, reduction of free radicals and excitatory neurotransmitters, and stabilization of membranes. Several reports of accidental hypothermia with good neurologic outcome after prolonged ischemic periods led to research in the use of hypothermia in the setting of injury and after surgery. Recent data show positive effects of mild therapeutic hypothermia after cardiac arrest. Some studies have demonstrated a decrease in mortality and a better neurologic outcome in patients who are cooled to 32°C to 34°C for 12 to 24 hours (25). Based on the published evidence, it has been recommended that mild therapeutic hypothermia be provided for the treatment of unconscious patients after prehospital cardiac arrest. Specifically, unconscious adult patients with ROSC after out-of-hospital cardiac arrest should be cooled to 32°C to 34°C within 6 hours and maintained in this range for 12 to 24 hours after cardiac arrest.

Initiating and Discontinuing Resuscitation Efforts

It was classically taught that CPR should be instituted for all patients in cardiac arrest, except in two circumstances: (a) The patient made it clear, while competent and informed, that he or she did not want resuscitation efforts to be instituted; or (b) successful resuscitation would be futile because the patient has clear signs of irreversible death, such as *rigor mortis,* dependent lividity, or decapitation.

In the last 15 years, several studies challenged the usefulness of initiating ACLS protocols in all patients. In most geographic areas, all cardiac arrest patients are transported to the nearest emergency department (ED) for definitive care despite the futility of the resuscitation efforts and the attendant hazards to motorists, pedestrians, and EMS personnel. Transportation of all patients to the nearest ED can limit the availability of EMS personnel to care for other patients; increase patient waiting time; decrease ED, hospital bed, and equipment availability; and increase the costs.

Termination of resuscitation (TOR) guidelines can identify nonsalvageable patients. There is ample evidence that patients that fail out-of-hospital ACLS interventions do not survive to hospital discharge and that ED interventions in this patient population result in survival with good neurologic outcome in $<1\%$ of patients (26). No survivors of asystolic patients have been documented in normothermic patients with a call to arrival time by EMS personnel >8 minutes. Once undertaken, resuscitation efforts are generally continued until it is clear that the patient is not responding to them. The longer the patient remains in cardiac arrest without response, the worse the prognosis is for survival. After 30 minutes of resuscitation attempts, the prognosis is very poor. Consequently, the clinician must exercise his or her judgment as regards TOR.

Emergency physicians and paramedics are obligated to respect patients' wishes regarding resuscitation. In most cases, these wishes may be known through documentation on advance directives. The patient and patient's healthcare provider should update these forms and have them ready for paramedics or ED personnel, so that they can be used in an emergency situation. Many communities have developed a standardized "do not resuscitate" form that patients and their physicians can fill out. These forms document the patients' wishes and provide guidance for both EMS and hospital personnel.

There are three cardiac arrest characteristics that are associated with survival to hospital discharge: ROSC prior to transport, a shock given prior to transport, and cardiac arrest witnessed by EMS personnel (26). In any case of cardiac arrest, the decision to either not initiate or terminate advanced care is determined by the clinician using the best clinical judgment and knowledge of futility situations.

Invasive Cardiopulmonary Resuscitation

Studies in animal models show that techniques of invasive CPR, such as open-chest CPR and cardiopulmonary bypass, and the use of direct mechanical-assist devices improve hemodynamics, resuscitation, and the chances of surviving cardiac arrest. It has also been demonstrated that when invasive CPR is applied late in the treatment protocol (after more than 15 minutes of total arrest time), there is no

improvement in resuscitation. The resources required to provide many of the interventions, principally invasive perfusion technologies, cannot be justified unless there is clear benefit. The allocation of such resources to provide intensive resuscitation and postresuscitation support needs to be addressed from both medical and societal viewpoints.

Quality of Resuscitation Efforts

The use of capnometry to monitor end-tidal CO_2 levels during CPR provides a noninvasive assessment of the cardiac output generated by CPR. Other measures, such as invasive hemodynamic parameters, although useful, cannot realistically be used in an acute resuscitation setting. The quality of resuscitation efforts should also be assessed retrospectively by systemically tracking key variables and the outcome of resuscitation efforts in both the in-hospital and out-of-hospital settings.

Postresuscitation

The goals of postcardiac arrest care are to optimize cardiopulmonary function and vital organ perfusion. The resuscitation of a cardiac arrest victim does not end with an ROSC. The underlying medical conditions leading to the arrest as well as the complications of prolonged global ischemia must be carefully managed to result in an optimal outcome. Although the neurologically intact victim of a cardiac arrest is rare, there is no reliable way to determine the prognosis of an individual patient immediately after resuscitation.

Because the majority of patients have a cardiac etiology for their arrest, immediate focus in the early postresuscitation period should involve looking for an acute coronary syndrome. An ECG should be performed to look for evidence of MI. Administration of all cardiac therapies can be initiated if ischemic heart disease is the presumptive diagnosis. Heparin, aspirin, thrombolytics, and angioplasty can all be considered. Antidysrhythmic therapy for all patients who presented with VF/pulseless VT should also be initiated. Patients with high-risk conduction abnormalities, such as right bundle branch blocks

associated with a hemiblock, second-degree type II blocks, third-degree heart blocks, or new left bundle branch block, should have transthoracic pacing pads placed and used if necessary.

Mild hypothermia seems to be a sufficient compromise between the beneficial effects of mitigation of ischemic membrane damage and reperfusion injury and the adverse risks of dysrhythmic, inflammatory, hemodynamic, and coagulation disorders. Mild hypothermia is potentially the first direct therapy for the brain after cardiac arrest.

DISPOSITION

Patients who survive initial resuscitation should be admitted to the intensive care unit where therapeutic hypothermia care may be continued and further intensive monitoring accomplished. Postresuscitation patients who have evidence of an acute coronary syndrome may be moved to the catheterization laboratory.

Common Pitfalls

- Failure to stay calm and approaching the patient in an organized fashion. It is important to remember that resuscitation efforts require a well-disciplined team in which each member plays a role. Optimal patient care depends on management in a well-controlled, calm environment that is focused on each individual task. The emergency physician should take control of the situation and lead all players in the resuscitation.
- Failure to provide consistent ongoing CPR during SCD.
- Administration of amiodarone, bicarbonate, magnesium, or procainamide endotracheally. The only medications that can be administered via the endotracheal tube are epinephrine, atropine, lidocaine, and naloxone.
- Erroneously giving intracardiac medications. There are no current indications to give intracardiac medications.
- Failure to suspect hyperkalemia in renal failure patients for patients in cardiac arrest. Resuscitation of these patients should include calcium gluconate, bicarbonate, and insulin with glucose. Be sure to look for monitor and ECG manifestations of

hyperkalemia such as hyperacute T waves, prolongation of the QRS complex, or a sine wave pattern.

- Failure to defibrillate in the appropriate manner. The majority of patients in VF can be defibrillated. If unsuccessful, review your technique. One paddle should be placed to the right of the sternum below the right clavicle, and the other should be placed in the midaxillary line at the level of the nipple. If the paddles are too close together, the skin, rather than the heart, may be getting the current. Alternatively, the AP position may be used over the left precordium. Firm pressure of approximately 25 lb should be applied to each paddle, and the appropriate contact gel must be used. The shocks should be given in pairs or triplets to decrease the transthoracic impedance and improve the chances of successful defibrillation.
- Mistaking *torsade de pointes* for VT or fibrillation. Although antidysrhythmic drugs are commonly ineffective in terminating torsades, electrical cardioversion is usually successful. Further treatment with magnesium sulfate, isoproterenol, or overdrive pacing decreases the QT interval and prevents recurrence.
- Failure to induce postresuscitation hypothermia.

CHAPTER 4
Shock

Emanuel P. Rivers, David Amponsah, John Gallien, and Anja K. Jaehne

More than 1.5 million cases of shock present to United States (US) emergency departments (EDs) each year, and the number is increasing, particularly in patients older than 65 years. The incidence of septic shock, for example, has increased markedly for the past 10 years, with an annualized increase of 8.7% and more than 600,000 cases presenting to EDs each year in US (1). The annual economic burden for the care of patients in US with septic shock alone is more than $60 billion. Mortality from shock remains high despite better understanding of the underlying pathophysiology and aggressive treatment. Approximately 30% to 45% of patients in septic shock and 60% to 90% of those with cardiogenic shock die within 1 month of presentation. Over the last decade, the illness severity and duration for shock patients has significantly increased in EDs in US (2,3). Because of this, ED management is a central role in improving outcomes for these fragile patients.

Shock is defined as an impairment of circulatory function leading to global tissue hypoxia. The presentation may be as subtle as mild decompensated heart failure (4,5) or as obvious as the ultimate shock state of cardiac arrest. It is estimated that 12% of patients with undetected severe sepsis and septic shock are admitted to general medical floors, which is frequently associated with morbid and lethal consequences after hospital admission (6,7). Irrespective of the type of ED presentation, timely diagnosis and aggressive intervention prevents complications and significantly improves survival (7), especially in the ED setting (7).

PHYSIOLOGY

The principles of oxygen delivery (Do_2) and utilization are paramount to the understanding of shock. A maximum of four molecules of oxygen are loaded onto each molecule of hemoglobin as it passes through the lungs. If all available oxygen sites are occupied (four per molecule of hemoglobin), then the arterial oxygen saturation (Sao_2) is 100% (Fig. 4.1). Arterial oxygen concentration (Cao_2) is the amount of oxygen bound to hemoglobin plus the amount dissolved in plasma. Oxygen delivery (Do_2) is the product of the Cao_2 and cardiac output (CO). Oxygen consumption ($\dot{V}o_2$) reflects a sensitive balance between supply and demand. Normally, the tissues consume about 25% of the oxygen carried on hemoglobin, and venous blood returning to the right heart is about 65% to 75% saturated venous oxygen saturation (Svo_2). When oxygen supply is insufficient to meet demand, the first compensatory mechanism is an increase in CO. If the increase in CO is inadequate, the amount of oxygen extracted from hemoglobin by the tissues increases (systemic oxygen extraction or OER), reflected in a decrease in Svo_2.

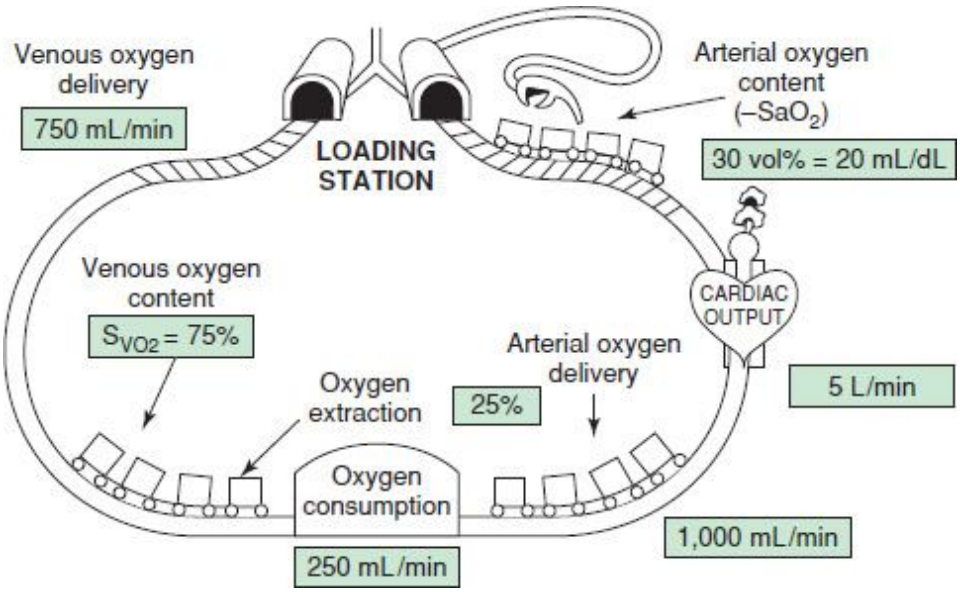

FIGURE 4.1 Oxygen saturation, content, and delivery.

When compensatory mechanisms (increased OER or decrease in SvO_2 less than 50%) fail to correct the imbalance between tissue supply and demand, anaerobic metabolism occurs, resulting in the formation of lactic acid (normally between 0.5 and 1.9 mmol/L). Most cases of lactic acidosis are caused by inadequate Do_2, but lactic acidosis occasionally can develop from an excessively high oxygen demand, as in status epilepticus or other nonhypoxic causes of lactic acidosis. In other cases, lactic acidosis occurs because of impairment in tissue oxygen utilization, as in septic shock, cyanide poisoning, and immediately after resuscitation from cardiac arrest. A normal Svo_2 and adequate Do_2 with an elevated lactate indicate such an impairment. An elevated lactate is a marker of impaired Do_2 or utilization and correlates with short-term prognosis of critically ill patients in the ED (8,9). However, a normal lactate is not infrequent in patients with shock (10,11). Svo_2 can also be used as a measure of the balance between tissue oxygen supply and demand. Svo_2 is measured through a pulmonary artery catheter, but similar information can be obtained from the central venous oxygen saturation ($Scvo_2$), which correlates well with Svo_2 and is more easily obtained in the ED setting (12).

Thus, shock is circulatory insufficiency caused by tissue Do_2 that is insufficient to meet oxygen demands. The result of shock is global hypoperfusion or tissue hypoxia and is manifested by a decreased venous oxygen content and metabolic acidosis (lactic acidosis). Global tissue hypoxia alone can independently activate the inflammatory response and serve as a comorbid variable in the pathogenesis of all forms of shock (13). The failure to diagnose and treat global tissue hypoxia in a timely manner leads to an accumulation of an oxygen debt, inflammation (14), organ dysfunction, and increased mortality.

CLINICAL PRESENTATION

The clinical presentation of shock can range from dramatic to subtle. Shock can be instantly apparent, as with acute myocardial infarction, anaphylaxis, or hemorrhage, whereas some patients may have few

symptoms other than generalized weakness, lethargy, or altered mental status. Symptoms that suggest volume depletion include bleeding, vomiting, diarrhea, excessive urination, insensible losses as a result of fever, or orthostatic light-headedness. A history of cardiovascular disease is important, particularly episodes of chest pain or symptoms of congestive heart failure (particularly systolic dysfunction). Prior neurologic diseases (e.g., Parkinson) can render patients more susceptible to complications from hypovolemia because of autonomic dysfunction. Use of medications, both prescribed and nonprescribed, is important. Some medications cause volume depletion (e.g., diuretics), whereas others depress myocardial contractility (e.g., β-blockers and calcium channel blockers) and others are vasodilators (e.g., niacin, erectile dysfunction, or prostatic hypertrophy drugs). The previous use of corticosteroids may predispose the patient to adrenal insufficiency. The possibility of an anaphylactic reaction to a new medication should also be considered.

The clinical presentation of shock varies depending on the precipitating cause such as cardiogenic, hypovolemic, obstructive, or distributive. Although not specific, physical findings taken as a composite may be useful in the assessment of patients in shock (Table 4.1). No single vital sign or physical finding is diagnostic of shock, as vital signs are frequently insensitive in detecting and assessing the severity of tissue hypoperfusion. Measurement of blood pressure can be particularly difficult because of peripheral vascular disease, tachycardia with a small pulse pressure, arteriovenous dialysis fistulas and dysrhythmias such as atrial fibrillation. Shock is usually, but not always, associated with systemic arterial hypotension, which is systolic blood pressure <90 mm Hg. Nonsustained hypotension, or a single episode, carries a significantly increased risk of death during hospitalization, which makes it a clinically significant and meaningful event (15).

TABLE 4.1
Clinical Findings in Shock

Temperature

- Hyperthermia, hypothermia, or afebrile, especially in the elderly

Skin

- Pale, dusky, clammy, cyanosis, mottling over the knees
- Sweaty
- Altered temperature
- Decreased capillary refill

Central Nervous System

- Acute delirium or brain failure
- Restlessness, disorientation, confusion, psychosis
- Coma

Neck

- Neck-vein distention or flattening

Respiratory

- Tachypnea
- Increased minute ventilation
- Increased dead space
- Bronchospasm
- Hypocapnia, respiratory failure, adult respiratory distress syndrome
- Respiratory alkalosis

Cardiovascular

- Tachycardia; S3 may result from high-output states
- Dysrhythmias
- Hypotension
- Increased then decreased pulse pressure
- *Pulsus paradoxus*
- Elevated shock index (heart rate: systolic blood pressure >1)
- β-Blockers may blunt response

Gastrointestinal

- Ileus
- Gastrointestinal bleeding
- Pancreatitis
- Acalculous cholecystitis
- Mesenteric ischemia from low-flow states

Renal

- Oliguria, anuria, and unexplained metabolic acidosis; paradoxical polyuria

Heme

- Hemoconcentration
- Decreased platelets
- Decreased fibrinogen
- Increased fibrin split products
- Increased D-dimers

Because blood pressure is the product of flow and resistance (mean arterial pressure [MAP] = CO × systemic vascular resistance [SVR]), the blood pressure may not fall in the presence of decreased CO if there is an increase in peripheral vascular resistance (Fig. 4.2). The insensitivity of blood pressure in detecting inadequate flow to tissues and global tissue hypoxia has been repeatedly confirmed. Thus, shock may occur with a normal blood pressure, and hypotension may occur without shock.

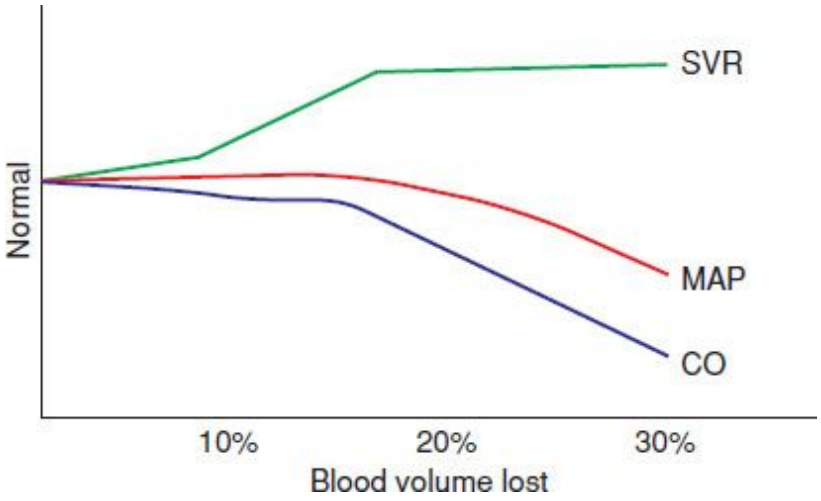

FIGURE 4.2 Relationship of SVR (systemic vascular resistance), MAP (mean arterial pressure), and CO (cardiac output) with volume loss.

The onset of shock provokes a myriad of autonomic responses, many of which serve to maintain perfusion pressure to vital organs. Stimulation of the carotid baroreceptor stretch reflex activates the sympathetic nervous system leading to (a) arteriolar vasoconstriction, resulting in redistribution of blood volume from the skin, skeletal muscle, kidneys, and splanchnic viscera; (b) an increase in heart rate and contractility that increases CO; (c) constriction of venous capacitance vessels, which augments venous return; (d) release of the vasoactive hormones epinephrine, norepinephrine, dopamine, and cortisol to maintain arteriolar and venous tone; and (e) release of antidiuretic hormone and activation of the renin–angiotensin axis to enhance water and sodium conservation to maintain intravascular volume. These compensatory mechanisms

attempt to maintain DO_2 to the most critical organs: the coronary and cerebral circulation. During this process, blood flow to other organs, such as to the kidneys and gastrointestinal tract, may be compromised, leading to organ failure.

The cellular response to decreased DO_2 is adenosine triphosphate (ATP) depletion, leading to ion pump dysfunction, influx of sodium, efflux of potassium, and reduction in membrane resting potential. Cellular edema occurs secondary to increased intracellular sodium while cellular membrane receptors become poorly responsive to the stress hormones insulin, glucagon, cortisol, and catecholamines. As shock progresses, lysosomal enzymes are released into the cells with subsequent hydrolysis of membranes, deoxyribonucleic acid, ribonucleic acid, and phosphate esters. As the cascade of shock continues, the loss of cellular integrity and the breakdown in cellular homeostasis result in cellular death (Fig. 4.3). The failure of the cell to utilize oxygen or perform cellular respiration is impaired, and thus endogenous heat generation is impaired. This process gives rise to hypothermia, a common clinical feature of shock. These pathologic events give rise to the metabolic features of hemoconcentration, hyperkalemia, hyponatremia, prerenal azotemia, metabolic acidosis, hyper- or hypoglycemia, and lactic acidosis.

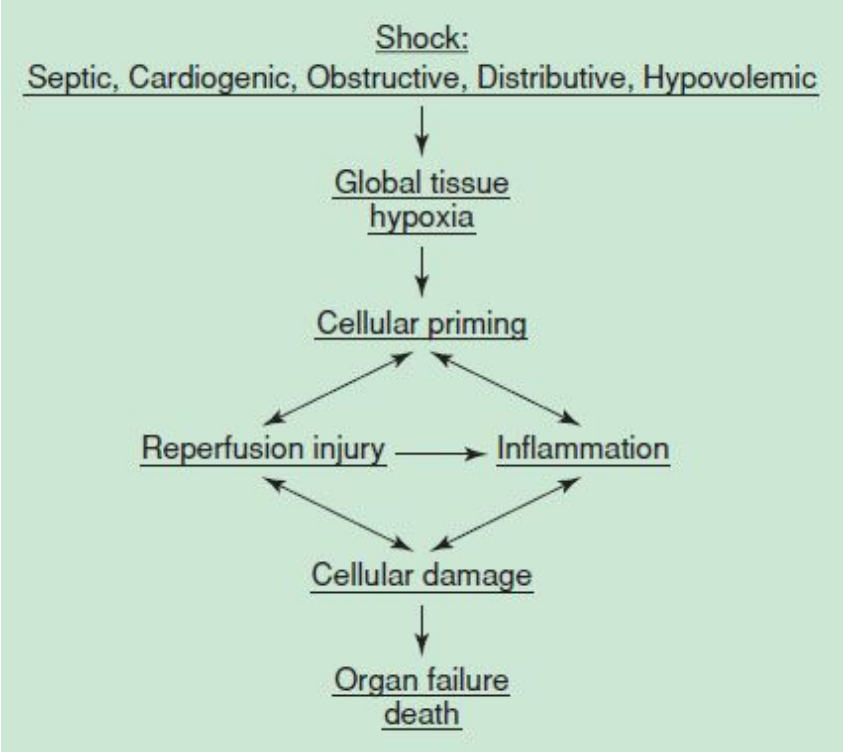

FIGURE 4.3 Mechanism of cell death.

The clinical presentation of early shock is often characterized as a syndrome called the systemic inflammatory response syndrome (SIRS). SIRS is defined as the presence of two or more of the following features: (a) temperature >38°C (100.4°F) or <36°C (96.8°F); (b) heart rate >90 beats/min; (c) respiratory rate >20 breaths/min; and (d) white blood cell count >12 × 10^9/L, <4 × 10^9/L, or with >10% immature forms or bands. SIRS may occur in any shock state. The stimulus for SIRS is a complex elaboration of humoral and cellular pro- and anti-inflammatory products, which induces a panendothelial cell disruption or generalized inflammation within the vast capillary network in each organ. The hemodynamic consequence of SIRS is the generation of global tissue hypoxia from hypovolemia, vasodilation, and myocardial suppression. There is an increase in oxygen demands secondary to fever or an increased work of breathing. Cytopathic tissue hypoxia develops when there is a defect in the peripheral utilization of oxygen in the tissues.

As SIRS progresses, organ dysfunction and the multiorgan dysfunction syndrome (MODS) ensue. This syndrome is characterized

by organ failures such as acute lung injury, adult respiratory distress syndrome, disseminated intravascular coagulation, hepatic failure, adrenal and renal failure, among others. Early detection and interruption of these hemodynamic perturbations are key for improving survival. Table 4.2 compares shock states.

TABLE 4.2
Comparison of Shock States

	Focused Ultrasound Assessment (16)	MAP	CVP	$Scvo_2$	Lactate	CI	SVR	Comment
Cardiogenic	Depressed left ventricular (LV) contractility Global hypokinesis Plethoric IVC, JVD Pulmonary edema/effusion	↓	↑	↓	↑	↓	↑	Myocardial infarction or decompensated heart failure
Obstructive	Large pericardial effusion or tamponade RV chamber dilatation and/or strain Right heart thrombus Paradoxic septal wall motion	↓	↑	↓	↑	↓	↑	Pulmonary embolus or pericardial tamponade, tension pneumothorax
Hypovolemic	Hypercontractile LV with small chamber size Decreased IVC diameter Ruptured aortic aneurysm Hemoperitoneum	↓	↓	↓	↑	↓	↑	Hemorrhagic or hypovolemic
Septic	LV contractility normal/abnormal IVC normal/abnormal Decreased CO/CI							
Stage 1	LV contractility normal/abnormal Decreased IVC diameter Decreased CO/CI	↓ or Normal	↓	↓	↑	↓	↑	Early sepsis, hypovolemia
Stage 2	IVC diameter normal	↓	Normal	↑	↑	↑	↓	Compensated
Stage 3	Depressed LV contractility	Normal	↑	↓	↑	Normal	Normal	Myocardial suppression
Stage 4	LV contractility normal/abnormal Decreased or normal CO/CI	↓	Normal	↑↑	↑	↑	↓	Impaired tissue oxygen utilization or cytopathic tissue hypoxia
Distributive	LV contractility normal/abnormal IVC normal or abnormal	↓	↓	↓	↑	↓	↓	Anaphylaxis, spinal shock

MAP, mean arterial pressure; CVP, central venous pressure; $Scvo_2$, central venous blood saturation; CI, cardiac index; SVR, systemic vascular resistance.

DIFFERENTIAL DIAGNOSIS

The four classifications of shock are based on etiology:

- Hypovolemic (caused by inadequate circulating volume), as in hemorrhagic shock
- Cardiogenic (caused by inadequate cardiac pump function), as in anterior wall acute myocardial infarction
- Distributive (caused by peripheral vasodilatation and maldistribution of blood flow), as in sepsis, anaphylaxis, or spinal cord injury
- Obstructive (caused by extracardiac obstruction to blood flow), as in a pulmonary embolus, cardiac tamponade, or tension

pneumothorax.

Although there may be an initial predominant cause of shock, as the shock state persists or progresses to irreversible end-organ damage, other pathophysiologic mechanisms become operative and can create a mixed picture.

ED EVALUATION

The clinical presentation and the presumptive etiology of shock dictate the use of ancillary studies. A battery of standard arterial blood gas, hematologic, coagulation, and biochemical tests usually provides an assessment of each organ function and may detect an abnormality that requires specific treatment. A wide range of laboratory abnormalities may be encountered in shock, but most abnormal values merely point to the particular organ system that is either contributing to or being affected by the shock state. No single laboratory value is sensitive or specific for shock. Additional studies, including an electrocardiogram (ECG), a chest radiograph (CXR), and source-specific plain radiographs or computerized tomography (CT), should also be done.

Most EDs in US have portable ultrasound systems available. These ultrasound systems used by appropriately trained ED physicians can be used in the evaluation of shock patients and may help to characterize the etiology of the shock state in a timely fashion. Bedside ultrasound assessment in the early evaluation of patients in shock should focus on volume status and anatomic function, with the assessment of the heart, IVC, jugular veins, and aorta (17).

Hemodynamic monitoring is important in the assessment of patients in shock and evaluation of response to treatment. Monitoring capabilities vary from institution to institution but should include pulse oximetry; ECG monitoring; continuous, noninvasive, preferably intra-arterial blood pressure monitoring if there is vasopressor-dependent or persistent hypotension; end-tidal CO_2 monitoring; central venous pressure (CVP) monitoring; and continuous central venous oximetry. Because hemodynamic measurements are physiologic values, they should be used to answer specific physiologic questions rather than to serve as therapeutic end

points. Table 4.3 outlines adjuncts to aid in the evaluation of patients in shock.

TABLE 4.3
Adjuncts that Guide Therapeutic Interventions

Base deficit	Base deficit is an indicator of metabolic acidosis and is an index of hemodynamic and tissue perfusion changes in shock. Base deficit predicts illness severity in intra-abdominal hemorrhage and blunt trauma.
Lactate and lactate clearance	Initial lactate levels have been shown to be predictive of outcome. Normalization of lactate levels or lactate clearance also is predictive of severity of the inflammatory response, morbidity, and mortality.
Invasive blood pressure monitoring	Intense vasoconstriction caused by sympathetic activity or vasopressors given will cause the cuff pressure to underestimate true blood pressure. A Doppler used in conjunction with a sphygmomanometer may provide a more accurate measure of systolic blood pressure once Korotkoff sounds are no longer audible. Intra-arterial pressure measurement is preferable because vasoactive drugs can cause rapid swings in blood pressure, and multiple blood samplings typically are required.
CVP	CVP aids in assessing volume status. CVP is preferred for the long-term administration of vasopressor therapy and provides rapid access to the heart if pacemaker placement is required. CVP may not reliably reflect the left ventricular filling pressure in clinical states such as pulmonary embolus, obstructive airway disease, right ventricular infarction, and pericardial effusion. Common iliac venous pressure can approximate CVP.
$Scvo_2$	$Scvo_2$ closely approximates $Smvo_2$ and can be monitored continuously using infrared oximetry. This technology enables the clinician to detect clinically unrecognized global tissue hypoperfusion in the treatment of myocardial infarction, general medical shock, trauma, hemorrhage, septic, hypovolemic, end-stage heart failure, cardiogenic shock during and after cardiopulmonary arrest.
Arterial–central venous Pco_2 difference	Increased $(a\text{-}v)Pco_2$ are seen in acute circulatory failure and inversely correlate with the CI. Central venous and mixed venous carbon dioxide values can be interchanged to determine cardiac index (5).
Pulmonary artery catheterization	The standard of care for assessing cardiac status. Catheterization is valuable in determining left-sided heart filling and pulmonary artery pressure and for assessing the cause of pulmonary edema. The physician can obtain cardiac output and mixed venous oxygen saturation. The physician will be able to calculate hemodynamic (i.e., SVR) and oxygen transport variables (Vo_2 and Do_2). The effectiveness of this monitoring technique on improving outcome is questionable.
Bedside ultrasound assessment (RUSH EXAM)	Three-step goal-directed ultrasound assessment of the pump (heart), the tank (inferior vena cava and jugular veins), and the pipes (aorta). This early ultrasound assessment may help to differentiate shock etiologies and guide treatment by focusing on anatomy and physiology (16).
Noninvasive CO	CO can be measured by transesophageal Doppler, cutaneous bioimpedance, and lithium dilution, transthoracic echocardiography (AV CSA × VTI).
Gastric tonometry and sublingual capnography	Serial measurements of gastric and sublingual mucosal blood flow are based on hydrogen ion diffusion and carbon dioxide elimination. Inadequate visceral perfusion, as evidenced by persistently low intramucosal pH or increased sublingual carbon dioxide concentration after resuscitation, is associated with subsequent organ dysfunction and death.
$Srao_2$	$Srao_2$ correlates with blood volume, central venous O_2 saturation, and arterial O_2 saturation
Metabolic cart	Metabolic cart is directly measured $\dot{V}o_2$ without a pulmonary artery catheter. A reduction in $\dot{V}o_2$ after acute myocardial infarction predicts cardiogenic shock and mortality after human cardiac arrest

CVP, central venous pressure; $Scvo_2$, central venous blood saturation; $Smvo_2$, mixed venous O_2 saturation; Pco_2, partial pressure of carbon dioxide; $(a\text{-}v)Pco_2$, arterial–mixed-venous carbon dioxide gradients; CI, cardiac index; SVR, systemic vascular resistance; Vo_2, oxygen consumption; Do_2, oxygen delivery; CO, cardiac output; $Srao_2$, retinal venous O_2 saturation.

ED MANAGEMENT

The *ABCDE* tenets of shock resuscitation are fundamental to deliver enough oxygen to the tissues to meet the metabolic demands of the tissues (Fig. 4.4). These tenets include establishing an Airway, controlling the work of Breathing, optimizing the Circulation, assuring adequate oxygen Delivery, and achieving End points of resuscitation.

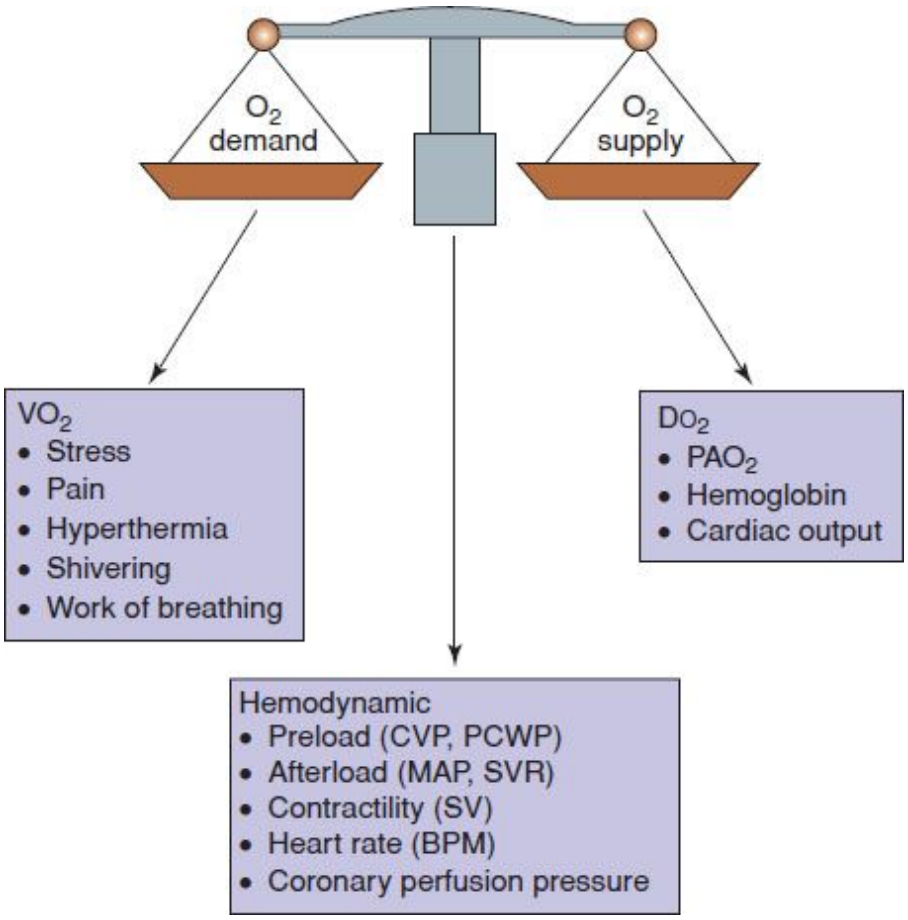

FIGURE 4.4 Balance between oxygen supply and demand. BPM, beats per minute; CVP, central venous pressure; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; SV, stroke volume; SVR, systemic vascular resistance.

Establishing an Airway

Airway control is best obtained through endotracheal intubation. This provides airway protection, positive pressure ventilation (oxygenation), patency, and pulmonary toilet. Sedatives, which are frequently used to facilitate intubation, can exacerbate hypotension through arterial vasodilatation, venodilation, and myocardial suppression. Etomidate, often used during the induction of intubation, has also been implicated in causing transient adrenal dysfunction; however, its impact on mortality is controversial (18–20). Furthermore, positive pressure ventilation reduces preload, increases pulmonary vascular resistance, and decreases CO. The

combination of these interventions can lead to acute hemodynamic compromise. Volume resuscitation or application of vasoactive agents may be required prior to intubation and positive pressure ventilation.

Controlling the Work of Breathing

Control of breathing is required when tachypnea accompanies shock. Respiratory muscles are significant consumers of oxygen during shock and contribute to lactate production. Mechanical ventilation, muscle relaxation, and sedation decrease the work of breathing and preserve the DO_2 used for more vital organs and have been shown to improve survival (21). Sao_2 should be restored to $>93\%$, and ventilation controlled to maintain an arterial carbon dioxide pressure ($Paco_2$) of 35 to 40 mm Hg. Attempts to normalize pH >7.3 by hyperventilation are not beneficial. Mechanical ventilation not only provides oxygenation and corrects hypercapnia, but it assists, controls, and synchronizes ventilation, which ultimately decreases the work of breathing. Ventilatory airway pressure (plateau) should be maintained less than 30 mm Hg to minimize barotrauma and hemodynamic embarrassment.

Optimizing the Circulation

In restoring the balance between systemic Do_2 and demands, optimization of circulatory dysfunction begins with a thoughtful manipulation of preload, afterload, contractility, and coronary perfusion pressure, while maintaining an optimal heart rate.

Circulatory or hemodynamic stabilization begins with intravascular access through large-bore peripheral venous lines. Trendelenburg positioning, historically considered necessary for maintaining perfusion in the hypotensive patient, does not improve cardiopulmonary performance in comparison with the supine position. Trendelenburg positioning may worsen pulmonary gas exchange and predispose to aspiration. If a volume challenge is urgently required, an alternative to the Trendelenburg position is to raise the patient's legs above the level of the heart with the patient

supine. Central venous access aids in assessing volume status (preload) and monitoring S_{CVO_2}. Central venous access is the preferred route for the long-term administration of vasopressor therapy and provides rapid access to the heart if pacemaker placement is required. Early central venous access has been associated with improved mortality in septic shock (22).

Fluid resuscitation begins with isotonic crystalloid; the amount and rate are determined by an estimate of the hemodynamic abnormality. Except for the patient in cardiogenic shock with pulmonary edema, most patients in shock have either an absolute or relative volume deficit. Fluid is given rapidly in set quantities (e.g., 500 or 1,000 mL) every 20 to 30 minutes, with reassessment of the patient after each bolus. Patients with a modest degree of hypovolemia usually require an initial 20 to 40 mL/kg of isotonic crystalloid. More fluids may be necessary with profound volume deficits (23).

The colloid-versus-crystalloid (24) resuscitation controversy remains despite evidence that there is a slight increase in mortality when colloids are used for volume replacement in critically ill patients (25). Some studies have found a lower incidence of pulmonary edema and possibly greater benefit in elderly patients with colloid resuscitation, although survival is not statistically improved. Recent data has associated albumin therapy with worse outcomes in head trauma patients, but with improved or equal outcomes in severe sepsis and septic shock. In addition, the use of starches has been associated with worse outcomes in severe sepsis and septic shock, leading to higher rates of renal failure and need for renal replacement therapy in a randomized clinical trial (26). In the acute situation with severe shock, colloids may be considered to achieve rapid plasma expansion using less volume than crystalloids. Without invasive hemodynamic monitoring, noncardiogenic pulmonary edema may be difficult to differentiate from cardiogenic pulmonary edema in the ED. Even though the former may respond to fluids, fluids should be minimized in a patient with clinical or radiographic evidence of pulmonary edema until appropriate monitoring is established.

Vasopressor agents (Table 4.4) are used when there has been an inadequate response to volume resuscitation or when a patient has contraindications to volume infusion. Vasopressor agents are most effective when the vascular space is “full” and least effective when the vascular space is depleted. However, vasopressors may be necessary early in the treatment of shock, before volume resuscitation is complete, to prevent potentially lethal consequences of prolonged systemic arterial hypotension. This is especially important in elderly patients with significant coronary and cerebrovascular disease. Rapidly restoring the MAP to 60 mm Hg or systolic pressure to 90 mm Hg might avoid the coronary and cerebral complications of decreased blood flow. Vasopressor agents have variable effects on the α- and β-adrenergic receptors (27).

TABLE 4.4
Commonly Used Vasoactive Agents

Drug	Dose/Mixture	Action	Effects				
			Cardiac Stimulation	Vasoconstriction	Vasodilation	Cardiac Output	Side Effects/Comments
Dopamine	0.5–25 µg/kg/min 200–400 mg/250 mL	α, β, and dopaminergic	++ at 2–10 µg/kg/min	++ at 7 µg/kg/min	+ at 0.5–5 µg/kg/min	Usually increases	Tachydysrhythmias; increases myocardial O_2 consumption; a cerebral, mesenteric, coronary, and renal vasodilator
Norepinephrine	0.01–0.5 µg/kg/min 4 mg/250 mL	Primarily α_1, some β_1	++	++++	0	Slight decrease	Dose-related, reflex bradycardia; useful when loss of venous tone predominates; spares the coronary circulation
Phenylephrine	0.15–0.75 µg/kg/min 10 mg/250 mL	Pure α	0	++++	0	Decrease	Reflex bradycardia, headache, restlessness, excitability, rarely dysrhythmias; ideal for patients in shock with tachycardia or supraventricular dysrhythmias
Ephedrine	5–25 mg	α and β	+++	++	+	Increase	Causes palpitations, hypertension, cardiac arrhythmias; an indirect-acting central nervous system stimulant; limited long-term value as therapy for shock
Vasopressin	0.01 to 0.04 U/min	α	++++				Primarily α; outcome data of its use is lacking. Infusions of >0.04 U/min may lead to adverse, likely vasoconstriction-mediated events; reserved for refractory hypotension
Epinephrine	0.01–0.75 µg/kg/min 1 mg/250 mL	α and β	++++ at 0.03–0.15 µg/kg/min	++++ at 0.15–0.30 µg/kg/min	+++	Increase	Causes tachydysrhythmia and leukocytosis; increases myocardial oxygen consumption
Dobutamine	2–20 µg/kg/min 250 mg/250 mL	β_1, some β_2, and α_1 in large dosages	++++	+	++	Increase	Causes tachydysrhythmia, occasional gastrointestinal distress, an increase in myocardial oxygen consumption, and hypotension in volume-depleted patient; has less peripheral vasoconstriction than dopamine; can cause fewer arrhythmias than isoproterenol
Isoproterenol	0.01–0.02 µg/kg/min 1 mg/250 mL	β_1 and some β_2	++++	0	++++	Increase	Causes tachydysrhythmia, facial flushing, and hypotension in hypovolemic patients; increases myocardial oxygen consumption; never use

Using vasopressors has potential pitfalls. While improving perfusion pressure in the large vessels, vasopressors may decrease capillary or microcirculatory blood flow and have been implicated with increased mortality in septic shock. Vasopressors also may alter the relationship between volume and pressure measurements through their effect on the pulmonary and peripheral vascular beds. In other words, vasopressors will falsely elevate intracardiac filling pressures (i.e., CVP). Vasopressors should be used judiciously, generally only after volume resuscitation. Volume assessment should

be a dynamic process. When multiple vasopressors are used, they should be simplified as soon as the most therapeutic agent is identified.

Assuring Adequate Oxygen Delivery

Once blood pressure is stabilized through optimization of preload and afterload, Do_2 can be assessed and further manipulated. Arterial saturation should be returned to physiologic levels (93% to 95%), and hemoglobin maintained at a level >10 g/dL. This hemoglobin threshold has been debated in steady-state critically ill patients but remains recommended in the shock phase of disease (28) more specifically when the $ScvO_2$ is less than 69.5% (29). If CO and stroke volume (SV) can be assessed, both of these parameters should be optimized using afterload-reducing agents, volume infusion, and inotropic agents in incremental amounts until Svo_2 or $Scvo_2$ and lactate are normalized.

The control of $\dot{V}o_2$ is important in restoring the balance of oxygen supply and demand to tissues. A hyperadrenergic state results from the compensatory response to shock, physiologic stress, pain, and anxiety. Shivering frequently results when a patient is unclothed for examination and then left inadequately covered in a cold resuscitation room. The combination of these variables increases systemic oxygen consumption. Pain further suppresses myocardial function, thus impairing Do_2 and $\dot{V}o_2$. Providing analgesia, muscle relaxation, warm covering, anxiolytics, and even paralytic agents, when appropriate, decreases this inappropriate $\dot{V}o_2$.

Tissue oxygen extraction assesses adequacy of the resuscitation in meeting the oxygen needs of the tissues. Sequential examination of lactate and Svo_2 or $Scvo_2$ is a method to assess adequacy of tissue oxygen extraction. Continuous measurement of Svo_2 or $Scvo_2$ through fiberoptic technology can be performed in the ED (12). Other technologies also have the potential to assess tissue perfusion during resuscitation.

Achieving End Points of Resuscitation

Normalization of blood pressure, heart rate, and urine output are traditional end points. Global tissue hypoxia can still persist in patients resuscitated from shock even with normalization of vital signs (30) and urine output (31,32). Because these parameters may underestimate the degree of remaining hypoperfusion and oxygen debt, more physiologic end points have been investigated (5,33). No therapeutic end point is universally effective; however, they are used to provide metabolic confirmation that adequate tissue oxygenation has been achieved (Table 4.3). The goals of resuscitation are to maximize survival and to minimize morbidity by using objective hemodynamic and physiologic values to guide therapy. A goal-directed approach at achieving urine output $\geq$0.5 mL/kg/h, CVP 8 to 12 mm Hg, MAP 65 to 90 mm Hg, and $Scvo_2$ $\geq$70% during ED resuscitation of septic shock significantly decreases mortality (7).

Bicarbonate Use in Shock

The primary treatment for acidosis in shock is to reverse the underlying cause. Because this goal is not rapidly attainable, intravenous bicarbonate is often administered. The rationale for giving bicarbonate is that it diminishes myocardial depression and counteracts the insensitivity to endogenous catecholamines attributed to acidosis. However, experimental data indicate that exogenous bicarbonate can actually worsen intracellular acidosis, and prospective studies do not show any benefit from its use. Bicarbonate (34) also shifts the oxygen–hemoglobin dissociation curve to the left and impairs tissue unloading of hemoglobin-bound oxygen. However, many clinicians are reluctant to withhold bicarbonate. A compromise is to partially correct the metabolic acidosis through the course of time. The bicarbonate deficit is determined, which is equal to

$$(\text{normal } HCO_3^- - \text{the patient's } HCO_3^-) \times 0.4 \times \text{body weight in kilograms}$$

Half of this amount is infused slowly, with the remainder infused throughout 6 to 8 hours to achieve a pH $\leq$7.25.

Resuscitative Adjuncts

Adjuncts that can guide therapeutic interventions are evolving. A variety of invasive and noninvasive adjuncts (Table 4.3) are available to monitor the response to shock resuscitation.

DISPOSITION AND PROGNOSIS

Pathogenic mechanisms such as cytopathic tissue hypoxia (a form of irreversible shock) can occur within the first few hours of an ED stay, rendering therapy in the intensive care unit less effective. Current national increases in ED patient acuity and overcrowding have resulted in extending the golden hour into hours and even days, consequently requiring the provision of critical care in the ED. The benefit of timely ED intervention in traumatic and nontraumatic critical illness is significant; standard ED care can significantly decrease morbidity and predicted mortality in as little as 6 hours of treatment (35). In addition, application of an algorithmic approach to optimize hemodynamic end points with early goal-directed therapy in the ED reduces mortality by an absolute 16% in patients with severe sepsis or septic shock (7).

Documentation and communication are important. Resuscitation in the ED is commonly performed in "ordered chaos." Even though resuscitation is systematic and thoughtful, miscommunication with the critical care specialist accepting the patient can undo the benefits of initial treatment. A system-oriented problem list with an assessment and plan, including all procedures and complications, should be verbally communicated and written or dictated prior to transfer. For prolonged ED stays, notations regarding patient status, diagnostic and therapeutic intervention, and sentinel events should be provided frequently.

Prediction of outcomes has not been fully studied; however, some clinical variables, for example, severity of shock, temporal duration, underlying cause, pre-existing vital organ dysfunction, and

reversibility, are associated with poor outcome. Persistently elevated lactate level, base deficits, and decreased $Scvo_2$ are prognostic for morbidity and mortality in trauma, septic shock, and after cardiac arrest. Outcome predictions using physiologic scoring systems in the ED are also being studied.

Common Pitfalls

- Failure to monitor appropriately. Be aware of malfunction of arterial blood pressure monitoring equipment, such as dampening of the arterial line or disconnection from the transducer.
- Failure to adequately volume resuscitate. Global tissue hypoxia may persist even after resuscitation to normal vital signs (30) and urine output (32). The hospital mortality in this subset of patients can be >50% (7). The early use of vasopressors may "falsely" elevate CVP and disguise hypovolemia.
- Failure to recognize a pneumothorax after placement of central venous access.
- Failure to recognize the underlying cause of shock when using only bedside ultrasound in patient assessment.
- Failure to recognize an occult penetrating injury (a bullet hole or stab wound) or occult bleeding (from a ruptured spleen or ectopic pregnancy).
- Failure to recognize anaphylactic shock caused by an administered medication (e.g., penicillin) or by medication taken before arrival.
- Failure to diagnose cardiac tamponade, e.g., in the dialysis patient or in the cancer patient.
- Failure to recognize adrenal insufficiency. The incidence of adrenal dysfunction can be as high as 20% in this subset of patients (18).

CHAPTER 5 Vascular Access

Eric F. Reichman

The practice of emergency medicine frequently requires access to the venous and sometimes the arterial circulation of a patient (1). Vascular access allows for blood sampling, medication administration, blood product administration, hydration, patient monitoring (i.e., arterial lines and pulmonary artery catheters), and insertion of cardiac pacing wires. Peripheral venous puncture is the most common invasive procedure performed in the emergency department (ED). Peripheral vein cannulation is performed on a daily basis and is the cornerstone of circulatory resuscitation.

There are many techniques with which to access a patient's venous or arterial circulation. Venous puncture (venipuncture) or arterial puncture with a needle is only indicated for the sampling of blood. Medications may be administered as a one-time dose via this technique, but the risk of extravasation is high. Venous cannulation (intravenous [IV] placement) is indicated for repeated sampling of venous blood. Venous cannulation is also performed for the administration of medications, fluid solutions, blood products, and nutritional support.

There are some general contraindications to peripheral vascular access. Arteries and veins should not be accessed through infected skin. Do not withdraw venous blood from a vein proximal to a running IV infusion. The blood sample will be tainted or diluted by the infused solution. A hole in the vein may allow blood, infused solutions, and medications to extravasate into the surrounding tissues. Venipuncture and venous cannulation of veins in an extremity with an arteriovenous fistula should be avoided. Veins in

the upper extremity that may be needed for arteriovenous fistula construction for hemodialysis in the future should not be punctured unless absolutely necessary.

Complications specific to each technique and site are discussed more fully in this chapter. Venous and arterial catheters should be assessed immediately after their placement and be reassessed frequently. The assessment must include the skin puncture site, catheter function, the neurovascular status of the distal extremity, and the patient's overall condition.

GENERAL PRINCIPLES FOR INTRAVENOUS ACCESS

Although veins can dilate and constrict somewhat on their own, they do so mostly in response to the pressure within them. The use of venous tourniquets, dependent positioning, "pumping" via muscle contraction, and the local application of heat or nitroglycerin ointment all contribute to venous engorgement. These maneuvers can be used to aid in the performance of a venipuncture or peripheral venous access.

The vascular anatomy can affect access (2). Deficient perivascular connective tissue permits the vein to "roll" from side to side and evade the needle. Tough connective tissue can impede the entry of a flexible catheter while serving to stabilize the vein and prevent its collapse. Venous valves allow unidirectional flow and prevent blood from pooling in the dependent portions of the extremities. Valves can block the passage of a catheter through and into a vein. Valves are more numerous at the points where tributaries join larger veins and in the lower extremities. Valves are almost absent within the large central veins, the veins of the head, and the veins of the neck.

Peripheral veins are easiest to access at the apex of the "Y," formed when two tributaries merge into a larger vein or where the vein is straight and free of branches and valves for two or so proximal to the site of puncture. These sites tend to be anchored and "roll" less than other sites.

The angle of insertion of the needle varies depending on the depth of the vein being punctured. A shallow angle (30 to 45 degrees) should be used for small and superficial veins. A more obtuse angle

(60 degrees) should be used to access deeper veins. Very small and superficial veins should be entered at a very acute angle (15 to 30 degrees).

Fluid Flow Considerations

Both the diameter and the length of the infusion device affect the flow rate through the catheter. Viscous fluids (e.g., blood products and albumin) infuse more slowly than less viscous fluids (e.g., saline). These relationships can be seen in the solution of Poiseuille equation for ideal fluid flow through a cylindrical tube. The pressure gradient and resistance to flow is inversely proportional to the length of the catheter tubing. Flow rates decrease as catheter length increases. Using the shortest possible catheter permits the highest fluid infusion rates. Catheter diameter changes will have the most effect on flow rates. The flow rate increases to the fourth power as the catheter internal radius increases. Maximal flow rates result from using the largest bore or largest internal diameter (i.e., smallest gauge) catheter that will fit inside the vein. Large-bore venous catheters are preferred for high-volume infusions.

Venous Cannulation

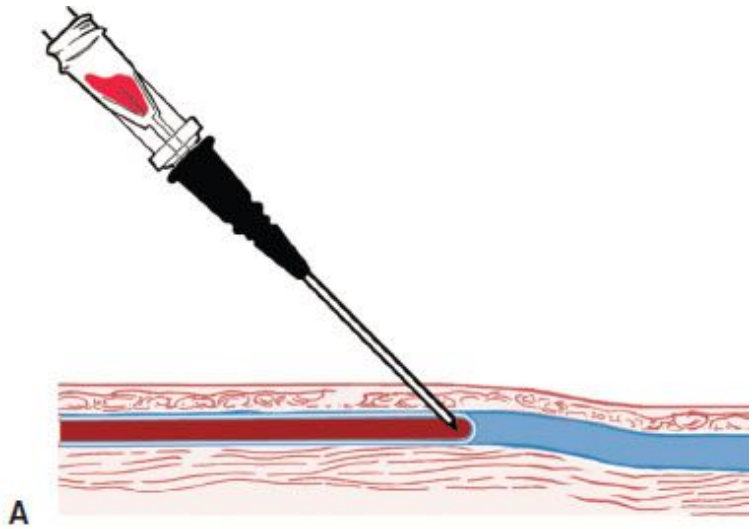
There are four main techniques of venous cannulation (2). The first is the needle-only technique using a butterfly-type needle. This method is seldom used today. The catheter-over-the-needle is the most commonly used technique for peripheral venous cannulation. The catheter-through-the-needle technique is occasionally used but not very popular. The Seldinger wire-guided technique is most commonly used for central venous access.

Identify the vein to be cannulated and the site of the skin puncture. Clean the area of any dirt and debris. Cleanse the skin with isopropyl alcohol, chlorhexidine, or povidone iodine. Apply a tourniquet to the extremity, proximal to the venous cannulation site, to engorge the vein. Additional engorgement of the vein can be accomplished by placing the extremity in a dependent position, “pumping” via muscle contractions of the extremity, and the

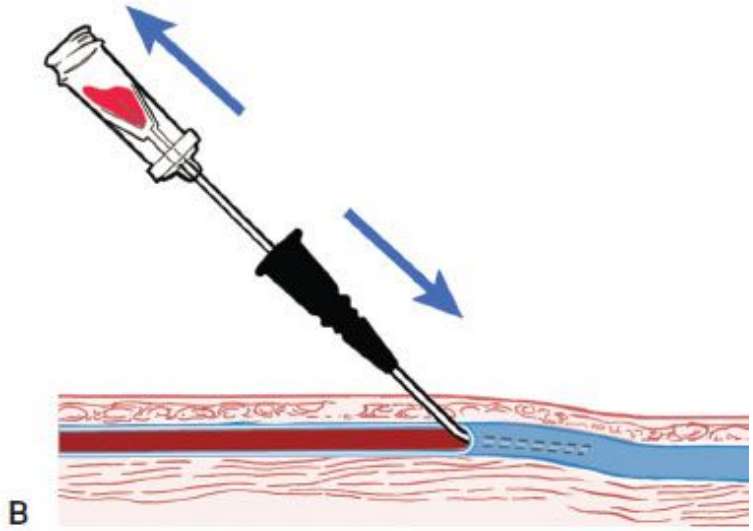
application of heat or nitroglycerin ointment over the vein. Optionally, a small subcutaneous wheal of local anesthetic solution may be placed at the skin puncture site to provide comfort to the patient.

The needle-only technique is used occasionally for short-term venous access in young children and elderly patients with fragile veins. This system is prone to malposition and infiltration. The tip of the needle can easily lacerate the vein if the needle is not secure and allowed to move. This technique is, therefore, recommended only for venous blood draws and not venous cannulation.

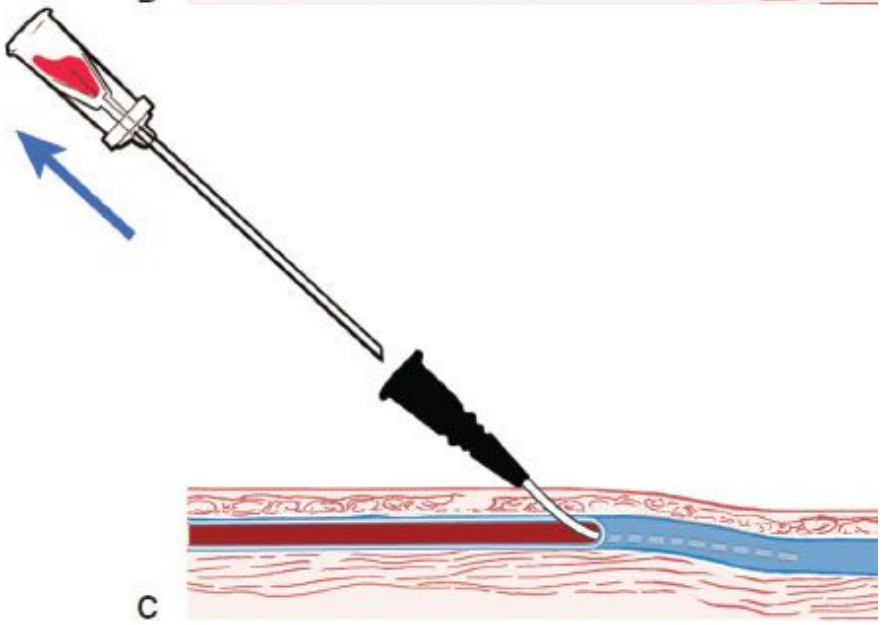
The catheter-over-the-needle systems are most commonly used for venous access (Fig. 5.1). The infusion catheter fits closely over a hypodermic needle. Placement of these catheters is usually quick and simple. Several considerations should always be kept in mind when using a catheter-over-the-needle. Intravascular placement is indicated by a flash of blood in the hub of the needle. If the patient's venous pressure is very low or if the needle is long and narrow, both sides of the vessel may be traversed (through and through) before the practitioner realizes that the needle was within the vein. If the tip of the needle is withdrawn from the vein, the catheter will not advance. If the catheter is advanced when the tip of the needle but not the catheter is within the vein, the catheter will not advance. The catheter will push the vein off the needle. Depressing the skin just distal to the puncture site and pulling it distally can prevent the vein from "rolling."



A



B



C

FIGURE 5.1 The catheter-over-the-needle technique. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

As opposed to the over-the-needle approach, the catheter-through-the-needle technique eliminates the need for a needle that is as long as the catheter and eliminates the possibility of pushing the vein off the end of the needle when the catheter is advanced (2). The main disadvantage of this technique is the possibility of the needle tip shearing off the catheter, resulting in a catheter embolism. This complication is prevented by using proper technique. Another disadvantage is an increased risk of hematoma formation because the needle used for venipuncture must be larger in diameter than the catheter.

The Seldinger technique allows for the placement of a catheter over a wire rather than directly over a needle. The wire used must be longer than the catheter. The needle used to insert the wire can be short and of a smaller gauge than the catheter. The Seldinger technique is most commonly used for central venous catheter insertion.

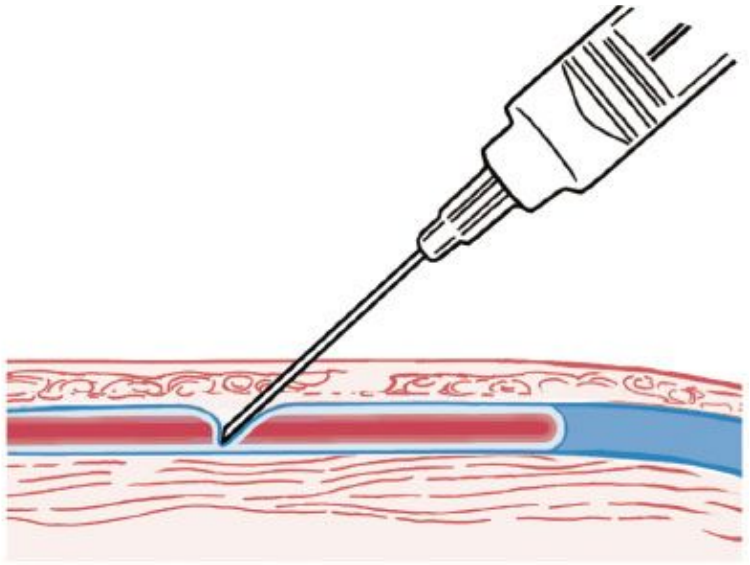
VENIPUNCTURE AND PERIPHERAL INTRAVENOUS ACCESS

The upper extremity is preferred to the lower extremity for vein cannulation (3). Distal placement should be attempted before moving more proximal (3). Avoid veins overlying a joint. These simple principles allow the patient maximum mobility and increase the chance of successfully cannulating a vein. It is easiest to insert a venous cannula where two tributaries merge and form a "Y." Choose a straight portion of vein without branches to minimize the chance of hitting valves within the vein and to make threading the catheter easier.

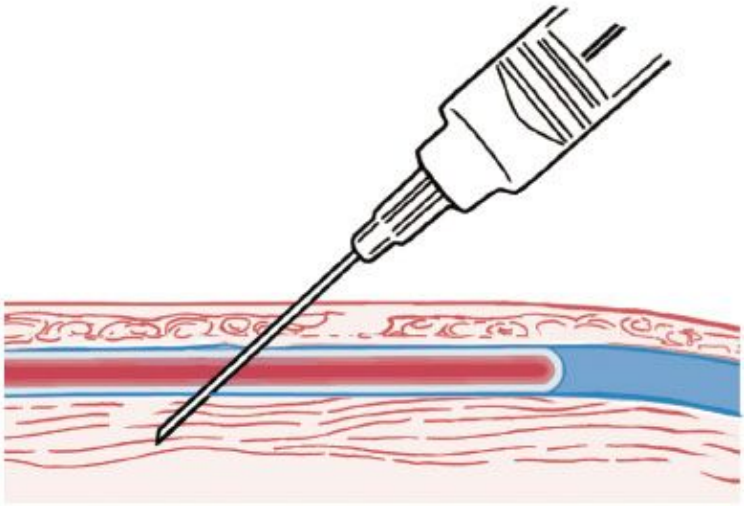
Peripheral Venipuncture

Stabilize the vein with the nondominant hand. Insert the needle attached to a syringe or vacuum tube adapter, with the bevel upward, into the vein at a 45- to 60-degree angle. Lower angles, at times nearly parallel to the skin, are often required to enter very narrow or superficial veins. Apply negative pressure to the syringe. A flashback of blood in the hub of the needle indicates that the tip of the needle is within the vein. Pulsatile blood indicates an arterial puncture. Unless venous blood is specifically needed for a test, collect the necessary samples before removing the needle. No additional harm will be done by withdrawing a blood sample from an artery that has already been punctured.

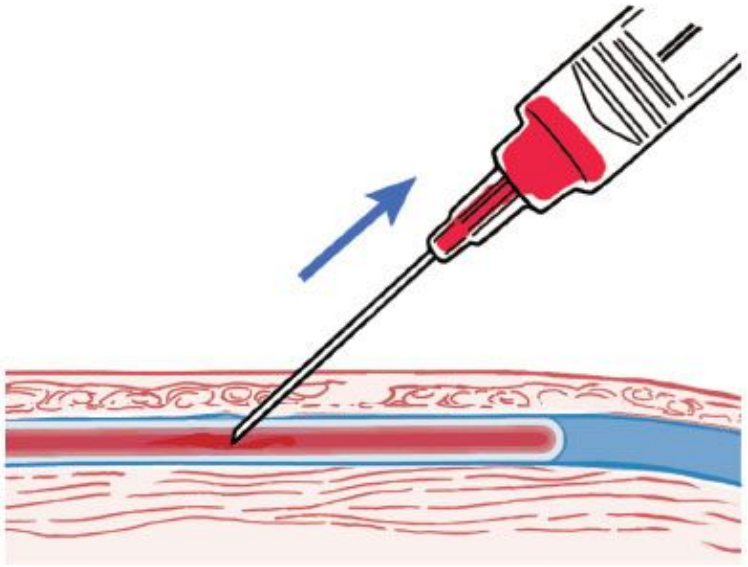
If no blood is obtained, slowly advance the needle until it is deeper than the judged depth of the vein. The tip of the needle can collapse the vein and prevent the flashback of blood (Fig. 5.2A). Slowly withdraw the needle to just beneath the skin. The vein will often have been punctured through-and-through (Fig. 5.2B). If this is the case, blood will flash back into the syringe as the needle is withdrawn (Fig. 5.2C). If no blood is obtained by the time the needle is withdrawn to just beneath the skin, redirect the needle, and make another attempt at puncturing the vein. Never sweep the point of the needle around without withdrawing it as the sharp bevel can lacerate nearby structures.



A



B



C

FIGURE 5.2 Through-and-through puncture of a vein. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Peripheral Intravenous Cannulation

Vein cannulation begins with a successful venipuncture (2). Insert the catheter-over-the-needle through the skin and into the vein (Fig. 5.1A). A flash of blood in the hub of the needle confirms that the tip of the needle is within the vein. Advance the catheter-over-the-needle an additional 2 to 3 mm to ensure that the catheter is within the vein. Securely hold the hub of the needle. Advance the catheter until its hub is against the skin (Fig. 5.1B). Withdraw the needle leaving the catheter in place (Fig. 5.1C). Apply pressure with the nondominant index finger over the catheter to prevent blood from exiting the catheter. Attach IV tubing to the catheter hub, and begin the infusion. Secure the catheter with tape.

A modified Seldinger technique (described later in this chapter) with a radial artery catheterization kit is very useful for deep brachial and external jugular venous catheterization (3). The depth of the deep brachial vein combined with overlying skin (which is often scarred from previous venous punctures) makes catheterization with the usual 1.25-in catheter difficult. The external jugular vein is quite mobile, and the overlying tissues are fairly tough. This combination can make threading an over-the-needle catheter into the vein, without pushing the vein off the end of the needle, quite difficult.

Pediatric Considerations

Venipuncture and peripheral venous access can be quite a challenge in the infant and small child (3). Proper restraint of the extremity will greatly aid the process. Aside from the techniques discussed above, there are a few techniques that can aid pediatric vascular access. The scalp veins can be used for venous access in newborns. Scalp veins are most easily cannulated with a small (23- to 25-gauge) butterfly needle or catheter. A rubber band can be placed about the

baby's head as a tourniquet. Other veins commonly used include those of the antecubital fossa, dorsal hand, dorsal foot, the external jugular vein, and the saphenous vein at the knee or groin. For small and superficial veins, place a small bend at the hub of the catheter-over-the-needle assembly. This bend provides a less-acute angle and easier entry into the vein. The best guide to the gauge (diameter) of catheter to use is to compare the catheter to the vein. The catheter should be at least slightly smaller than the vein. In practice, the smallest readily available catheters are 24 gauge. Keeping a peripheral IV line from being pulled out by an active toddler is quite a challenge. Each institution has its own "recipe" for securing pediatric IVs including taping securely, covering the catheter with a cut plastic medicine cup, and covering the whole assembly with a gauze roll or stockinette.

Assessment

The IV line should flush easily. Any infusions should flow by gravity alone. Progressive swelling at the catheterization site indicates a hematoma formation or extravasation of infused fluids. Peripheral infusions of vasopressors, IV contrast, and caustic solutions require the skin puncture site to be assessed frequently and carefully as extravasation may lead to extensive local soft tissue necrosis. Pain at the IV access site must be taken seriously and should prompt a search for the cause.

Complications

The main complications of venipuncture are pain and hematoma formation. Other complications include nerve injury and usually reversible paresthesias. Infection is uncommon from simple venous sampling. In addition to these complications, venous catheters have additional risks. IV catheters increase the risk of superficial venous thrombosis and thrombophlebitis. It is possible to injure a number of structures in the neck or cause a pneumothorax during external jugular vein cannulation with inadvertent deep penetration. Extravasation of some IV solutions can cause local skin necrosis.

Extravasation of large volumes into a muscle compartment can lead to a compartment syndrome, although this is rare with superficial peripheral venous lines. Infections can often be prevented by using aseptic technique, using sterile dressings, and changing peripheral catheters every 48 to 72 hours. The rare complications of peripheral nerve palsies, pressure necrosis, and compromised peripheral circulation do occasionally occur. Complications can be prevented by making frequent neurovascular checks to any restrained extremity, padding all pressure points, and avoiding the placement of circumferential tape on an extremity.

CENTRAL VENOUS ACCESS

Percutaneous cannulation of the central veins is an essential technique for both long-term and emergent medical care (4). Access to the major veins of the torso allows rapid high-volume fluid resuscitation, administration of concentrated ionic and nutritional solutions, and hemodynamic measurements. The right internal jugular vein is generally preferred to the left internal jugular vein as the site of central venous cannulation. The right internal jugular vein provides a nearly straight and direct route to the superior vena cava. The dome of the right lung is somewhat lower than that of the left lung and thus decreases the chance of a pneumothorax during catheter placement. The thoracic duct is relatively large and lies high in the left chest. These anatomic considerations favor the right internal jugular approach to central venous cannulation to minimize complications.

The internal jugular route is acceptable for central venous access in most cases. This route allows ready access to the superior vena cava for long-term central venous access, caustic or concentrated infusions, and central venous pressure monitoring. Pulmonary artery catheters and transvenous pacing wires can be introduced through the right internal jugular vein. The internal jugular vein is accessible without terminating cardiopulmonary resuscitation (CPR) efforts, although chest compressions and the lack of carotid pulsations make accessing it difficult. The risk of a pneumothorax is probably less with the internal jugular vein cannulation as opposed to the

subclavian vein route, although patient mobility is less and discomfort is greater. In a coagulopathic patient, the internal jugular vein puncture site is compressible, but hematoma formation may lead to compromise of the airway.

The subclavian vein is the preferred route for longer-term central venous access. This site allows for ambulation (unlike a femoral line) and neck movement without discomfort (unlike a jugular line). The catheter is concealable under clothing, making outpatient use more acceptable.

The femoral vein is often the preferred route for emergency central venous cannulation in many patients. The femoral vein is not a suitable route for ambulatory patients beyond the initial resuscitation and stabilization period. Femoral venous access is relatively easy during CPR and often does not require the cessation of chest compressions. The femoral vein is easily compressible. This makes it preferable to the subclavian vein in coagulopathic patients or those undergoing thrombolysis, although peripheral access would be preferred in these cases. A femoral vein central line should be changed as soon as possible to another site because of the increased rates of infection compared to other locations.

Internal Jugular Vein

Central Approach

Place the patient in the Trendelenburg position with their head down 15 to 30 degrees. Rotate the patient's head away from the side that will be cannulated. Excessive rotation will distort the anatomic landmarks and may bring the internal jugular vein closer to the carotid artery.

Insert the needle at a 30- to 60-degree angle at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle (Fig. 5.3). Direct the needle toward the ipsilateral nipple. Shallower angles cause a greater amount of subcutaneous tissues and structures to be traversed before entering the vessel but are generally necessary in children whose

vessels are smaller. Steeper angles make insertion of the catheter over the guidewire difficult as the guidewire tends to kink.

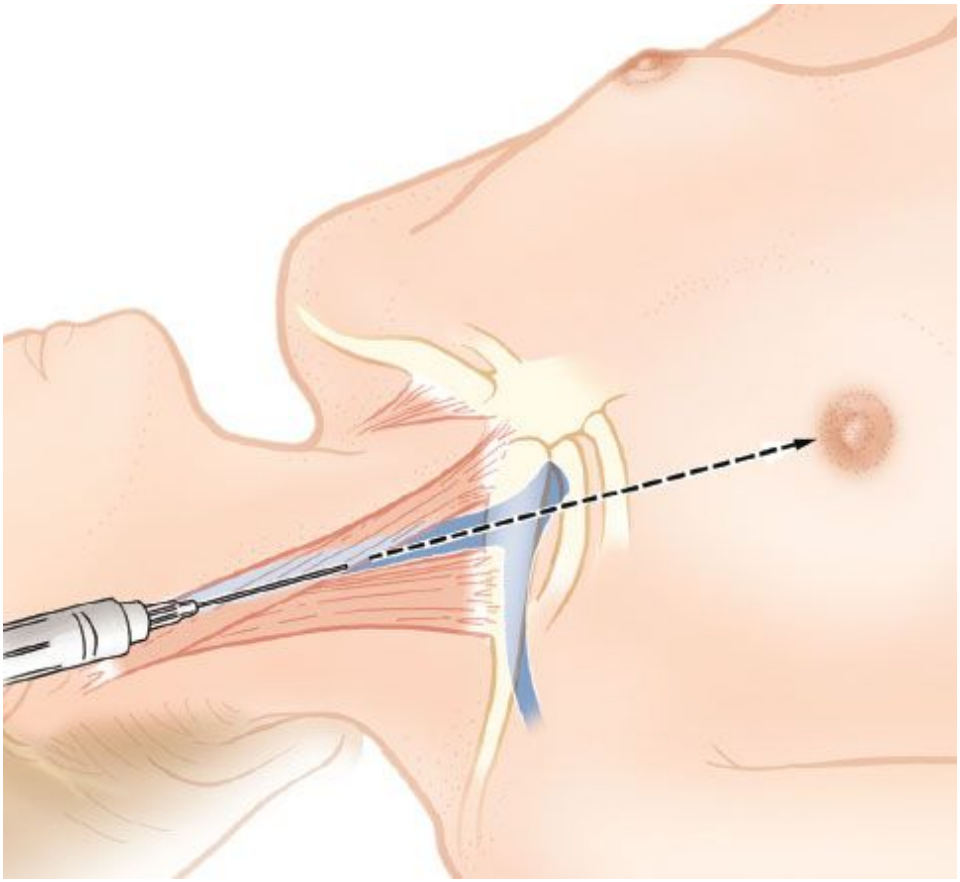


FIGURE 5.3 Central approach to the right internal jugular vein. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Anterior Approach

The skin puncture site is at the anterior border of the sternal head of the sternocleidomastoid muscle, just lateral to the carotid artery (Fig. 5.4). Enter the skin at a 45- to 60-degree angle. Direct the needle toward the ipsilateral nipple. The internal jugular vein should be encountered within 3 to 5 cm in an adult. If the vein is not encountered by 5 cm, withdraw the tip of the needle to the subcutaneous space, and redirect it slightly medially.

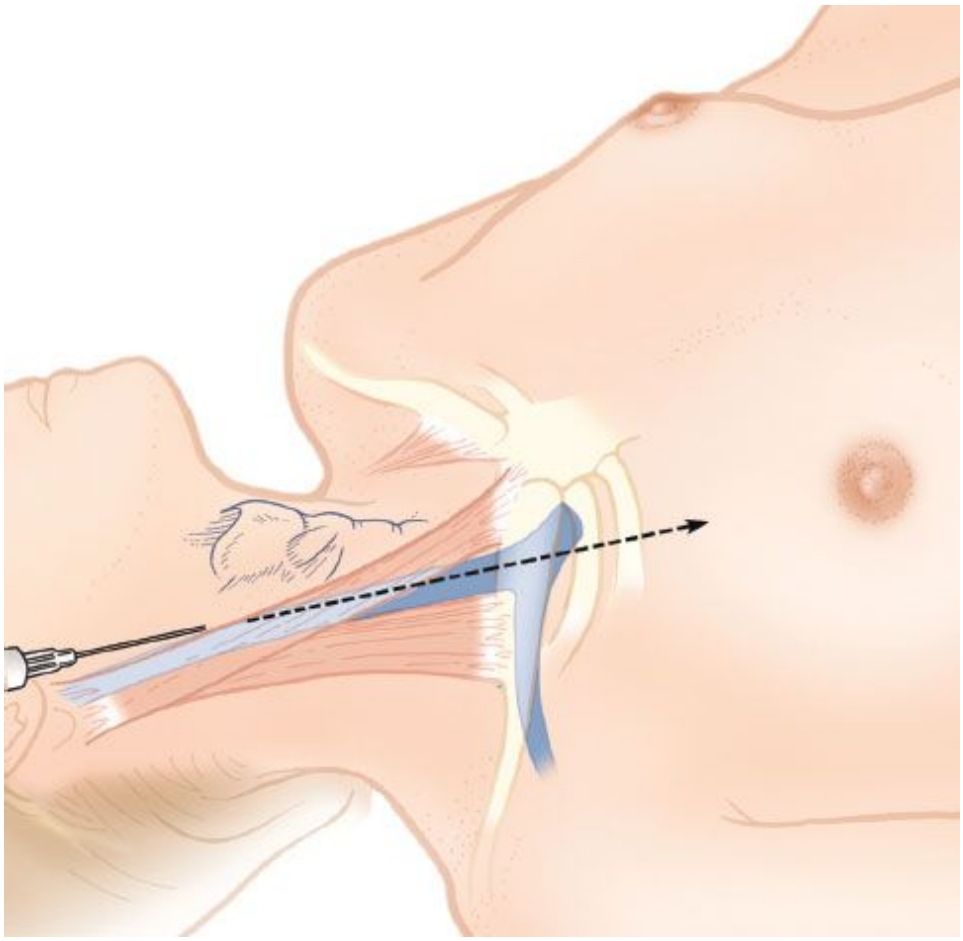

FIGURE 5.4 Anterior approach to the right internal jugular vein. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Posterior Approach

Enter the skin at the posterior edge of the sternocleidomastoid muscle, one-third of the way from the clavicle to the mastoid process (Fig. 5.5). Alternatively, the point where the external jugular vein crosses the lateral border of the sternocleidomastoid muscle can be used. Direct the needle under the muscle at a 30- to 45-degree angle to the skin toward the sternal notch. Place the index finger of the nondominant hand in the sternal notch to provide a landmark with the patient draped. The internal jugular vein should be encountered within 5 cm in an adult. This approach is not recommended in children.

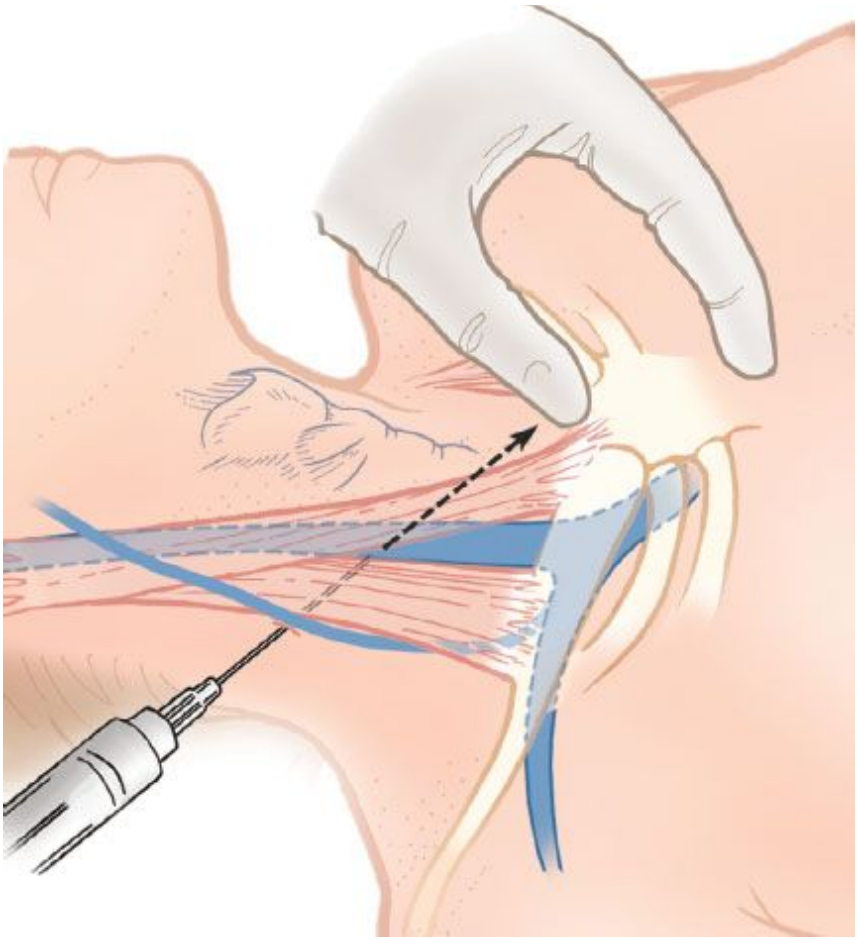

FIGURE 5.5 Posterior approach to the right internal jugular vein. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Subclavian Vein

Infraclavicular Approach

The infraclavicular approach to the subclavian vein is most commonly used. This technique is easier to perform and less likely to result in a pneumothorax than the supraclavicular approach. Several different skin entry sites have been described (4). Some clinicians feel that the preferred entry site is 1 cm caudal to the junction of the medial third and middle third of the clavicle. The subclavian vein lies just posterior to the clavicle at this site. Direct the needle just superior and posterior to the suprasternal notch while staying as close to the frontal (coronal) plane as possible. The needle and

syringe should be parallel to the bed (Fig. 5.6A,B). Placing the nondominant index finger in the sternal notch will help to guide placement (Fig. 5.6A).

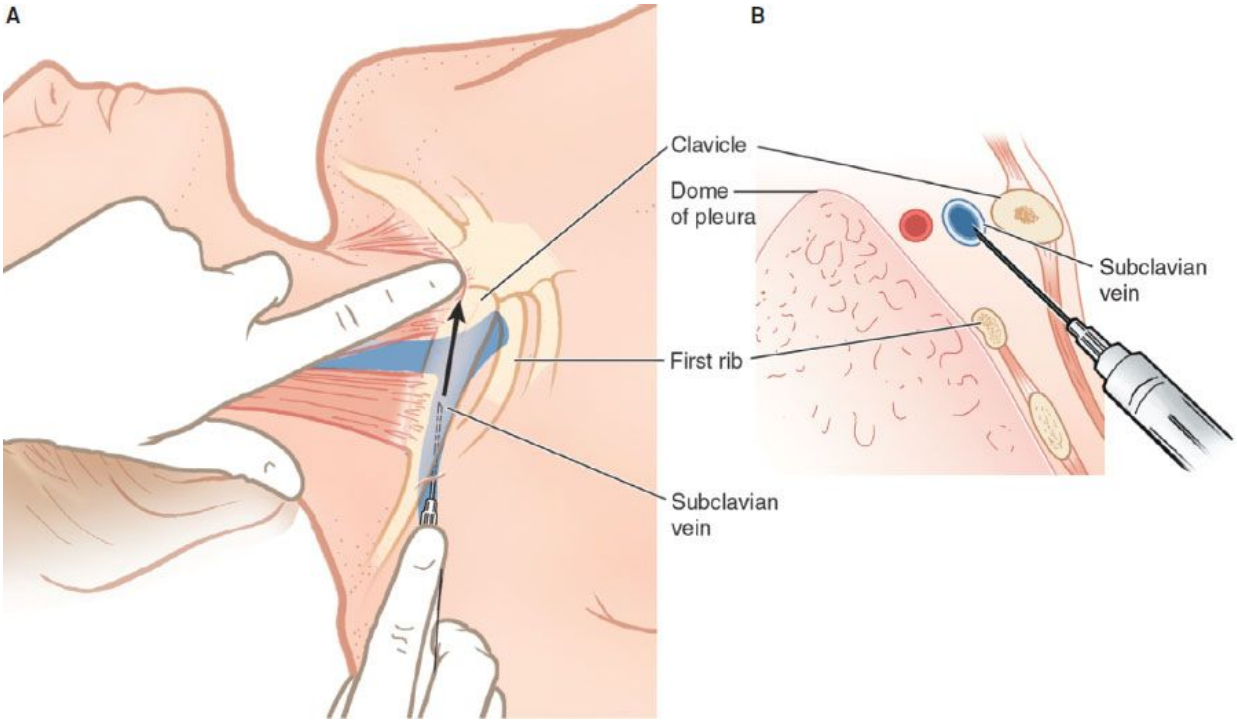

FIGURE 5.6 Infraclavicular approach to subclavian vein cannulation. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Some practitioners prefer to enter the skin inferior to the clavicle at the deltopectoral groove, or the point just lateral to the midclavicular line along the inferior surface of the clavicle. This is the point where the skin may be maximally depressed. Direct the needle parallel to the bed and toward the sternal notch. This entry site may make it easier to keep the needle in the coronal plane. The distance before entering the subclavian vein is longer than in the preceding approach, and the protection offered by the first rib is lost.

An additional alternative landmark exists. Palpate the bony tubercle, or protrusion, on the inferior surface of the clavicle and approximately one-third to one-half the length of the clavicle from the sternoclavicular joint. The advantage of this site is that it is a definitive landmark and avoids approximating distances as described

for the other sites previously described. The needle is inserted parallel to the bed and aimed just posterior to the sternal notch.

Supraclavicular Approach

Although most practitioners are more comfortable with the infraclavicular approach to the subclavian vein, the supraclavicular approach offers some advantages (4). These advantages include the subclavian vein being closer to the skin, the route from a right-sided skin puncture site to the superior vena cava being more direct, the procedure avoiding the hazards of a left-sided puncture (i.e., the thoracic duct), and the skin entry site being more accessible during CPR. The complication rate for the supraclavicular approach is probably lower than that for the infraclavicular approach with an experienced clinician.

The skin is entered at a point 1 cm lateral to the lateral border of the clavicular head of the sternocleidomastoid muscle and 1 cm superior to the clavicle (Fig. 5.7A,B). The needle should bisect the angle formed by the clavicle and the lateral border of the sternocleidomastoid muscle (Fig. 5.7A). Direct the needle toward the contralateral nipple or a point just superior and posterior to the sternal notch. Orient the needle bevel medially. The subclavian vein should be entered within 2 to 3 cm in an adult. The length of catheter inserted will be a few centimeters less than that for the infraclavicular approach.

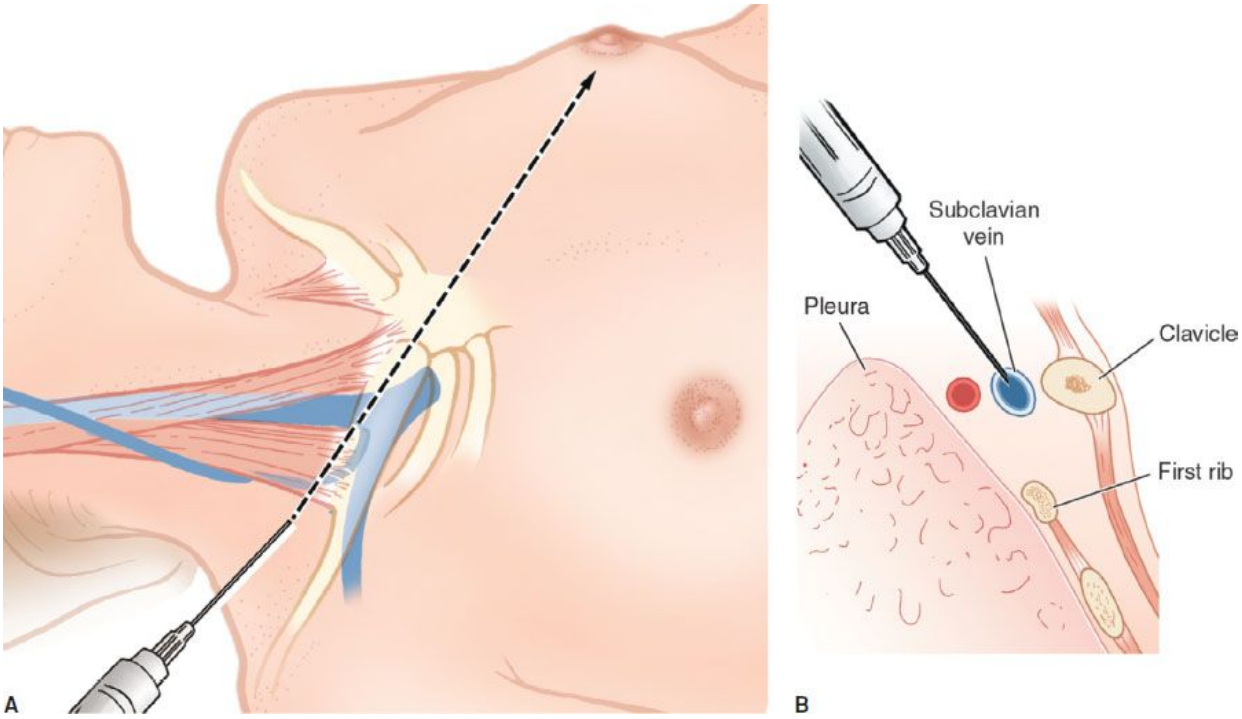

FIGURE 5.7 Supraclavicular approach to subclavian vein cannulation. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Alternative skin entry sites and approaches have been described. Enter the skin 1 cm medially and 1 cm superiorly to the midpoint of the clavicle with the needle directed toward the ipsilateral sternoclavicular joint. The skin can be entered just posterior to the clavicle, at the junction of the medial third and middle third of the clavicle, with the needle directed toward the ipsilateral sternoclavicular joint and parallel to the coronal plane. This last approach is probably the simplest, although the study cited was performed on cadavers rather than live patients.

Femoral Vein Catheterization

Premeasuring from the insertion site to the xiphoid process will give the maximum catheter insertion depth. The needle should enter the skin 2 to 4 cm inferior to the midpoint of the inguinal ligament and 1 cm medial to the femoral artery pulse (Fig. 5.8). The needle should

enter the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 cm medial to the femoral artery pulse in an infant or young child.

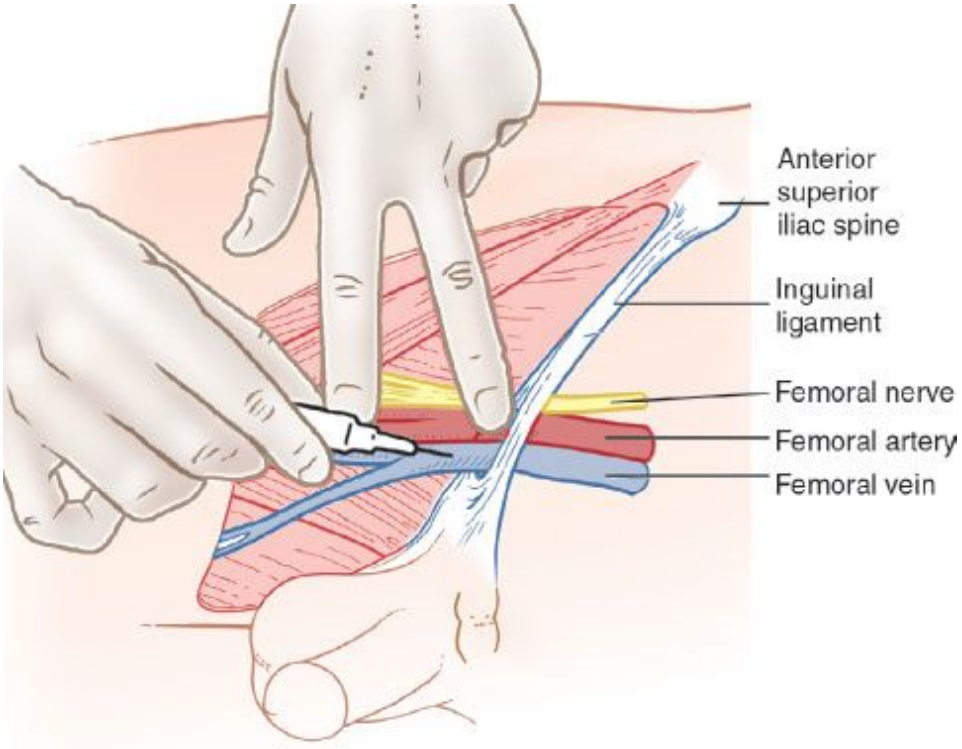

FIGURE 5.8 Femoral vein cannulation. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Two site-specific considerations deserve mention. The use of a "finder" needle is unnecessary because there are no vital structures in the area other than the femoral artery that is compressible if it is punctured. The introducer needle is directed at a 45- to 60-degree angle to the skin and parallel to the long axis of the thigh. Shallower angles may be necessary in very small and thin patients. Use caution to avoid puncturing the posterior wall of the vein above the inguinal ligament because this can result in a retroperitoneal hemorrhage.

Seldinger Technique

There are numerous anatomic approaches to obtain central venous access (4). This includes three approaches to the internal jugular vein, two approaches to the subclavian vein, and one approach to the

femoral vein. A more detailed discussion of the anatomy and approaches can be found elsewhere (1,4). Regardless of the approach, the Seldinger technique is the preferred method.

Clean, prep, and drape the area. Position the patient based on which central vein is to be accessed. Several cardinal rules for the insertion of the catheter should be observed. Always occlude the open hub of a needle or catheter in a central vein to prevent an air embolism. Never let go of the guidewire to prevent its embolization into the central venous circulation. Never apply excessive force to the guidewire on insertion or removal if resistance is met. Doing so may injure the vessel, break the guidewire, or embolize a piece of the guidewire.

Attach the thin-walled needle to a 5-mL syringe containing 1 mL of sterile saline. Insert the needle while applying negative pressure to the syringe by withdrawing the plunger. Advance the needle into the vein (Fig. 5.9A). If the vein is not located within 3 to 5 cm, stop advancing the needle. Withdraw the needle slowly while continuing to aspirate. Often, the vessel will have been completely traversed upon insertion, and blood will flash back into the syringe as the needle is withdrawn. Stabilize and hold the needle perfectly still with the nondominant hand once blood returns in the syringe. Remove the syringe. Occlude the open hub of the needle with the thumb of the nondominant hand while keeping the small finger of the hand in contact with the patient’s skin.

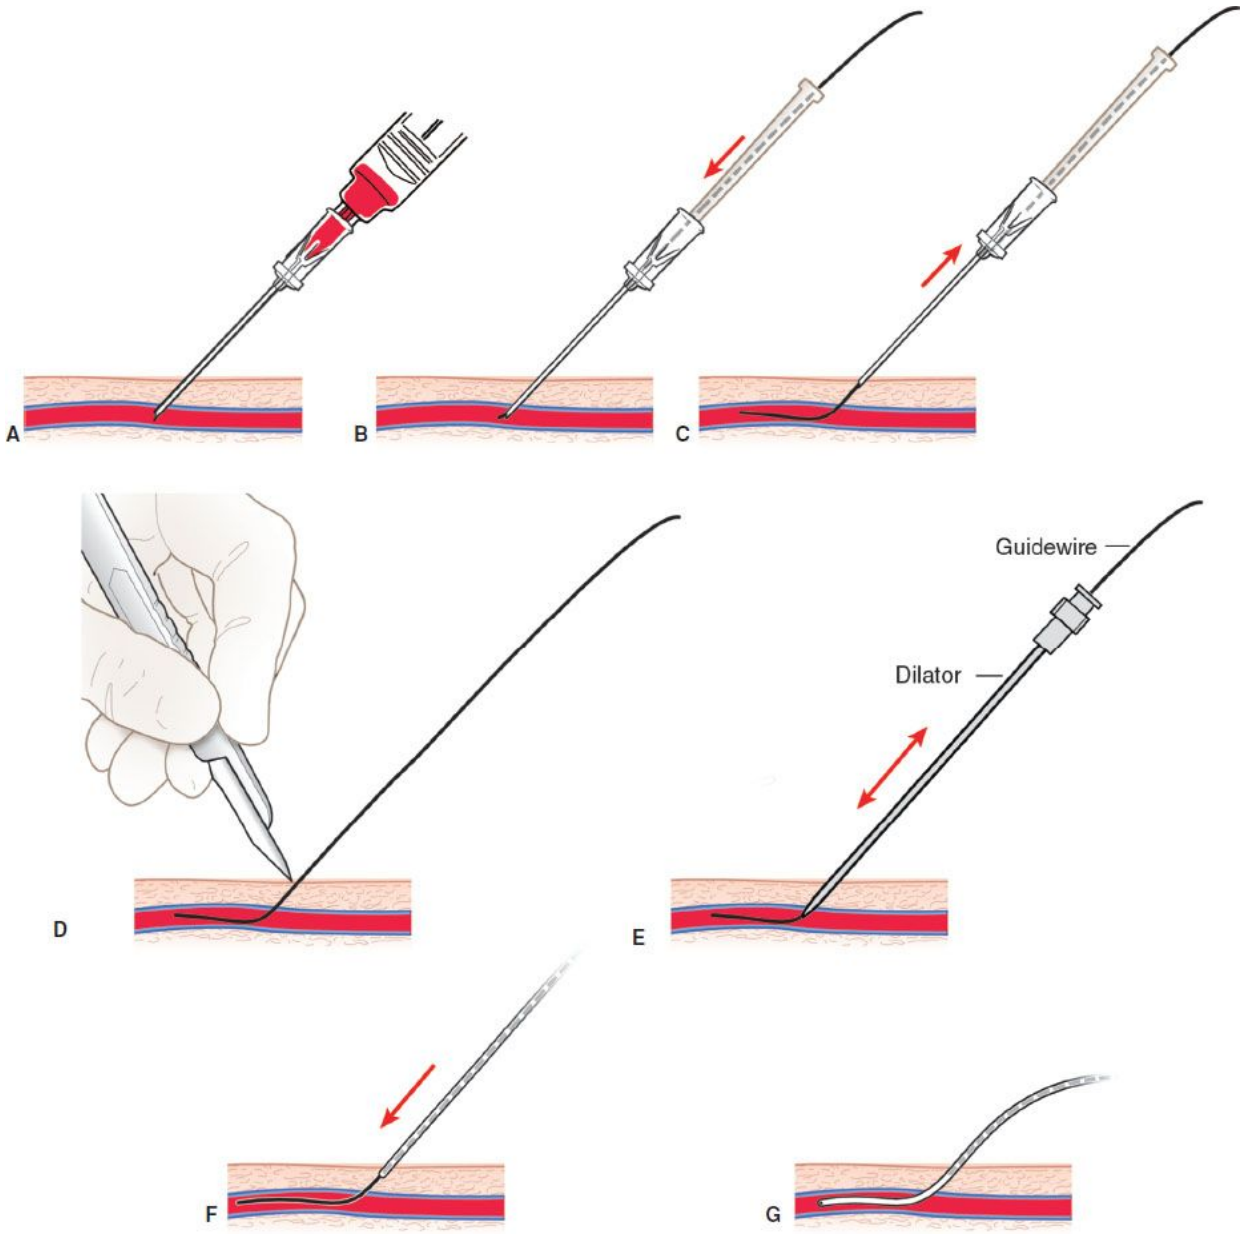

FIGURE 5.9 The Seldinger technique for central venous access. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Grasp the guidewire and its sleeve with the dominant hand. Slide the sleeve forward to straighten out the "J" of the guidewire. Insert the wire sleeve into the hub of the needle (Fig. 5.9B). Advance the guidewire through the needle and into the vein (Fig. 5.9B). The guidewire should advance easily into the vein. Withdraw the needle and guidewire sleeve over the guidewire while securely holding the

guidewire (Fig. 5.9C). Grasp the guidewire with the nondominant hand as soon as the guidewire is visible between the tip of the needle and the skin.

Make a small incision in the skin adjacent to the guidewire using a no.11 scalpel blade (Fig. 5.9D). Place the dilator over the guidewire, and advance it into the vein (Fig. 5.9E). Continue to advance the dilator until its hub is against the skin. Do not release hold of the guidewire at any time. Remove the dilator over the guidewire. Place the catheter tip over the guidewire. Advance the catheter over the guidewire and into the vein to the desired depth (Fig. 5.9F). The depth is typically 10 to 15 cm for the internal jugular or subclavian approaches, or completely to the hub for femoral central venous lines. Securely hold the catheter in place, and remove the guidewire (Fig. 5.9G). Occlude the open catheter lumen with a sterile-gloved finger to prevent air embolization and excessive blood loss.

Attach a syringe to the catheter hub, and aspirate blood to confirm that the catheter is within the vein. Withdraw any necessary blood samples. Attach infusion tubing or a cap to the port, and flush the catheter to prevent a blood clot from obstructing the lumen. Securely attach the catheter to the skin with nylon or silk sutures. Cover the skin puncture site with a sterile dressing. Obtain a chest radiograph to evaluate for central line placement complications such as a pneumothorax, hemothorax, hematoma, and/or line malpositioning.

Pediatric Considerations

The anterior or central approach to the internal jugular vein is preferred for children. Appropriate catheter sizes and lengths are shown elsewhere (4). The child must be sedated and immobilized prior to attempts at cannulation of the internal jugular or subclavian vein.

The femoral vein is the vein of choice if central venous access is needed in a combative child who cannot be completely restrained. The patient need not be in Trendelenburg position, the consequences of a misdirected needle are less severe, and the procedure is less threatening as the face is not draped. A shallower angle of skin entry is necessary to access the femoral vein compared to an adult. Enter

the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 mm medial to the femoral artery.

Assessment

Examine the patient after central line placement. Examine the lung fields carefully to exclude a significant pneumothorax. Vital signs should be rechecked. Obtain a portable anteroposterior chest radiograph to verify line tip placement in the superior vena cava and to rule out a procedural-related pneumothorax. Check the catheter site for hematoma formation or hemorrhage along the dilated catheter track. Control any hemorrhage with direct pressure. Check the function of the catheter by aspiration and infusion through all ports.

Most femoral vein catheters can be fully inserted. Premeasurement is recommended to make sure that the catheter tip will not reach the right atrium. If there is any doubt about the catheter position, postinsertion abdominal and chest radiographs should be obtained. The tip of the catheter must be at or below the xiphoid process of the sternum. Reassess the lower extremity distal to the catheter to determine any change in the neurovascular status after line placement.

Removal of the Central Venous Catheter

Place the patient in the Trendelenburg position when removing a central venous catheter from the internal jugular or subclavian vein. Place the patient supine to remove a femoral vein catheter. Remove the dressing overlying the skin puncture site. Cut the suture securing the catheter to the skin. Ask the patient to exhale and hold their breath. Briskly remove the catheter, and cover the puncture site with a gauze dressing. Apply an occlusive dressing to the site for the first 1 to 2 days after the catheter has been removed if the catheter had a large diameter or had been in place for more than 2 to 3 days. The skin puncture site should be observed for signs of infection twice a day for 48 hours.

Complications

Complications associated with central venous access are numerous. The internal jugular and subclavian access has a myriad of potential complications (1,4). These complications include infection, vessel laceration, catheter malposition, pneumothorax, hemothorax, chylothorax, carotid artery puncture, stroke, airway compromise, air embolism, cardiac dysrhythmias, cardiac puncture, pericardial tamponade, and death. The guidewire can become entrapped, necessitating surgical or interventional radiology removal. Thrombosis of the catheter or vein may lead to pulmonary embolism. Infection may result in septic emboli or endocarditis. Complications during catheterization occur in proportion to the operator's inexperience (6). If the patient is unlikely to survive complications, the most experienced person available should perform the procedure.

Deep venous thrombosis of the femoral and more distal veins is a recognized complication of femoral venous lines. Inadvertent cannulation of the femoral artery may occur. This is particularly true during an episode of severe hypotension or cardiac arrest during central venous line placement. If intra-arterial placement is unrecognized, infusion of vasopressors into the artery may result in ischemic injury to the distal limb.

ULTRASOUND GUIDANCE FOR VASCULAR ACCESS

Ultrasound is a very useful tool to assist with peripheral or central vascular access, whether arterial or venous (8). Ultrasound can provide direct visualization of vessel cannulation, which can reduce the number of attempts and minimize complications. Although somewhat controversial because most community-based EDs do not yet have ultrasound capabilities, it is likely to emerge as the standard of care in the near future.

There are both static and dynamic ultrasonographic methods to assist in vascular access. The static method uses ultrasound to identify the vessel to be cannulated, but ultrasound is not used during the actual puncture. Rather, ultrasound is used to identify the vessel's location. A mark is made on the skin above the vessel. The

ultrasound probe is then slid 0.5 to 1 cm along the course of the vessel, and a second mark on the skin is made. This mark provides the direction of needle entry. An estimation of the angle required to reach the vessel can be determined by evaluating its depth. This technique allows the operator to remove the probe from the field and have both hands free to perform the procedure. The dynamic method uses ultrasound to visualize the puncture of the vessel in real time.

A high-frequency (5 to 10 MHz) linear probe should be used when attempting vascular access. High-frequency probes sacrifice tissue penetration for increased resolution. High-frequency probes provide better resolution at shallow depths and thus a better picture of superficial tissue. This resolution is important when visualizing vascular structures that are generally small and superficial.

The operator can place the vessel in the center of the screen and maximize its size by adjusting the depth (Fig. 5.10). Using the centimeter scale that is usually at the side of the screen, the operator can gauge the degree to which a needle should be inserted to enter the vessel based on the distance of the insertion site to the probe and the distance from the probe to the vessel (Fig. 5.11).

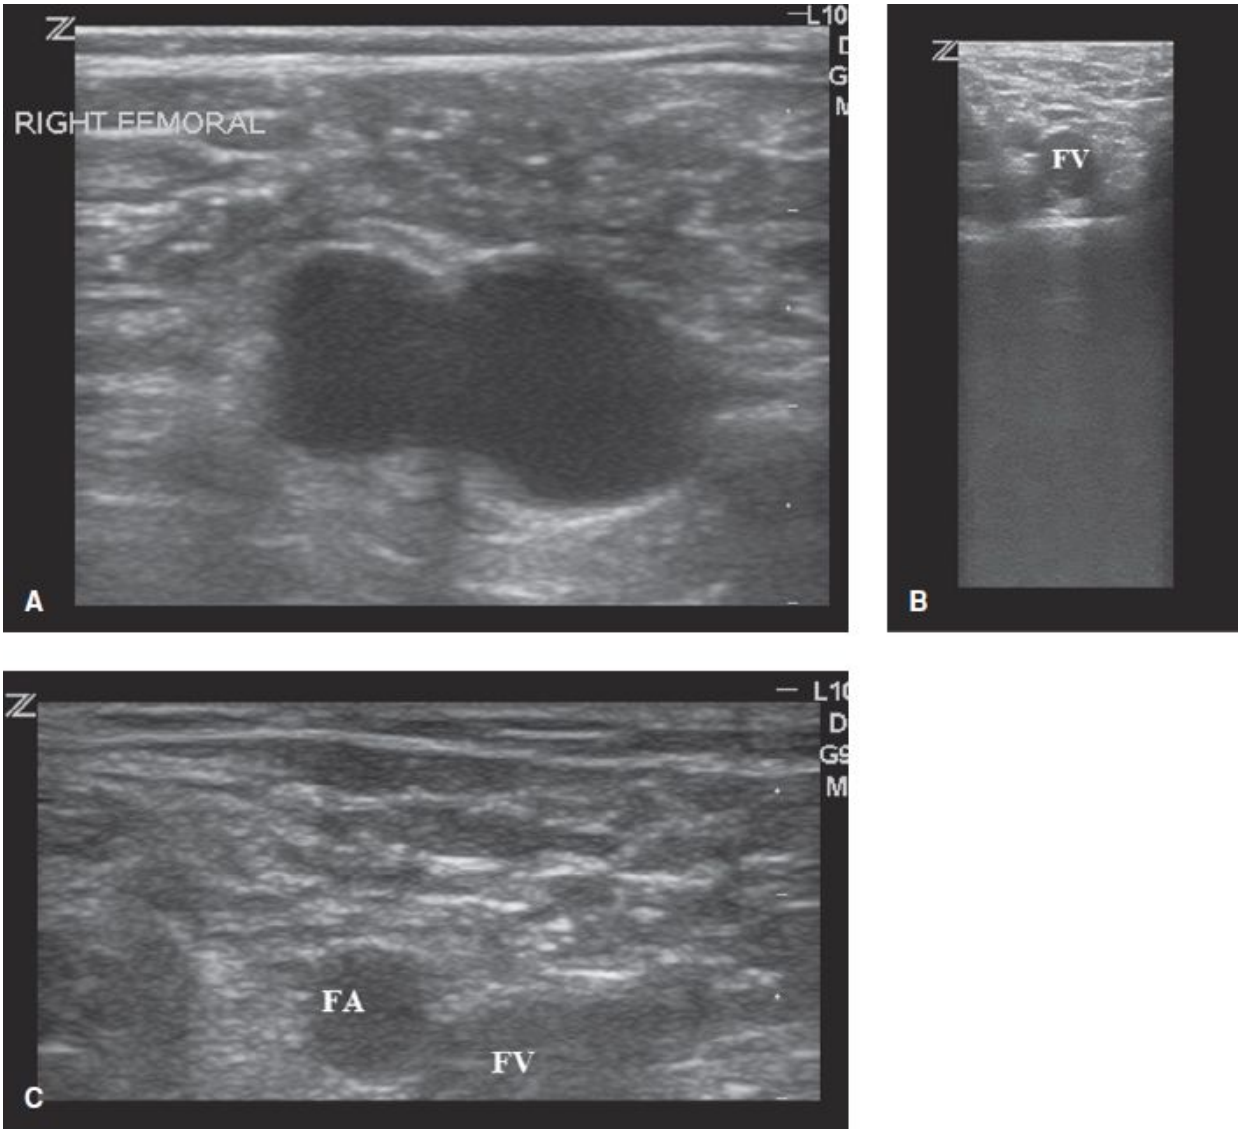

FIGURE 5.10 Ultrasound field of depth. **A:** Appropriate depth. **B:** Inappropriate settings of depth. Deep depth is not required and results in a small image on the ultrasound machine screen. **C:** Inappropriate depth setting as vascular structures should be completely visible and in the center of the screen. FA, femoral artery; FV, femoral vein.

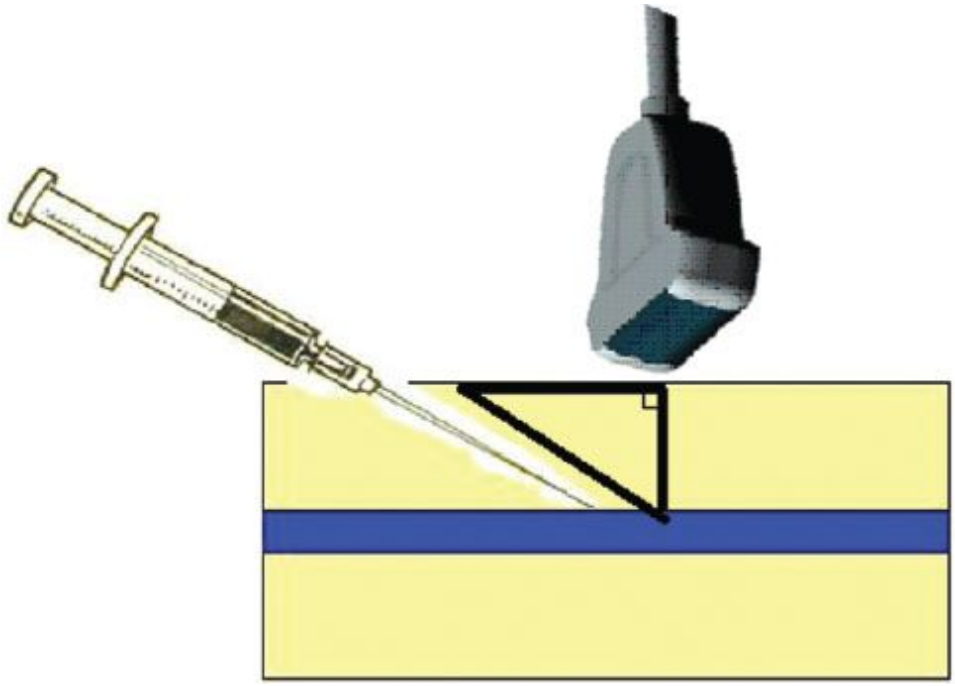

FIGURE 5.11 Estimation of needle insertion angle and depth.

Before beginning the procedure, one must always ensure that the catheter chosen is of sufficient length to penetrate the soft tissues and enter the target vessel.

Basic Principles

Ultrasound requires a gel between the probe and the skin surface to transmit the acoustic signals. Most commercially available gels are good transmitters but are not sterile. When using ultrasound for vascular access, the probe should be placed inside a commercially available probe cover or sterile glove with transducer gel inside the cover or glove and with sterile gel between the probe cover and the skin to maintain a sterile environment and protect the probe from contamination.

Long-Axis Approach

This approach allows the operator to see the length of the needle enter the vessel as well as to appreciate the angle of insertion and length of catheter required to adequately cannulate the vessel. Place the probe on the site determined by anatomic landmarks with the

probe marker toward the patient's head and perpendicular to the patient's skin (Fig. 5.12A). Locate the long-axis view of a fluid-filled (black) vessel (Fig. 5.12B). Adjust the depth to maximize the size of the vessel, and position the vessel in the center of the ultrasound machine screen. Adjust the gain as previously described.

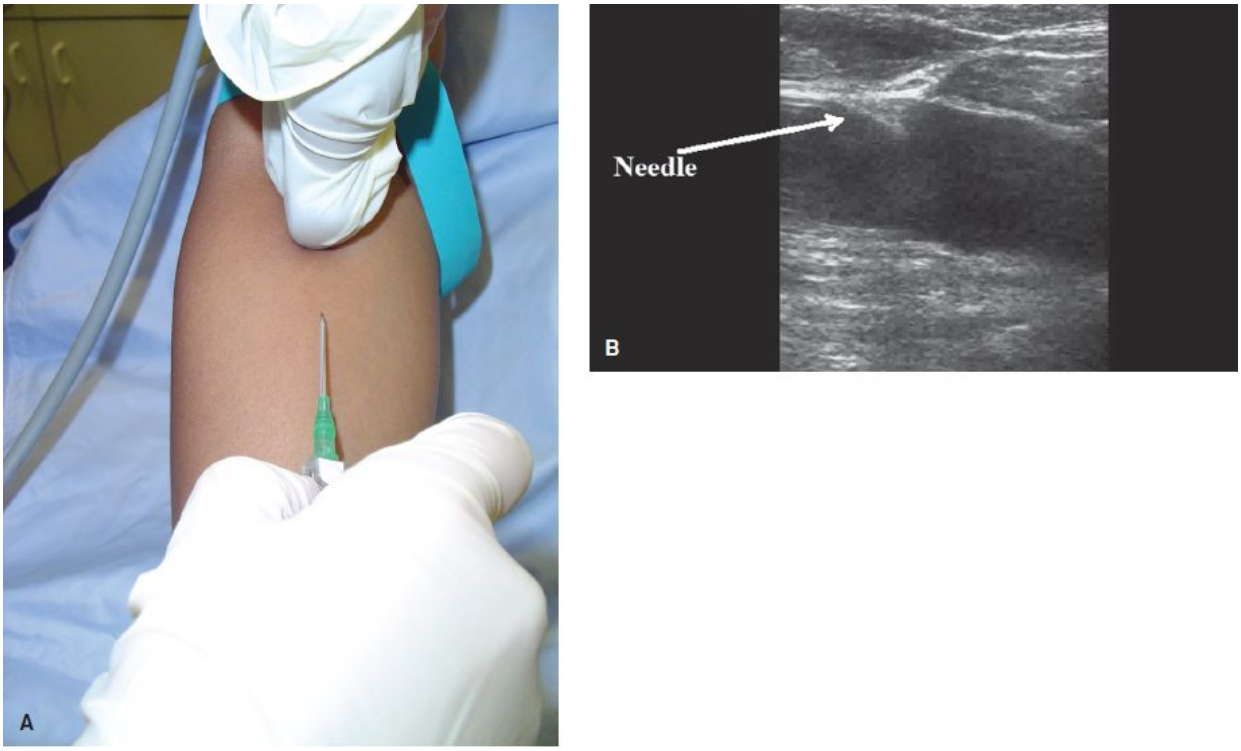

FIGURE 5.12 Long-axis approach. **A:** Probe marker toward patient's head. **B:** Needle entry into the vessel.

To determine if the vessel is arterial or venous, apply downward pressure on the area. Venous structures should be fully compressible, except in the setting of a thrombus. Arterial structures will not be fully compressible and should be pulsatile. Slide the probe several millimeters medially and laterally to locate the paired vessels (artery and vein), and determine which is the artery and which is the vein. Once the operator is certain of the vessel to be cannulated, enter the skin with the needle aligned directly with the long axis of the probe (Fig. 5.12A), and observe as the needle enters the vessel. The needle will appear as a bright white linear object as it travels through the

tissue below the probe. There may be a degree of tenting of the vessel as the needle enters (Fig. 5.12B).

Short-Axis Approach

This approach allows visualization of both the artery and the vein on the ultrasound machine screen. Place the probe on the site determined by anatomic landmarks with the probe marker toward the operator's left, perpendicular to the patient's skin (Fig. 5.13A). Locate the short-axis view of the fluid-filled (black) vessels. Adjust the depth to maximize the size of the vessels, and position them in the center of the ultrasound machine screen. Identify the artery and vein by applying vertical pressure to the area as described previously. The operator may see the needle tip on the screen as a bright white dot that casts a shadow (Fig. 5.13B). Distortion of the soft tissues as the needle passes or tenting of the vessel wall just before the vessel is entered may sometimes be the only signs seen.

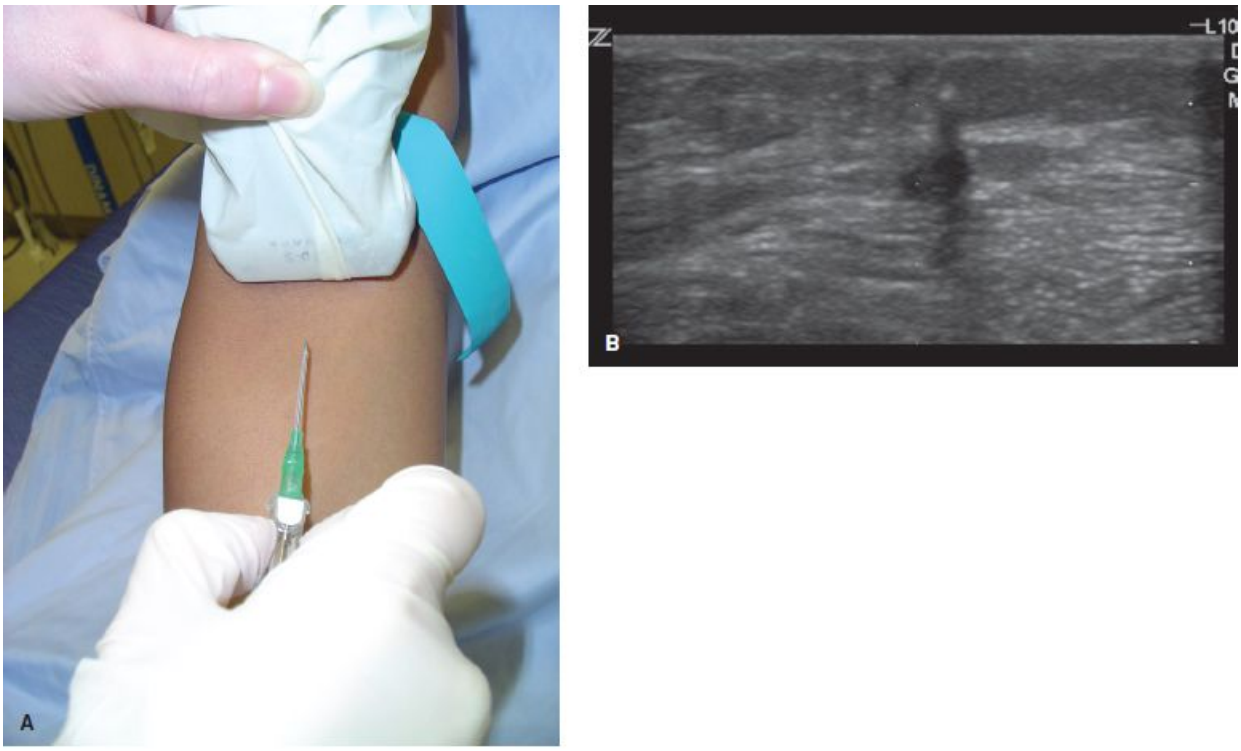

FIGURE 5.13 Short-axis approach. **A:** Probe marker toward operator's left. **B:** Needle entry into the vessel with shadowing and tenting of the vessel wall visible.

It is important to remember that the probe should be in a position to visualize the point of entry of the needle into the vessel and not so close to the skin insertion site that the operator only sees a point of passage of the needle through soft tissue, which means the needle tip is actually passing out of the view on the ultrasound machine screen. If the first attempt is unsuccessful and the needle needs to be repositioned, withdraw it to just below the surface of the skin before redirecting it toward the vessel. If the probe marker is to the operator's left and the ultrasound machine screen marker is also to the left, by directing the needle to the left it will move appropriately on the screen.

The use of color Doppler to help distinguish an artery from a vein may be beneficial when using the short-axis approach (Fig. 5.14). Doppler signals depend on direction of flow. Convention dictates that red represents flow toward the probe and blue represents flow away from the probe. Alter the tilt of the probe so that arterial flow is directed toward the probe and causes arteries to appear red on the ultrasound machine screen.

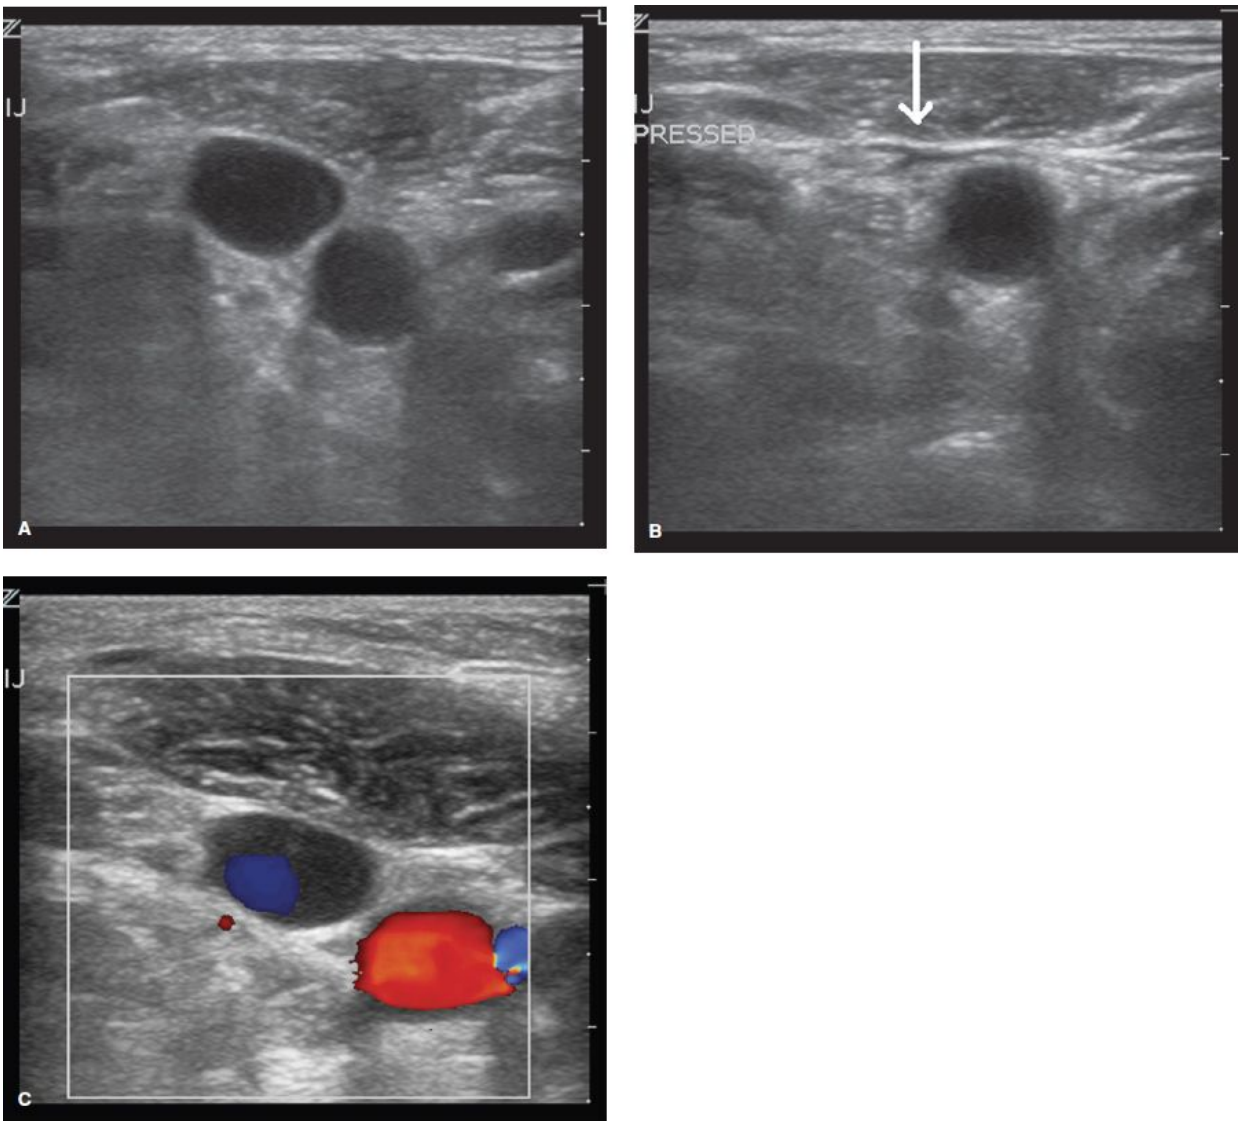

FIGURE 5.14 Distinguishing an artery from a vein. **A:** The left internal jugular vein and adjacent carotid artery. **B:** Compression of the skin with the ultrasound probe results in compression of the vein (arrow) and not the artery. **C:** Doppler reveals more intense flow in the carotid artery than in the internal jugular vein.

The short-axis approach is the preferred, though slightly less intuitive, method for vascular access in most cases. Because it gives the operator direct visualization of the artery and the vein, the operator can see which vessel (i.e., artery or vein) has been entered and can easily guide lateral movement's if the first attempt is unsuccessful.

SPECIAL CONSIDERATIONS FOR PERIPHERAL VENIPUNCTURE

Emergency physicians are often faced with patients who have difficult vascular access. Prior IV drug abuse, peripheral vascular disease, hypotension, and debilitation increase the likelihood of difficulty in obtaining peripheral vascular access (9). Ultrasound can provide direct visualization of deep peripheral veins and confirmation of catheter placement.

External Jugular Vein Cannulation

Place the patient in the Trendelenburg position to distend the external jugular vein. Turn the patient's head toward the opposite side. Clean and prep the skin of the neck. Place the nondominant thumb or index finger above the midportion of the clavicle to obstruct outflow and distend the external jugular vein. Align the catheter-over-the-needle parallel to the vein with the bevel of the needle upward. Enter the vein midway between the angle of the mandible and the midclavicle. Insert the catheter-over-the-needle during inspiration, when the valves of the external jugular vein are open. Be sure to cover the hub of the needle or catheter with a finger at all times to prevent an air embolism. The remainder of the technique is similar to that described previously.

Deep Brachial Vein Cannulation

Extend the patient's arm. Identify by palpation the brachial artery pulse in the antecubital fossa. Clean and prep the skin of the antecubital fossa. Place a tourniquet on the upper arm. Reidentify the brachial artery pulse. Place a catheter-over-the-needle onto a 5-mL syringe. Insert the catheter-over-the-needle just medial or lateral to the brachial artery pulse and at a 30- to 45-degree angle to the skin with the tip of the needle pointing cephalad. Advance the catheter-over-the-needle while applying negative pressure to the syringe. A flash of blood in the syringe indicates that the vein has been entered. The remainder of the technique is similar to that described previously.

Ultrasound can be used to facilitate brachial vein cannulation. First, cleanse and prepare the site, apply a tourniquet, and prepare the probe as described previously. Using the short-axis approach, identify the vessel to be cannulated. Scan proximally and distally to isolate the portion of vessel that is at the shallowest depth and of the greatest diameter to increase the likelihood of successful cannulation.

It is extremely important to estimate the distance the needle will need to be inserted to enter the vessel (the hypotenuse to the triangle; Fig. 5.11). The risk of failure or subsequent infiltration is increased if the catheter used is not longer than this estimate. The cannulation site should be reconsidered or a longer catheter obtained.

Although ultrasound does allow direct visualization of the vessels, it does not change the chance of vessels "rolling." Use the minimal pressure required to maintain probe contact with the skin and to prevent venous compression of peripheral veins, which are shallow and pliable.

ACCESSING INDWELLING CENTRAL VENOUS LINES

A variety of indwelling central venous access devices have been developed to avoid repeated venipunctures and permit direct access to the central circulation (5). These devices may be partially or completely implanted under the patient's skin and include tunneled catheters, Perm-a-Caths, Hickman catheters, Groshong catheters, and Mahurkar catheters. The emergency physician must be able to access these devices to administer medications and withdraw blood samples without damaging the device or causing it to thrombose. The most important elements after accessing indwelling lines are to prevent the central venous line from clotting off and to avoid contaminating the line.

There are several contraindications to accessing indwelling central venous lines. Fully implanted devices should not be accessed through infected skin. Phenytoin and diazepam cannot be given via silicone indwelling central venous lines as they can crystallize and permanently obstruct the catheter lumen. Devices used for hemodialysis should only be accessed in a true emergency and if no

other method of venous access can be readily obtained. This guideline is intended to prevent loss of the patient's dialysis access.

Accessing a partially implanted central venous catheter is simple and similar to accessing a capped peripheral IV catheter. The Luer cap can be removed entirely and the catheter lumen accessed directly with a syringe if an infusion is to be subsequently started.

A noncoring Huber-type needle must be used to access subcutaneous injection ports. A small-gauge standard hypodermic needle can be used in a dire emergency if a noncoring needle is not available. The diaphragm covering the injection reservoir can be damaged by a standard hypodermic needle, leading to subcutaneous hemorrhage and requiring surgical replacement of the implanted device.

It is extremely important to prevent the indwelling central venous catheter from becoming thrombosed after it is used. Flush the Hickman and Broviac catheters with 3 to 5 mL of heparinized saline (100 U/mL). Flush the Groshong catheter with 5 mL of normal saline. Flush dialysis catheters with the volume printed on the catheter (usually $\leq$2 mL) with heparinized saline (1,000 U/mL). Flush fully implanted catheters with 3 to 5 mL of heparinized saline (100 to 200 U/mL). Heparin may be contraindicated in some patients because of bleeding or thrombocytopenia. Sterile saline is an alternative but may result in catheter thrombosis.

PERIPHERAL VENOUS CUTDOWN

Venous access in the critically ill patient is of utmost importance. Peripheral venous access can be extremely difficult because of vascular collapse from shock, previous injury to the vessel, obesity, or scars. Direct visualization of the vein to be cannulated will often be quicker and more successful than indirect visualization with central venous lines (10). To perform peripheral venous cutdowns, one must understand the anatomy and details of venous cannulation (10). Practicing the cutdown technique before its critical need will help with placement in the emergent setting. Emergency physicians should be knowledgeable of the anatomy of the saphenous vein at

the ankle, the saphenous vein at the groin, and the basilic vein at the elbow.

The primary indication for a peripheral venous cutdown is the need for venous access in a patient with no peripheral access and in whom central access is not obtainable or contraindicated (10). This is the ideal procedure for the IV drug user with no peripheral veins, burn patients, the patient in cardiorespiratory arrest, or the hypovolemic trauma patient. This is also an excellent technique for emergent pediatric vascular access after other access attempts (i.e., intraosseous access, central venous access, peripheral venous access —including scalp veins) have failed.

Greater Saphenous Vein Isolation at the Ankle

The saphenous vein is easily found and isolated at the ankle (Fig. 5.15). Extend and externally rotate the lower extremity. Identify the medial malleolus of the tibia. Find the spot 2.5 cm anterior and 2.5 cm superior to the medial malleolus. The greater saphenous vein will be found at this site. Alternatively, the vein will be found two fingerbreadths above and two fingerbreadths in front of the medial malleolus (Fig. 5.15A).

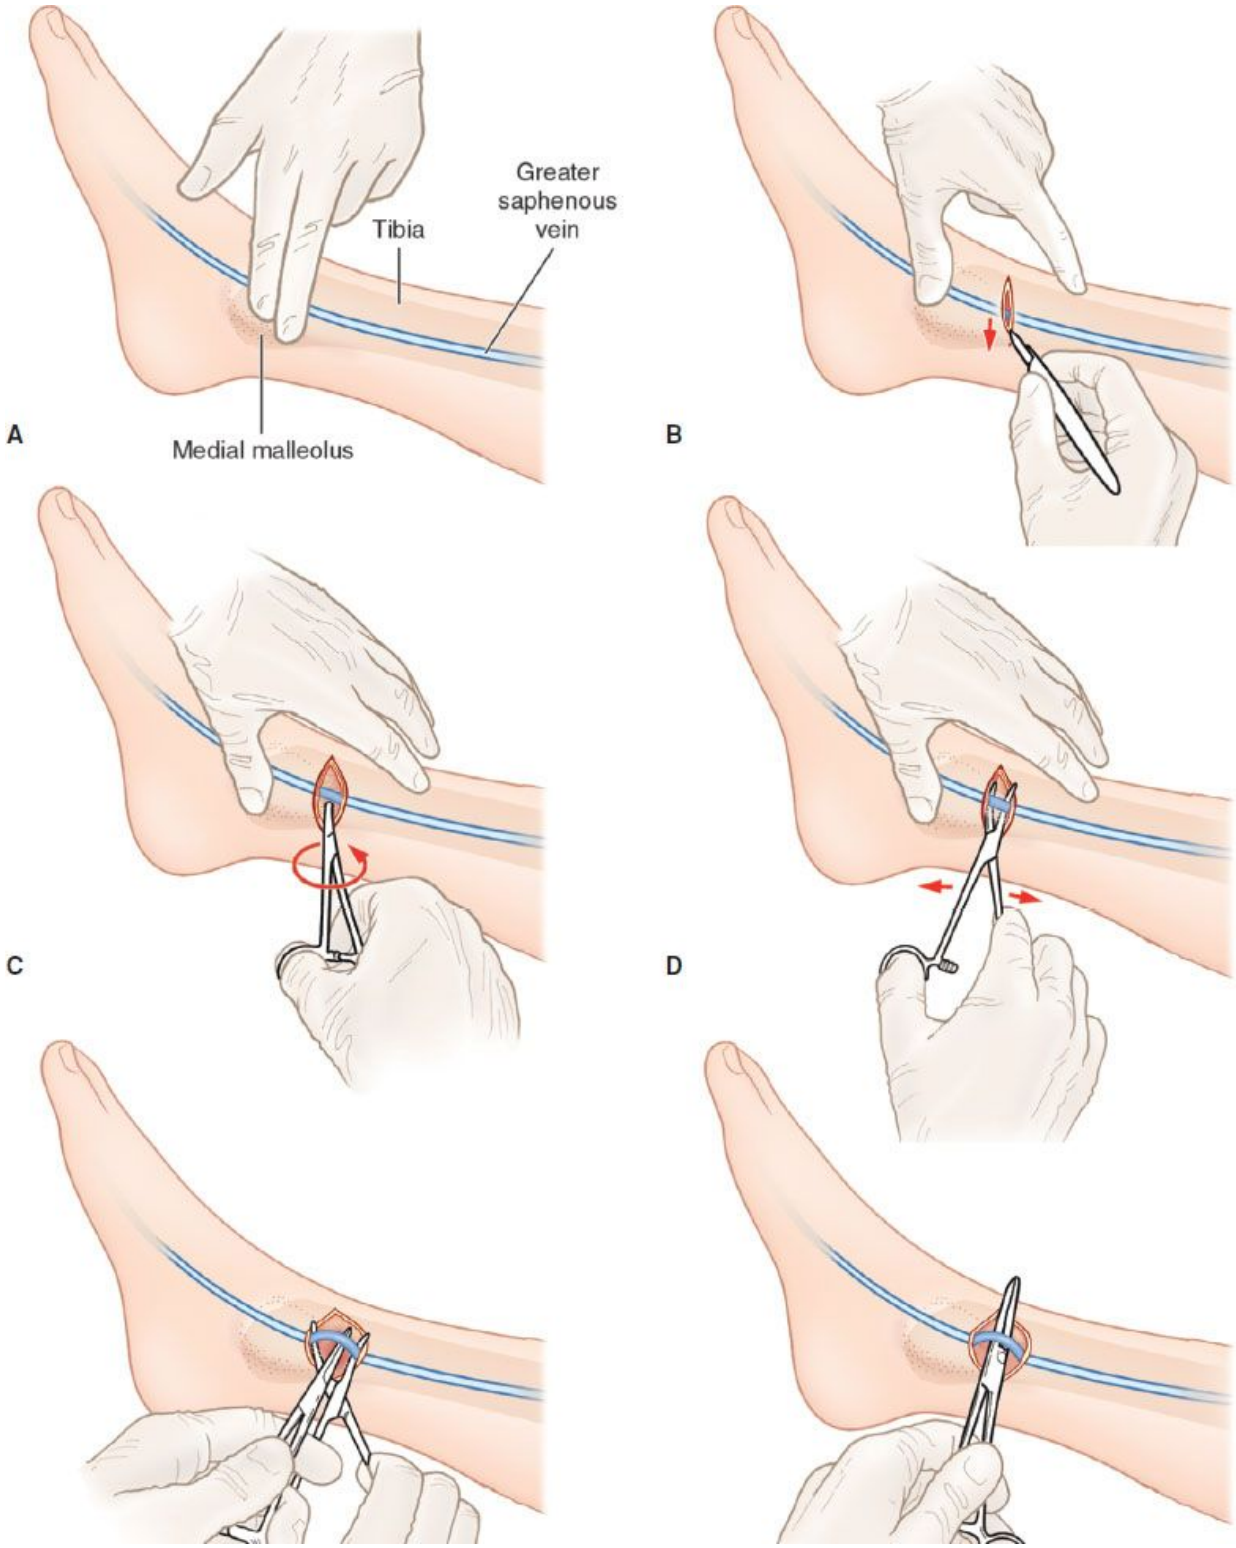

FIGURE 5.15 Isolation of the greater saphenous vein at the ankle. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Stretch the skin taught over the distal tibia with the nondominant hand (Fig. 5.15B). Transversely incise the skin overlying the greater saphenous vein using a no. 10 scalpel blade, from the anterior tibial border to the posterior tibial border (Fig. 5.15B). This incision should be superficial to expose only the subcutaneous tissue. An incision into the subcutaneous tissue may transect the vein causing significant bleeding, difficulty visualizing the surgical field, and difficulty finding the ends of the vein, which may retract proximally and distally.

Isolate the greater saphenous vein. Insert a curved hemostat along the posterior border of the tibia, and scrape the tip along the tibia. Advance the hemostat along the tibia while scraping the periosteum until the tip reaches the anterior border of the tibia (Fig. 5.15C). Widely open the arms of the hemostat (Fig. 5.15D). This motion will open the jaws of the hemostat and separate the saphenous vein from the saphenous nerve and fibrous strands of connective tissue. Insert a straight hemostat (Kelly clamp) between the jaws of the curved hemostat and below the greater saphenous vein (Fig. 5.15E). Remove the curved hemostat to leave the straight hemostat elevating the greater saphenous vein (Fig. 5.15F).

Greater Saphenous Vein Isolation at the Groin

The groin vasculature offers the potential for massive infusion of blood or fluids in a matter of minutes. These vessels are closer to the central circulation and large enough to easily accommodate IV tubing, cut off at a 45-degree angle, as a catheter. The greater saphenous vein is superficial at the groin and lies in a meshwork of subcutaneous tissue superficial to the femoral artery and vein.

Identify the location where the scrotal or labial fold meets the thigh (Fig. 5.16). Identify the lateral edge of the mons pubis. Identify the point where a vertical line from the lateral edge of the mons pubis meets a horizontal line from the scrotal/labial fold. Make a 6-cm, transverse, medial-to-lateral incision with a no.10 scalpel blade on the patient's thigh starting where the scrotal or labial fold meets the thigh. Extend the incision laterally until it meets the vertical line

from the lateral edge of the mons pubis. Dissect the subcutaneous tissue to locate the greater saphenous vein.

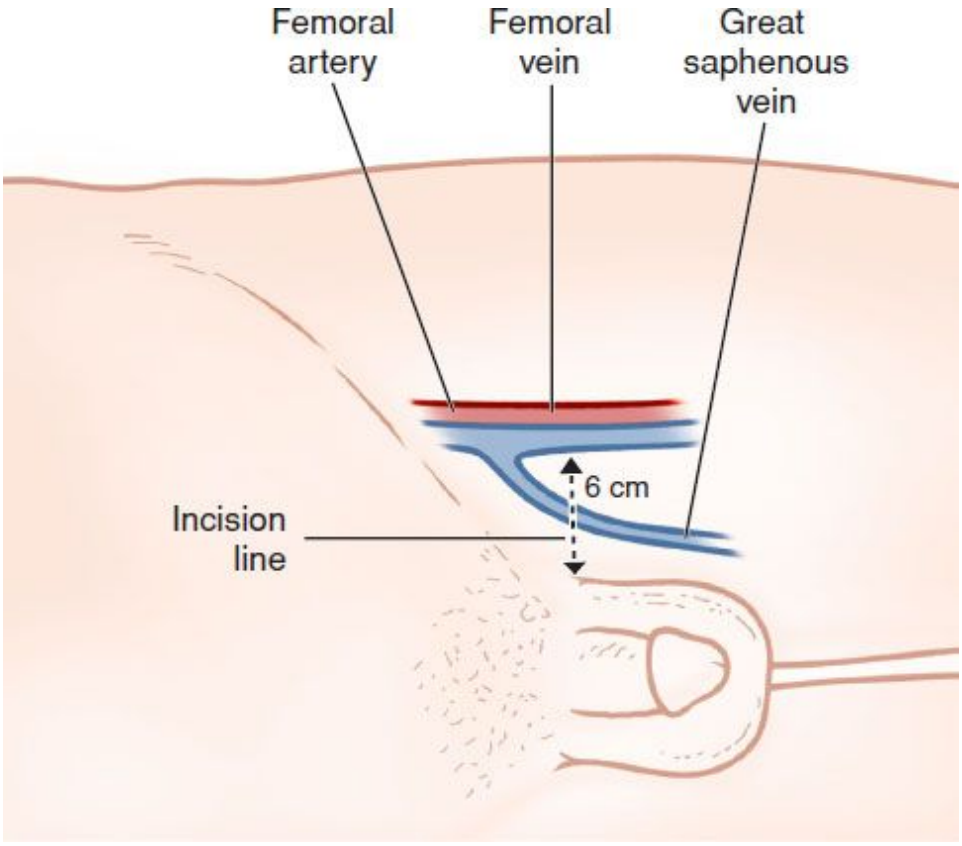

FIGURE 5.16 Isolation of the greater saphenous vein at the groin. (Reprinted with permission from Reichman EF. *Emergency Medicine Procedures*. 2nd ed. New York, NY: McGraw-Hill; 2013.)

Basilic Vein Isolation at the Elbow

The basilic vein may be used for a peripheral venous cutdown. This procedure is often performed when the greater saphenous vein cannot be accessed because of lower-extremity amputation, deformity, injury, or trauma. This site is not ideal as accessing it may interfere with resuscitative efforts. The vein is deep, small, and often hard to find.

Techniques for Cannulation of the Vein

There are a number of techniques to cannulate a vein after it has been isolated (10). Either of the following techniques can be used to cannulate the greater saphenous vein or basilic vein. The techniques include a surgical technique using IV tubing, a Seldinger technique, a modified Seldinger technique, and an IV catheter technique. It is important to realize that this may be a lifesaving procedure in an emergent setting, and the rapid and definitive cannulation of the vessel is the primary goal and not the technique chosen.

The complications of a peripheral venous cutdown include arterial injury, nerve injury, phlebitis, thromboembolism, wound dehiscence, and wound infection. The incidence of complications ranges from 2% to 15% (10). The difficulty in reporting complications is that there is a high mortality rate in patients undergoing this procedure because of the underlying problem requiring emergent vascular access (i.e., hypovolemia, sepsis, shock, trauma, etc.).

INTRAOSSEOUS INFUSION

Obtaining peripheral vascular access in the critically ill pediatric or adult patient may be difficult and time consuming. An alternative route to IV infusion for blood, drug, and fluid administration is to insert an intraosseous line (11). Intraosseous infusion is quick, safe, and effective in compromised neonates and adults when other vascular access techniques fail or are contraindicated (11). The procedure is technically straightforward.

The intraosseous needle is inserted through the cortex and into the bone marrow (medullary) cavity of a long bone. Numerous anatomic sites can be used to access the medullary cavity. The most traditional site, which is favored in pediatric patients, is the flat anteromedial surface of the proximal tibia. The distal tibia just above the medial malleolus and the greater tuberosity of the humerus are the preferred sites in adults. It is easier to penetrate the cortex of the medial malleolus and the greater tuberosity of the humerus in the adult than the thicker cortex of the proximal tibia. A third site for intraosseous access is the flat anterior surface of the distal femur. The sternum can be used, but this route is difficult and associated with numerous complications.

Intraosseous line placement is contraindicated in diseased or osteoporotic bone. Avoid placement of an intraosseous line through areas of cellulitis, abscess, or burns. Fractures in the ipsilateral bone increase the risk of extravasation-induced compartment syndrome and nonunion of the fractures. Failed placement of an intraosseous line in the same bone is a relative contraindication.

Use only specifically designed intraosseous needles for this procedure. Spinal needles bend, do not penetrate the cortex, and have increased resistance to fluid flow. Standard hypodermic needles often bend and do not penetrate the cortex of the bone. Both of these types of needles may break while being inserted and may injure the healthcare provider.

The most common complication of intraosseous infusion is extravasation of fluid. Localized infections may occur after intraosseous needle placement. Injury to the growth plate and bone marrow embolism are possible. The flow rate of fluid through an intraosseous line is slower than that through a peripheral IV line.

UMBILICAL VESSEL CATHETERIZATION

Umbilical vessel catheterization can be used as a reliable method for vascular access, fluid resuscitation, blood transfusion, medication administration, frequent blood sampling, and cardiovascular monitoring. Either the umbilical artery or vein may be used for vascular access (12). It is possible to access the umbilical artery up to 7 days after birth. The umbilical vein can be accessed for up to 2 weeks of age.

Umbilical artery catheterization is more desirable than umbilical vein catheterization because it allows frequent arterial blood gas sampling and continuous blood pressure monitoring in addition to fluid, blood, and medication administration. Unfortunately, umbilical artery catheterization is more difficult and time consuming to perform, especially in unskilled hands. Therefore, umbilical vein catheterization is the preferred procedure for the infant in shock in need of rapid resuscitation. Arterial access can be obtained later in a more controlled environment, such as in the neonatal intensive care unit.

The umbilical vein and arteries can easily be differentiated by examination of a cross section of the umbilical cord. The umbilical vein is a single vessel with thin walls and a large lumen. It is usually flattened in one direction. There are two thick-walled umbilical arteries that are significantly smaller in diameter than the umbilical vein. Occasionally, only a single umbilical artery is present.

Umbilical vessel catheterization in the ED should only be performed on severely ill neonates in whom peripheral vascular access attempts have failed. Never insert an umbilical catheter if there are any signs of infection on or around the remnant of the umbilical cord. Umbilical vessel catheterization is contraindicated if a neonate is older than the previously stated ages or an abdominal abnormality exists.

ARTERIAL PUNCTURE AND CANNULATION

Arterial blood gas sampling is an essential component of the care of many ED patients (13). Arterial blood gas sampling provides key information regarding a patient's oxygenation and acid–base status. Arterial cannulation allows for continuous and accurate blood pressure monitoring and frequent blood gas sampling in the care of the critically ill patient. A modified Allen test should be performed to assess the adequacy of the collateral circulation to the hand prior to radial artery puncture or cannulation. An alternative method of evaluating the collateral circulation involves the use of a pulse oximeter with a visual pulse waveform display.

The preferred site for the initial attempt at arterial puncture or cannulation is the radial artery. Other acceptable second-attempt sites of access include the femoral, dorsalis pedis, brachial, posterior tibial, and superficial temporal arteries. Arterial puncture may be performed to obtain a single blood sample.

Arterial cannulation can be accomplished by numerous techniques (1,13). The catheter-over-the-needle technique is the most basic method, yet possibly the one associated with the lowest rate of successful cannulation. It is the direct introduction of the catheter-over-the-needle in a manner similar to that of inserting an IV catheter. The second technique for arterial cannulation is a

Seldinger-type technique (i.e., catheter-over-the-wire) utilizing one of a number of prepackaged commercially available kits. A double arterial wall puncture technique may offer an advantage in passing the guidewire and catheter into the true arterial lumen. This technique for cannulation theoretically may be associated with greater vascular damage. Finally, a cutdown technique may be performed to cannulate an artery. This technique is primarily used for the brachial or radial arteries but may be used to access other peripheral arteries.

Arterial puncture and catheterization are generally safe procedures with an incidence of clinically significant complications under 5% (14). The primary complications of arterial catheterization are infection, bleeding, arterial injury, and intra-arterial thrombosis. Infection is usually limited to the site of catheterization. Nerve injury can occur from direct puncture or neuropathy as a result of a hematoma formation and subsequent nerve compression. Small hematomas are common after arterial puncture. Major bleeding is unusual. Rare complications include the formation of a pseudoaneurysm or arteriovenous fistula.

Common Pitfalls

- Know the anatomy and common variations of the major veins used for vascular access.
- Be familiar with the equipment and techniques for venous access before performing the procedure.
- Have a backup plan for an alternative vascular access site if the attempts at the primary site are unsuccessful.
- Anticipate difficult central venous line placement or complications because of a particular patient's anatomic variation from normal.
- Be sure to align the ultrasound probe marker and the screen marker.
- Always optimize the ultrasound machine screen depth and gain.
- Always differentiate artery from vein if ultrasound is available.
- Always maintain sterile technique.
- Involve a second operator to make both hands available when using ultrasound.

SECTION II
High-Risk Chief Complaints

Section Editor: CARLO L. ROSEN

CHAPTER 6 Chest Pain

Judd E. Hollander

Chest pain is the second most common chief complaint in patients presenting to the emergency department (ED). However, when combined with other symptoms that potentially represent myocardial ischemia, pulmonary embolism (PE), or aortic dissection (such as back pain, neck pain, shortness of breath, etc.), the evaluation of patients with "chest pain equivalents" is the most commonly evaluated diagnostic entity.

The evaluation of chest pain is complicated by the fact that the differential diagnosis includes several life-threatening entities that must be rapidly diagnosed (acute myocardial infarction [AMI], aortic dissection, PE) while recognizing that the majority of patients with chest pain have less urgent conditions. The emergency medicine approach to determining the etiology of chest pain cannot focus solely on what is more likely and what is less likely. It must focus on reducing the likelihood of the serious causes of chest pain to an acceptable threshold. This is usually considered to be less than a 1% to 2% likelihood of missing the diagnosis or having 30-day adverse events (1–3).

CLINICAL PRESENTATION

Chest pain, shortness of breath, and other symptoms of potential acute coronary syndrome present an initial diagnostic challenge. The cardiac, pulmonary, gastrointestinal, abdominal, and musculoskeletal systems all share somatic or visceral nerve roots, making it difficult to accurately distinguish the etiology of chest

pain based upon history and physical examination. Demographic characteristics, traditional risk factors, chest pain characteristics, and physical examination are insufficiently accurate to exclude life-threatening diagnoses by themselves (4,5), but they can help direct appropriate diagnostic testing. Unfortunately, there is no sufficient availability of diagnostic tests for acute coronary syndrome with enough sensitivity to confidently rule out the condition rapidly in the ED. Therefore, after a thorough evaluation, the clinician is often left admitting or observing many patients to rule out acute coronary syndrome. Patients with AMI can have a wide variety of symptoms, making diagnosis difficult—in fact, atypical symptoms are so common that up to 40% of non–ST-segment elevation AMIs go unrecognized by the patient (6).

Classically, the pain of an AMI or acute coronary syndrome is substernal or left chest pressure or aching and may have radiation to the arm or neck. High-risk features of AMI, such as left arm radiation, substernal location, and past history of AMI are reliable with good interrater reliability and can be used to predict increased risk of AMI. On the other hand, low-risk features such as pleuritic, positional, and sharp chest pain have poor reliability making it difficult to rule out ACS (4). Traditional cardiac risk factors, such as hypertension, family history of heart disease at a young age, diabetes, and increased cholesterol help predict development of coronary disease over decades, but the absence of them is not useful to risk stratify patients in the ED (5).

Aortic dissection classically presents with a severe anterior tearing pain that may radiate to the back between the shoulders. The pain can be perceived as migratory, as the dissection extends. Patients often appear sick and may be writhing in pain. A pulse differential is actually very uncommon and lack of one should not be considered to exclude the condition.

A prominently pleuritic pain with or without shortness of breath can be caused by pleural inflammation from PE, pneumonia, pleurisy, and pericardial inflammation (from pericarditis or myocarditis). Pericarditis may be positional and is classically worse with lying down but the pericardial rub is easier to hear when

patients are sitting up. Pneumothorax is usually sudden onset and worse with breathing. Fever and purulent cough suggest pneumonia.

Esophageal spasm, gastroesophageal reflux disease, and other GI causes of chest pain can be difficult to diagnose in the ED. They can have pain similar to ACS in terms of quality, location, radiation, and intensity and can also be associated with ill appearance and diaphoresis, although shortness of breath is less common. Cholecystitis and biliary colic are likely to have right upper quadrant or midepigastric tenderness and as long as complete physical examination is performed, they should be able to be diagnosed.

The ability to reproduce pain by pushing on the chest wall is likely to be misleading. Although musculoskeletal causes of chest pain are common, approximately 6% of patients diagnosed with costochondritis are actually having an AMI (7). Undressing the patient and examining their skin should identify most cases of herpes zoster, although patients can have burning dermatomal pain for a couple of days before the rash becomes evident.

Patients may improve with either a “GI cocktail” or with nitroglycerin whether or not their symptoms were from a GI or cardiac etiology. Clinicians should not rely on response to treatment in determining the etiology of pain (8,9).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chest pain is large. Although often broken down into the organ system involved (cardiac, pulmonary, gastrointestinal, abdominal, or musculoskeletal), it is better broken down into diagnostic categories in terms of levels of urgency. The treatment of each of these conditions is not covered in this chapter, but can be found in the chapters on each specific disease.

Critically time-sensitive conditions are those that can worsen rapidly if left untreated or can benefit from time-sensitive surgical or medical interventions. These include Type A and B aortic dissection, ST-segment elevation myocardial infarction (STEMI), hemodynamically significant PE, tension pneumothorax, pericardial

tamponade, esophageal perforation, and mediastinitis. All these conditions have interventions that can improve outcome, if the diagnosis is made in a timely manner.

Urgent or emergent diagnoses to consider before ED disposition include acute coronary syndromes (non–ST-segment elevation myocardial infarction [NSTEMI] or unstable angina), submassive (nonhemodynamically significant) PE, pneumonia, pneumothorax, pericardial effusion, pericarditis, cholecystitis, pancreatitis, and Fitz-Hugh–Curtis. Significant delays in treatment of patients with these conditions can result in adverse outcomes.

Chest pain can result from cardiac conditions where myocardial demand outstrips myocardial supply, or myocardial injury occurs even without coronary artery disease. Such conditions include cocaine- or amphetamine-induced ischemia, hypertropic cardiomyopathy, myocarditis or valvular heart disease (aortic stenosis in particular).

Less urgent conditions that may still cause significant discomfort to patients include intercostal strain, costochondritis, rib pain, radicular pain from cervical or thoracic spine disease, and herpes zoster or postherpetic neuralgia all of which may be radicular in nature. Gastrointestinal conditions such as gastroesophageal reflux disease or peptic ulcer disease may be suggested by symptoms. Pleurisy or epidemic pleurodynia can mimic more severe conditions. Mitral valve prolapse is associated with chest pain, the etiology of which is unclear. Fibromyalgia and psychiatric causes of chest pain should also be considered and they can be difficult to distinguish from more serious causes of chest pain.

DIAGNOSTIC APPROACH

Since the differential diagnosis of chest pain is broad and the history and physical examination often lack sufficient accuracy to exclude the most serious conditions, the diagnostic approach must take into account the pretest probability of these serious conditions while performing diagnostic testing to reduce the posttest probability of missing one of the serious causes to less than 1% to 2%. Clinical

features particularly concerning for high-risk conditions are noted in Table 6.1. The absence of any of these features should not be used to exclude the possibility of these conditions. More detailed descriptions of the classic presentations of each condition can be found in the chapter specific to that disease.

TABLE 6.1
Selected Clinical Features that Raise Particular Concern for Serious Conditions in Patients with Chest Pain[a]

Feature	Raises Particular Concern About
Severe tearing pain	Aortic dissection
Sudden onset of pain	Aortic dissection, PE, pneumothorax
Pain radiation to back, shoulders	Aortic dissection, AMI
Migratory/extending pain	Aortic dissection
Pain similar to but worse than prior AMI	AMI
Symptoms only on exertion	Unstable angina/AMI, aortic stenosis
Pain worse supine, better sitting	Pericarditis
Pleuritic chest pain	PE, pericarditis, myocarditis, AMI, pneumothorax, pneumonia
Chest pain following severe vomiting	Esophageal rupture, mediastinitis
Shortness of breath	PE, pneumothorax, AMI, pericardial tamponade, pneumonia
Cough	Pneumonia, PE
Syncope	Aortic dissection, AMI, PE, pericardial tamponade, valvular heart disease
Hypotension	Aortic dissection, AMI, tension pneumothorax, pericardial tamponade, severe sepsis (pneumonia, mediastinitis, abdominal conditions)
Fever	Pneumonia, AMI, PE/infarction, mediastinitis, abdominal infections
Crepitance in chest wall or neck	Esophageal rupture, mediastinitis, pneumothorax
Distant heart sounds	Pericardial tamponade
Hypoxia	Pneumonia, pulmonary embolism, heart failure

[a]The absence of these symptoms should never be used in isolation to exclude any serious condition.

AMI, acute myocardial infarction; PE, pulmonary embolism.

12-Lead Electrocardiogram

The diagnostic approach should begin with a 12-lead electrocardiogram (ECG). Ideally the ECG should be accomplished within 10 minutes of arrival and is often done in conjunction with triage and before or concurrent with the history and physical examination. The 12-lead ECG will identify STEMI and allow STEMI

protocols to be activated in a timely manner (see chapter on AMI). ST-segment depressions or T-wave inversions may identify patients with non–ST-segment elevation acute coronary syndromes. PR depression or diffuse ST-segment elevations can suggest pericarditis or myocarditis. P pulmonale, right axis deviation, right ventricular strain pattern, right bundle branch block, or an S1Q3T3 suggest PE. Electrical alternans suggests pericardial tamponade. Unfortunately, a normal ECG cannot exclude any of these conditions—it is normal in 5% and nondiagnostic in as many as 50% of patients with AMI. Similarly, it is normal or nondiagnostic in up to 85% of patients with aortic dissection.

If the ECG does not show STEMI, further diagnostic testing is usually dictated by the history, physical examination, and results of chest radiography.

Chest Radiography

Most but not all chest pain patients will receive chest radiography. The diagnosis of pneumonia, pneumothorax, esophageal perforation, mediastinal emphysema, free air under the diaphragm, and pleural effusion are easily made.

Most patients with ACS will have nondiagnostic chest radiography. A widened mediastinum raises concerns regarding aortic dissection (10). A widened aortic knob or widened mediastinum increases the odds of aortic dissection 11-fold. It can be found in up to 76% of such patients. Aortic displacement and pleural effusions are other findings that can be associated with aortic dissection.

Although most patients with PE will not have pathognomonic findings on chest radiography, a Hampton hump (wedge-shaped pleural defect), Westermark sign (decreased vascularity distal to the occlusion) can suggest its diagnosis. More commonly seen are nonspecific findings such as atelectasis, pleural effusion, or elevated hemidiaphragm.

After consideration of the history, physical examination, ECG, and chest radiograph further diagnostic testing is usually dictated based upon likelihood of each item remaining in the differential diagnosis.

Cardiac Troponins

Most patients with chest pain will receive laboratory testing for cardiac troponin. Cardiac troponin elevation is the gold standard for the diagnosis of AMI, although it can also be elevated in conditions of myocardial injury unrelated to thrombotic occlusion. Current ACC/AHA guidelines still advise serial troponin values for 8 to 12 hours or at least one cardiac troponin 8 to 9 hours after chest pain onset (11).

High-sensitivity cardiac troponin, which is expected to be on the market in the US in late 2013, has approximately 90% sensitivity and 80% to 85% specificity for the diagnosis of AMI at the time of ED arrival and the sensitivity rises to nearly 100% within 3 hours of arrival (12–14). This will allow more rapid "rule outs" than contemporary assays (15).

Regardless of the etiology of the troponin elevation, more troponin is always worse than less troponin. By definition, high-sensitivity troponins will result in measurable troponin values in 50% of the health population. Measurable amounts of troponin, even though below the upper limit of normal conventional assays (for example, still below 0.04) portend a worse prognosis than when below the level of detection. Troponin is associated with a worse prognosis in AMI, heart failure, renal failure, sepsis, GI bleeds, cocaine use, and asymptomatic volunteers.

High troponin elevations are most likely from AMI, but other etiologies of chest pain such as PE can have low-grade troponin elevations. The use of delta troponins (two troponins 2 hours apart) can determine whether the troponin is rising, in which case it is most likely due to myocardial ischemia, or is stable, in which case it is usually due to some other etiology. The precise delta value is assay and patient population dependent, so the EP should know the test performance characteristics at his or her own institution.

D-Dimer

D-dimer is a relatively nonspecific test that can be useful to assist in the diagnosis of PE and aortic dissection. In patients with a low pretest probability for PE, a negative D-dimer can obviate the need

for further diagnostic testing. D-dimer is a nonspecific test, and is often elevated in the absence of PE in patients who are elderly, have recent surgery, malignancy, trauma, or infections. Therefore, it should not be ordered indiscriminately and when ordered routinely at triage, should not mandate further testing for PE. Pretest probability assessment and pulmonary embolism "rule out" criteria testing should be used to determine whether patients need further noninvasive testing for PE (3) (see Pulmonary Embolism chapter). A negative D-dimer reduces the likelihood of aortic dissection dramatically, as the LR is 0.07 (16). It may be used to rule out the diagnosis in low-risk patients.

Computed Tomography

CT scans can help identify pneumothorax, pericardial effusion, mediastinitis, esophageal perforation, pneumonia, and abdominal causes of chest pain. CT angiography can be used to diagnose aortic dissection, coronary artery disease and myocardial ischemia, and PE. The timing of contrast injection, amount of contrast, and imaging protocol differ depending upon whether the CT is being done for evaluation of PE, aortic dissection, or coronary anatomy. There are three randomized controlled trials demonstrating that coronary CTA is safe, effective, more efficient, and cost-effective for the evaluation of low- to intermediate-risk patients with potential acute coronary syndromes and nondiagnostic ECGs. There was a less than 1% event rate in patients with normal coronary CTA over the ensuing 30 days, 6 months, and 1 year, and coronary CTA resulted in a shorter length of stay and higher ED discharge rate (17–19).

Some advocate "triple rule-out" scans where the contrast bolus is timed to provide diagnostic information about all three of those serious conditions. There are comparisons of triple rule-out scans with dedicated coronary CTA but there have not been comparative studies evaluating diagnostic utility of triple rule-out scans with dedicated PE and aortic dissection scans (20).

Bedside Ultrasound

Bedside ultrasound can be used to identify intra-abdominal catastrophes (abdominal aortic aneurysm/rupture), cholecystitis,

biliary colic, pneumothorax, pleural effusion, pericardial tamponade and pericardial effusions, cardiac wall motion abnormalities suggestive of myocardial ischemia, ventricular dysfunction, and valvular heart disease. It cannot, however, distinguish old from new wall motion abnormalities and cannot be used to "rule out" an acute coronary syndrome, since it misses approximately 6% of NSTEMI.

Myocardial Perfusion Imaging

Resting sestamibi imaging can identify myocardial ischemia at the time of presentation. Technetium sestamibi is distributed within the myocardium in proportion to myocardial blood flow and it has prolonged retention with minimal redistribution. A normal scan identifies patients with a very low likelihood of AMI or cardiac death (none of 338 patients) over the ensuing year (21). The ERASE trial found that, when compared to the typical ED evaluation (cardiac markers and ECG), the use of rest sestamibi scans resulted in similar diagnostic ability but a higher rate of ED discharges (22).

Stress myocardial perfusion imaging or stress echocardiography is common postacute care and often used in observation units to exclude exercise-induced ischemia. Patients with an uneventful observation period, negative cardiac markers, and a normal stress test can be safely discharged with a referral for follow-up. There is evidence supporting the use of immediate exercise testing in low-risk ED chest pain patients without known ventricular dysfunction and with normal or nonspecific ECGs, even without serial cardiac marker determination (23,24).

CRITICAL INTERVENTIONS

- Obtain an ECG within 10 minutes of arrival.
- Obtain cardiac troponin results within an hour of arrival.
- Obtain chest radiography to help identify many possible causes of chest pain.
- Treat tension pneumothorax clinically without waiting for radiographic imaging.
- Do not forget to assess skin, chest wall, and abdominal causes of chest pain.

- Treat vital signs depending upon differential diagnosis. Some conditions (aortic dissection) require more aggressive treatment of blood pressure and heart rate.
- Safely reduce pain, regardless of etiology. Since response to nitrates and GI cocktail do not help you discern pain etiology, some patients can be given analgesics, nitrates, and a GI cocktail to help make them comfortable, regardless of the cause of the pain.

DISPOSITION

The disposition of the patient with chest pain depends upon which conditions remain in the differential diagnosis after the initial evaluation. Most STEMI patients will go from the ED to the cardiac catheterization laboratory for primary percutaneous intervention. NSTEMI and type B aortic dissection should be admitted to the intensive care unit. Type A dissection requires surgical intervention and will either go directly to the operating room or to an intensive care unit for management while awaiting operative intervention. Massive PE (PE with hemodynamic instability), pericardial tamponade, esophageal perforation, and mediastinitis are other conditions that might require immediate surgical intervention.

Pneumothorax, cholecystitis, biliary colic, and pancreatitis are usually admitted to the hospital. Submasssive PE can be treated either as an inpatient or an outpatient as long as anticoagulation can be assured. In some practices, patients with a pneumothorax can be discharged home following tube thoracostomy. Likewise, some patients who improve rapidly with biliary colic or mild pancreatitis and can take fluids by mouth may be referred for outpatient management. Most gastrointestinal etiologies of chest pain and most chest wall causes can be treated as an outpatient.

Unfortunately, the majority of patients who present to the ED with chest pain or the equivalent are not found to have a specific cause for their symptoms and therefore are placed in a pathway to “rule out” an acute coronary syndrome. Most commonly, these patients are placed in observation where they receive serial cardiac

troponin measurements over 8 to 24 hours followed by some form of stress testing either prior to departure or within 72 hours. These protocols are compliant with ACC/AHA and European Society of Cardiology guidelines. Low-risk patients with potential ACS or PE do not require telemetry monitoring (25).

Patients less than 40 years old without cardiac risk factors or an abnormal ECG are safe for discharge without a "rule-out" protocol (26–28). Recent data strongly suggests that it may be appropriate to discharge patients with a Thrombolysis In Myocardial Infarction (TIMI) score of 0 or 1, a nonischemic ECG and two negative high-sensitivity troponin values within 2 hours (15).

Three randomized controlled trials have now shown the coronary CTA enables discharge of a greater percentage of patients in a shorter time frame (17–19). Patients with a maximal stenosis of less than 50% can be safely discharged with an exceedingly low likelihood of an adverse event in the near term. Angiographic presence of a stenosis or lack thereof is more useful than the coronary calcium score, which is best thought of as analogous to a cholesterol—a test to suggest patients who might benefit from primary preventive measures.

Appropriate referral for outpatient management should be made for those patients discharged home in whom a diagnosis was not made. Although they may not have life-threatening causes for their pain, the symptoms will require further investigation and treatment.

Common Pitfalls

- Relying too heavily on clinical judgment or classic clinical characteristics to determine the diagnostic approach.
- Using lack of traditional cardiac risk factors or a normal ECG to exclude acute coronary syndrome for the differential diagnosis.
- Relying on the response or lack of response to a GI cocktail or sublingual nitroglycerin to help diagnose a patient with chest pain.
- Assuming a troponin elevation is "false positive." More troponin is always worse than less troponin in every condition that has

been studied.
- Being too focused on ACS and not considering other serious causes of chest pain, such as aortic dissection or esophageal rupture.
- Overzealous pain management (e.g., with nitroglycerine or narcotics) resulting in adverse events in patients who otherwise did not have a serious condition.
- Believing "close follow-up" will identify at-risk patients with serious causes of chest pain.

CHAPTER 7

Abdominal Pain

Diane M. Birnbaumer and Daniel P. Runde

Abdominal pain is simultaneously one of the most common and challenging chief complaints in emergency medicine. Abdominal pain accounts for 8% of the >120 million annual emergency department (ED) visits and is among the top 10 most common reasons people come to the ED (1). Its causes range from benign processes that present with severe pain to fatal processes that present with subtle findings. Despite improving imaging modalities, patients with abdominal pain continue to be diagnostically challenging. Even in patients who have undergone an appropriate workup, approximately 30% of patients will be discharged with the diagnosis of undifferentiated abdominal pain.

CLINICAL PRESENTATION

The importance of a thorough history and physical examination is absolutely paramount, as it helps narrow the vast differential diagnosis and focuses diagnostic testing. Failure to actually gather the relevant information (history and physical examination) is a more frequent cause of misdiagnosis than is misinterpretation of the data gathered.

When obtaining the history and performing a physical examination, it is important to understand that there are three major types of abdominal pain: *visceral, somatic,* and *referred* pain. They differ based on the anatomic pathway relaying the pain signal.

Visceral pain is relayed by afferent visceral fibers that are located in the walls of hollow organs and capsules of solid organs. These

fibers are stimulated by stretching, distension, and excessive contraction. The visceral pain fibers originate from both sides of the spinal column, and enter the spinal column at multiple levels. This results in the perception of a poorly localized, midline pain that is described as dull or aching.

Somatic pain results from irritation of the parietal peritoneum. Pain is relayed by myelinated, unilateral afferent fibers that travel to a specific level in the spinal cord, making this pain more localized. It is usually described as sharp, intense, and well localized. Somatic pain is responsible for the physical findings of tenderness to palpation, guarding, and rebound.

Abdominal pain often begins as visceral pain and then progresses to somatic pain as the inflammation spreads to involve the parietal peritoneum. As an example, the early epigastric pain of gallbladder distension is characteristic of visceral pain whereas the right upper quadrant (RUQ) pain caused by local peritoneal inflammation with cholecystitis is deep somatic pain.

Referred pain is discomfort perceived at a site distant from the diseased organ. The diseased organ and the body area to which the pain is referred have overlapping transmission pathways at the level of the spinal cord. A common example of referred pain is shoulder pain caused by irritation of the diaphragm from free air or blood. In the same manner, extra-abdominal organs may cause referred pain to the abdomen, such as myocardial ischemia or pneumonia causing epigastric pain.

History

When evaluating the patient with abdominal pain, a thorough history of the abdominal pain is crucial. Specifically, the physician should determine the onset, time course, character, location, aggravating and alleviating factors, associated symptoms, and whether there are previous episodes of abdominal pain. The general medical and social history should also be obtained, including past medical and surgical history, medications, allergies, tobacco, alcohol and illicit drug exposure, recent travel, and toxic exposures.

Onset

Sudden onset of severe pain is very concerning and is assumed to be due to a surgical condition, until proven otherwise. Vascular emergencies such as mesenteric ischemia or a ruptured abdominal aortic aneurysm, aortic dissection and intestinal perforation, or torsion of a viscus may all present this way. Sudden onset of severe pain with an unimpressive physical examination is typical for a vascular catastrophe or torsed organ. Nonsurgical causes of abrupt onset of abdominal pain include renal colic and myocardial infarction. The physician should determine what the patient was doing when the pain began. Pain related to eating may be secondary to peptic ulcer disease, gallbladder disease, or mesenteric ischemia (intestinal angina). Pain that began during physical activity may be caused by a rectus abdominal muscle tear and hematoma, or myocardial ischemia.

Progression of Pain

The physician should question the patient about whether the pain is constant or intermittent and, if constant, whether it has been increasing or decreasing in severity. Pain that begins slowly and gradually progresses is typical of an inflammatory or infectious process such as appendicitis, diverticulitis, or salpingitis. Pain that is improving over time is less likely to be surgical in nature.

Location

In addition to onset, location may be one of the most useful pieces of information in determining the etiology of pain. Visceral pain is perceived either as epigastric, periumbilical, or infraumbilical, depending on the embryologic origin of the involved organ. Visceral pain tends to be poorly localized and midline whereas parietal (somatic) pain tends to be well localized and unilateral. It is important to determine whether the location has changed over time or radiates to a distant site.

Character

The severity and character of the pain are important historical factors. Dull aching pain is more likely to be visceral, and sharp

pain is more likely to be somatic. Crampy intermittent pain is often because of bowel obstruction. Colicky pain often indicates nephrolithiasis or gallstone disease. Severe tearing back pain is classic for aortic dissection.

Aggravating and Alleviating Factors

The patient should be asked about how the pain changes with food, movement, position, or medications. Pain that is intensified by the car ride to the hospital or other movement is indicative of peritoneal irritation. The pain of pancreatitis is often exacerbated by lying in the supine position. The pain of myocardial ischemia may be relieved with rest.

Associated Symptoms

The physician should determine the presence or absence of fever, nausea, vomiting, diarrhea, constipation, hematemesis, hematochezia, melena, dysuria, or hematuria. It is important to ask women about abnormal or increased vaginal discharge or vaginal bleeding and to ask men about testicular or penile complaints (swelling or pain). When patients complain of vomiting and abdominal pain, it is useful to determine which came first. Typically, in surgical diseases, the abdominal pain almost always precedes the vomiting, whereas the converse is true in most cases of gastroenteritis and nonspecific causes. As both cardiac and pulmonary processes can present with abdominal pain, an appropriate history should include questions about the presence of chest pain, shortness of breath, or cough. Also, the patient should be asked about the presence of flank or back pain. Patients with abdominal aortic aneurysm, aortic dissection, or renal colic may have pain that radiates to these areas.

Previous Episodes

Previous episodes of the pain should be investigated. Chronic recurrent abdominal pain involves a wide differential diagnosis; when obtaining the history, it is important to try to identify triggers of the abdominal pain. If the patient has undergone diagnostic studies in the past, there may be no point in repeating the workup

unless there is a significant change in symptomatology or an emergent concern. If pain is recurrent, it may be related to the menstrual cycle. Pain that begins 2 weeks after the start of the menstrual cycle is suggestive of mittelschmerz, but this remains more or less a diagnosis of exclusion.

Past Medical History

Cardiovascular diseases including hypertension, atrial fibrillation, and valvular disease place patients at higher risk for vascular diseases such as mesenteric ischemia, abdominal aortic aneurysm, aortic dissection, and myocardial infarction. A gynecologic history should be obtained, including menstrual history, history of sexually transmitted diseases, and previous ectopic pregnancy.

Past Surgical History

Previous abdominal surgeries place patients at greater risk for conditions such as bowel obstruction resulting from adhesions (2).

Medications

A medication history should be obtained, including prescription medications, over-the-counter preparations, herbal supplements, and steroid use. It is essential to investigate any recent use of antibiotics which increases the risk of developing a *Clostridium difficile* infection. Certain drugs place patients at higher risk for hepatitis and pancreatitis.

Social History

Alcohol abuse increases the risk of gastroinestinal (GI) bleeds, pancreatitis, hepatitis, and cirrhosis. Heroin withdrawal may present with abdominal pain, nausea, and vomiting. Cocaine and amphetamine use may increase the risk of mesenteric ischemia.

Other

Recent traumatic events such as motor vehicle collisions or blows to the abdominal wall or back can result in rectus sheath hematoma, intraperitoneal bleeding, duodenal hematoma, or traumatic pancreatitis. A history of recent food intake, sick contacts, and travel is important for patients with suspected gastroenteritis.

Finally, a history of any toxic exposures (e.g., lead) may also reveal the cause of the abdominal pain.

Physical Examination

The physical examination should always begin with an evaluation of the vital signs. When interpreting the vital signs, the emergency physician should take into account any medications that may affect heart rate or blood pressure (i.e., β-blockers). Tachycardia and hypotension should alert the physician to possible sepsis, dehydration from volume loss or third spacing, or hemorrhage from gastrointestinal bleeding, abdominal aortic aneurysm, or ruptured ectopic pregnancy. Fever makes an infectious etiology more likely, although absence of a fever should not be used to rule out an infectious cause of the pain. This is especially true in the elderly or immunocompromised patient who may present with infectious etiologies, but no fever. Because an oral temperature may be falsely low owing to factors such as mouth breathing or consumption of cold liquids, the more reliable rectal temperature should be obtained if infection is suspected. Tachypnea may be secondary to pain, hypoxia, sepsis, anemia, or metabolic acidosis. Pulse oximetry should be obtained to assess for hypoxia.

The general appearance of the patient may reveal clues to the diagnosis. A patient with peritonitis will lie still whereas a patient with renal colic may present writhing in the bed. The patient's level of alertness, mental status, and orientation are also important. Lethargy and confusion are concerning for toxic ingestions, sepsis, or other causes of hypoperfusion.

The patient's skin should be carefully examined. Pale, cool, diaphoretic skin suggests shock or a low-volume state (dehydration or bleeding). Jaundice may be present in patients with biliary or hepatic disease. The skin should be examined for rashes. Skin findings such as petechiae and spider hemangiomas are suggestive of liver disease. Whether the mucous membranes are moist or dry should be noted; dry membranes suggest dehydration. Oral thrush or hairy leukoplakia may indicate undiagnosed immunocompromise.

When examining the heart and lungs, the physician should listen for rales, rhonchi, wheezing, or other abnormal breath sounds that indicate a pulmonary etiology of abdominal pain. The patient's rhythm and the presence of murmurs should be noted, as atrial fibrillation and valvular disease put patients at risk for mesenteric ischemia caused by emboli.

The abdominal examination should start with inspection. The physician should look for distention, hernias, and the presence of surgical scars and auscultate for bowel sounds noting their frequency, quality, and pitch. Obstruction and processes that cause inflammation within the GI tract result in increased bowel sounds whereas processes that cause inflammation outside of the GI tract such as peritonitis result in diminished bowel sounds. With obstruction, high-pitched tinkling bowel sounds may be present; in patients with an ileus, bowel sounds may be absent. Percussion may aid in the diagnosis of ascites, obstruction, organomegaly, or perforation, and tenderness to percussion may indicate peritonitis.

When palpating the abdomen, the physician should assess for location of tenderness, the presence of voluntary and involuntary guarding, and peritoneal signs. It is recommended to begin with gentle palpation, starting farthest away from the suspected location of tenderness. If the patient is able to tolerate gentle palpation, then deeper palpation should be used to localize the area of tenderness. Palpation at one location may cause pain at a different location. An example of this is seen in patients with appendicitis and is referred to as *Rovsing sign* (pain experienced at *McBurney point* during deep palpation of the left lower quadrant). The physician should examine for masses or organomegaly. In assessing for RUQ pathology, the physician should note the presence of a *Murphy sign*. During deep palpation of the RUQ, the patient is asked to take a deep breath. If inspiration is arrested in midcycle, this is suggestive of cholecystitis (positive *Murphy sign*). In elderly patients, the physician should assess for an abdominal aortic aneurysm by listening for bruits and assessing for the presence of an infraepigastric pulsating mass.

Voluntary guarding may be due to anxiety, fear, or discomfort. Maneuvers that aid in relieving voluntary guarding include warming

of the hands, examination with the patient's thighs flexed, deep inspiration by the patient, and reassurance from the physician. Involuntary guarding or rigidity will not resolve with these maneuvers and is more indicative of surgical disease. *Peritoneal signs* are markers of surgical disease. Classically, peritonitis was assessed by examining for the presence of *rebound tenderness,* increased tenderness when the examiner let go after deep palpation of the abdomen. Rebound tenderness may be present even in the absence of peritonitis, and some advocate using other methods to look for peritonitis. These include the *cough test* (the abdominal pain will worsen abruptly when the patient coughs), jostling the gurney, or striking the patient's heels to precipitate the pain. Rigidity and peritoneal signs may be absent in the elderly even in the presence of peritoneal irritation and surgical disease. This may be attributed to the relatively thin musculature of the abdominal wall in older patients.

Carnett's test can be used to help determine whether abdominal pain arises from the abdominal wall. While in the supine position, the patient is asked to lift the head off the stretcher, and the abdomen is palpated. If the source of the pain is intra-abdominal, the contracted musculature of the abdominal wall will provide shielding and diminish tenderness. If the source of pain is the abdominal wall, the tenderness will be the same or even increased.

It is important to examine for umbilical, inguinal, femoral, and surgical incision hernias, especially in the elderly. In this age group, approximately 10% of cases of obstruction are due to hernias, and they are often undiagnosed.

Examination of the back is necessary to check for costovertebral angle tenderness that may indicate either pyelonephritis or ureteral obstruction.

Women of childbearing age with lower quadrant or suprapubic pain should undergo a pelvic examination to aid in differentiating salpingitis or ovarian pathology from appendicitis or diverticulitis. The results of the pelvic examination should be interpreted carefully, as women with appendicitis may also have cervical motion tenderness and adnexal tenderness. Adnexal or cervical

motion tenderness suggests pelvic inflammatory disease; if present, mucopurulent discharge from the cervical os increases the likelihood. In women with RUQ pain, particularly if evaluation for gallbladder disease is negative, the pelvic examination may also be helpful. *Fitz-Hugh–Curtis* syndrome, a perihepatitis caused by pelvic inflammatory disease, may present with complaints of right upper abdominal pain, and the patient may have no pelvic complaints. The diagnosis can be missed if the pelvic examination is not performed, especially as transaminases and other liver function tests are generally not elevated in this condition.

The digital rectal examination is helpful in assessing for a positive stool guaiac, melena, or hematochezia, and it may also aid in the diagnosis of prostate disease, perirectal disease, and rectal foreign bodies. A testicular examination should be performed to assess for torsion, epididymitis, or masses.

Patients with abdominal pain may remain in the ED for hours during their evaluation and workup. Repeat abdominal examination is very useful in these patients as changes over time may clarify the cause of their illness.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of abdominal pain is extensive and includes both intra-abdominal and extra-abdominal sources of pain (Tables 7.1 and 7.2). A thorough history and physical examination are crucial in determining the etiology of the pain and narrowing down this vast list of possible causes.

TABLE 7.1
Surgical Causes of Abdominal Pain

Abdominal aortic aneurysm[a]	Diverticulitis[b]
Mesenteric ischemia[a]	Ovarian torsion[b]
Ectopic pregnancy[a]	Cholecystitis
Perforated viscus[a]	Cholelithiasis
Aortic dissection[a]	Ascending cholangitis[b]
Appendicitis[b]	Ovarian cysts

[a]Immediate life threat.
[b]Surgical urgency.

TABLE 7.2
Nonsurgical Causes of Abdominal Pain

Myocardial infarction	Acute intermittent porphyria
Diabetic ketoacidosis	Heavy metal poisoning
Pneumonia	Abdominal tabes (Dietl crisis)
Inflammatory bowel disease	Abdominal epilepsy
Irritable bowel syndrome	Abdominal migraine
Esophagitis	Black widow spider bite
Prostatitis	Vasculitis
Intra-abdominal malignancy	Abdominal angina
Mesenteric lymphadenitis	Intestinal pseudo-obstruction
Gastroenteritis	Sickle cell crisis
Peptic ulcer disease	Right-sided colonic diverticulitis
Gastritis	Meckel diverticulitis
Hepatitis	Familial Mediterranean fever
Pelvic inflammatory disease	Massive intravascular hemolysis
Tubo-ovarian abscess	Narcotic withdrawal
Mittelschmerz	Factitious or drug-seeking behavior
Endometriosis	Psychogenic abdominal pain
Herpes zoster	Addisonian crisis
Abdominal wall contusion	Spastic colon
Acute glaucoma	

It is of utmost importance to rule out the immediately life-threatening causes of abdominal pain. These include immediate life threats such as ruptured or leaking abdominal aortic aneurysm, splenic rupture, ruptured ectopic pregnancy, and myocardial infarction and potential life threats, including perforated viscus, intestinal obstruction, mesenteric ischemia, and pancreatitis. Once

the life threat is ruled out, focus should be placed on diagnosing emergent surgical entities such as testicular and ovarian torsion, incarcerated hernia, ascending cholangitis, appendicitis, cholecystitis, gallstone pancreatitis, and diverticulitis.

Although many causes of abdominal pain originate from the abdominal organs, extra-abdominal causes of abdominal pain also occur. Upper abdominal pain may have a pulmonary etiology such as pneumonia, pneumothorax, or pulmonary embolism or a cardiac etiology such as myocardial infarction. Lower abdominal pain may be of genitourinary or pelvic origin.

Certain groups of patients presenting with abdominal pain deserve special attention because of their higher rates of misdiagnosis and increased morbidity and mortality. These groups include the elderly patients with human immunodeficiency virus (HIV) infection, women of childbearing age, and the very young. The pediatric patient with abdominal pain is discussed in Chapter 228, Abdominal Pain."

Abdominal Pain in the Elderly

The conditions causing abdominal pain in elderly patients are usually more serious and urgent, but despite this they may present with a relatively benign history and physical examination. Of patients older than age 60 who present to the ED with abdominal pain, nearly 60% are admitted, 18% go directly to the operating room or have an invasive procedure, and 5% die within 2 weeks of presentation (3). The elderly often have comorbid illnesses confusing the clinical situation and may have hearing loss or underlying dementia or aphasia, making obtaining an adequate history more difficult. Elderly patients may be unable to physiologically mount the typical response to pain and infection. They may lack fevers despite surgical disease, and laboratory values may be normal. As the risk of mortality in patients presenting with abdominal pain increases with each decade of life, the clinician's suspicion for a serious disease must be higher in elderly patients. The spectrum of disease is also different in elderly patients, with

surgical causes accounting for more than half of the cases in patients presenting to the ED and nonspecific abdominal pain accounting for only 15% of cases (3). Elderly patients are also at increased risk for abdominal catastrophes such as mesenteric ischemia, ruptured abdominal aortic aneurysm, and intestinal volvulus. Further adding to the diagnostic difficulty, elderly patients presenting with acute coronary syndrome are much more likely to present with atypical symptoms such as shortness of breath, generalized fatigue, and abdominal pain.

Abdominal Pain in Patients with HIV

HIV-positive patients with abdominal pain are at risk for unusual conditions related to their immunocompromised state, the associated disease processes, and the side effects caused by the antiretroviral medications. In the HIV-positive patient with abdominal pain, the pain is attributable to the immunocompromised state or medications in 65% of cases (4); the three most common disorders are GI non-Hodgkin lymphoma, pancreatitis, and cytomegalovirus (CMV) enterocolitis. The latter may be life threatening, as it can cause a toxic megacolon and colonic perforation. Drug-induced pancreatitis may be fulminant and has a mortality rate of approximately 10% (4). This is most often associated with didanosine but is also reported with the use of lamivudine (especially in children), zalcitabine, or stavudine. In the immunocompromised patient it is essential to rule out infectious and surgical causes of abdominal pain before attributing it to a medication side effect (see Chapter 191).

Women of Childbearing Age

Women of childbearing age presenting with abdominal pain are often among the most challenging patients. A pregnancy test is of utmost importance for women early in their pregnancy or for any sexually active woman of childbearing age presenting with abdominal pain, as a positive result raises the possibility of ruptured ectopic pregnancy. The differential diagnosis of abdominal pain in

this group is broadened by a number of possible genitourinary and pelvic pathology (ovarian torsion, ovarian cysts, ruptured ovarian cyst, mittelschmerz, pelvic inflammatory disease, and ectopic pregnancy), complicating the diagnostic workup and potentially leading to misdiagnosis. The difficulty in accurately diagnosing these patients is underscored by the fact that up to one-third of nonpregnant women of childbearing age with appendicitis are initially misdiagnosed (5).

In pregnant women, the gravid uterus becomes an intra-abdominal organ later in pregnancy and may shift the anatomic location of other organs, resulting in confusing presentations. By the second half of pregnancy, in some patients the appendix has moved out of the right lower quadrant, so appendicitis may present with tenderness ranging anywhere from the right lower quadrant, the midabdomen, the right flank, or even under the ribs. For more information on abdominal pain and pelvic pain in women of childbearing age, see Chapter 129, “Pelvic Pain.”

Many of the more common causes of abdominal pain are covered in separate chapters in this book. In addition, several other causes of abdominal pain deserve special mention.

Porphyria

The porphyrias affect the biosynthesis of heme and result in the accumulation of excessive porphyrins and their precursors. They are inherited enzyme disorders, almost always autosomal dominant with poor penetrance. They are characterized by abdominal pain with or without manifestations of autonomic dysfunction or neuropsychiatric symptoms. Other presenting conditions in patients with porphyria include demyelinating syndromes, syndrome of inappropriate antidiuretic hormone secretion, hypertensive crisis, and acute psychosis. There are many variants depending on the particular enzyme deficiency and the heme precursor that accumulates. The most common porphyria that causes abdominal pain is acute intermittent porphyria. Many drugs can precipitate attacks; a partial list is in Table 7.3.

TABLE 7.3
Drugs that May Precipitate Attacks of Acute Porphyria

Alcohol	Imatinib mesylate
Barbiturates	Mephenytoin
Carbamazepine	Meprobamate
Chloroquine	Methyprylon
Chlorpropamide	Metoclopramide
Clonazepam	Phenytoin
Danazol	Progestins
Diclofenac	Pyrazolones
Ergots	Rifampin
Estrogens	Succinimides
Ethchlorvynol	Sulfonamide
Glutethimide	Valproic acid
Griseofulvin	

The diagnosis is difficult, given the low prevalence. The pain of porphyria is usually out of proportion to physical signs, and fever is usually absent. A family history is helpful but not always present. Although not totally sensitive or specific, a Watson–Schwartz urine test should be ordered to look for porphobilinogen. The urine dipstick for urobilinogen yields a strong false-positive result. The diagnosis is made by a finding of elevated 24-hour levels of urine and stool porphyrins.

Abdominal Vasculitis

Abdominal vasculitis occurs in several disease processes, but polyarteritis nodosa, systemic lupus erythematosus, and Henoch–Schönlein purpura are among the most common. The spectrum of presentation varies from acute severe ischemia to mild pain, malabsorption, and abdominal angina.

Patients with abdominal vasculitis may have peripheral manifestations as well. The abdominal pain may be epigastric or periumbilical, reflecting ischemia of the foregut or midgut, respectively. Fever is prominent in some cases. The key issue in these cases is to consider the diagnosis in the first place, and then to

obtain the appropriate tests, such as angiography. Abdominal vasculitis should always be considered in patients with abdominal pain who also have a history of rheumatologic disease.

Angioedema

Hereditary angioneurotic edema is transmitted as an autosomal dominant trait. Symptomatic patients have low levels of C1′ esterase inhibitor (type 1), or they have a dysfunctional inhibitor (type 2); either condition allows activation of the complement system. Initial symptoms usually arise in adolescence but can have their onset in later life.

Classically, patients with angioedema do not have urticaria. Angioneurotic edema of the skin involves the deeper portions of the dermis and the subcutaneous layers as well and does not cause pruritus, whereas urticaria results from edema in the superficial layers of the skin and is pruritic.

Attacks of hereditary angioneurotic edema may begin with abdominal pain due to angioedema of the bowel wall. The pain is often colicky and is associated with nausea and vomiting, but there are scant physical findings in the abdomen. Fever is usually absent, and white blood cell counts are normal. During an attack, serum levels of C2 and C4 are low. Between attacks, the diagnosis can be established by assaying for the presence of the C1′ esterase inhibitor. Attacks of angioedema are self-limited but generally last 24 to 72 hours.

Use of angiotensin-converting enzyme inhibitors (ACE inhibitors) has also been associated with angioedema of the small bowel. Strong consideration should be given to withholding ACE inhibitors in patients with persistent, unexplained abdominal pain. See Chapter 176, “Angioedema.”

Sickle Cell Disease

Patients with sickle cell disease and vasoocclusive painful crisis can present with pain almost anywhere in the body, including the abdomen. What is not commonly appreciated is that a few patients

with homozygous sickle cell disease have their first painful crisis in their late teens or early 20s, frequently presenting with cryptogenic abdominal pain. Patients with established sickle cell disease can also pose a diagnostic challenge because their abdominal pain can be caused by a vasoocclusive event involving any of the abdominal viscera or the abdominal wall.

In addition, almost all patients with sickle cell disease have gallstones; acute cholecystitis, common duct obstruction, and ascending cholangitis are ever-present dangers in these immunocompromised patients. Abdominal pain also can develop for reasons unrelated to sickle cell disease, but the primary process may be misdiagnosed as crisis pain.

The laboratory evaluation of sickle cell patients with abdominal pain is often misleading. Many vasoocclusive crises are not associated with fever, and the white blood cell count is typically chronically elevated in these patients, commonly with a left shift. In addition, many sickle cell disease patients may be icteric because of chronic hemolysis. Many have intrinsic liver disease as well, but liver function test abnormalities are not helpful unless there is a significant deviation from baseline values. For patients presenting with RUQ pain, diagnosis can be assisted by the use of abdominal ultrasonography, nuclear scans of the biliary system, or abdominal computed tomography (CT) scanning. See Chapter 199, “Sickle Cell Disease.”

Chronic Lead Intoxication

Chronic lead intoxication can present as a painful abdominal crisis (lead colic). Abdominal pain can be slowly progressive or subacute in onset. There is abdominal tenderness with voluntary guarding, but true peritoneal findings are rare. Patients commonly complain of fatigue, weakness, musculoskeletal pains, irritability, and constipation. Anemia is usually evident, and the red blood cells show basophilic stippling. An occasional patient may have the triad of lead nephropathy, “saturnine” gout, and hypertension. The

diagnosis is made by determining blood lead and erythrocyte protoporphyrin levels.

Addison Disease

Although rare, Addison disease can present as a dramatic acute syndrome with vasomotor collapse, altered mental status, and characteristic electrolyte abnormalities. A subacute-to-chronic form of the disease, however, can present with recurrent abdominal pain, often associated with nausea and vomiting and usually with a negative abdominal examination. Other presenting complaints include salt craving, anorexia, weight loss, and generalized weakness. Characteristic physical findings include orthostatic hypotension, freckling and hyperpigmentation of the skin, and surgical scars. Classic laboratory findings include hyperkalemia, hyponatremia, mild azotemia, mild metabolic acidosis, and hypoglycemia.

The most common cause of primary adrenal insufficiency is idiopathic or autoimmune destruction of the gland. Patients with AIDS have a high incidence of adrenal gland involvement from a number of mechanisms. See Chapter 209, “Adrenal and Pituitary Disorders.”

Opioid Withdrawal

Opioid withdrawal frequently produces crampy abdominal pain, often associated with nausea, vomiting, and diarrhea. Diagnosis of this syndrome is frequently difficult unless the patient admits to narcotic addiction. Other signs and symptoms of opioid withdrawal (e.g., mydriasis, rhinorrhea, and piloerection) may be present, but these features are rarely prominent.

Psychogenic Abdominal Pain

Psychogenic abdominal pain involves a diverse group of psychiatric disturbances, including somatoform disorders, eating disorders, conversion reactions, depression, Munchausen disorder, and

hypochondriacal neurosis. Abdominal pain can also occur as a somatic delusion or as a hallucinatory phenomenon, but it generally is found in association with bizarre symptoms and evidence of underlying thought disorder. Women represent a disproportionately large percentage of patients with psychogenic abdominal pain. Early psychiatric consultation is important, but it must be kept in mind that psychogenic abdominal pain must always remain, to some degree, a diagnosis of exclusion.

DIAGNOSTIC APPROACH

Appropriate laboratory and imaging tests should be ordered in the context of the history and physical examination.

Laboratory Testing

Women of childbearing age should have a pregnancy test; sensitive and rapid bedside urine pregnancy tests can be used. A positive pregnancy test in a patient with abdominal pain should raise the concern for an ectopic pregnancy.

A complete blood count, although frequently ordered, should be interpreted with caution. A normal white blood cell count should not be used to rule out appendicitis, an elevated white blood cell count is not specific to the diagnosis, and even serial white blood cell counts may not aid in making the diagnosis. Although low hemoglobin suggests occult blood loss, it may be normal initially in rapid, acute blood loss.

Like the complete blood count, the urinalysis, although often indicated in the workup, should also be interpreted with caution. Any inflammatory process adjacent to the ureters (such as appendicitis) can cause a positive urinalysis in the absence of a urinary tract infection. Hematuria may be due to a urinary tract infection, nephrolithiasis, trauma, tumor, or an abdominal aortic aneurysm. Hematuria in patients with an abdominal aortic aneurysm may be misleading and can delay the diagnosis while a urinary workup is performed. Therefore, a patient with risk factors for abdominal aortic aneurysm who presents with flank or

abdominal pain and hematuria should be evaluated for an aneurysm as well as for urinary tract disease. If there is concern that the patient may become hemodynamically unstable, a rapid bedside ultrasound should be performed to assess for the aneurysm. If there is little concern that the patient may become unstable, then the abdominal CT can assess for both conditions.

The measurement of serum electrolytes (sodium, potassium, chloride, bicarbonate, blood urea nitrogen, and creatinine) is helpful in determining hydration status, in guiding volume replacement, and in diagnosing metabolic disturbances. The creatinine is necessary to assess renal function and to determine whether a patient can receive IV contrast for imaging. Assessing the blood glucose may help diagnose new onset or poorly controlled diabetes. Diabetic ketoacidosis can present with abdominal pain and nausea and vomiting.

A lipase should be ordered when pancreatitis is suspected. Lipase is a more sensitive and specific indicator of pancreatitis than amylase, and an elevation of three times the normal value of the lipase is suggestive of pancreatic inflammation. Less sensitive and specific than lipase, amylase levels may be elevated in many disease processes including peptic ulcer disease, small-bowel obstruction or ischemia, common duct stone, ectopic pregnancy, renal failure, alcohol intoxication, or facial trauma (salivary amylase).

Serum transaminases, bilirubin, alkaline phosphatase, and coagulation studies are often ordered in certain patients with a tender RUQ or symptoms suggestive of biliary or liver disease. However, these studies are of little to no clinical utility for making the diagnosis of biliary colic or cholecystitis. Thus, if biliary colic or cholecystitis is suspected, an ultrasound should be performed to make the diagnosis (6).

Other studies may be useful when specific diagnoses are considered. For instance, the serum lactate may be elevated in patients with mesenteric ischemia, although this is generally a late finding, and a normal lactate should not be used to exclude the diagnosis in a patient with a concerning history or examination.

Radiographic Studies

Plain films are primarily useful when certain disease processes are suspected: obstruction, perforation, and foreign body. The acute abdominal series includes supine and upright views of the abdomen and a single upright chest view. Of these three views, the upright chest x-ray is the single most useful view to assess for free air, although free air may be absent on plain films in as many as one-half of patients with visceral perforation. If the patient is unable to stand upright, a left lateral decubitus film can be obtained to look for air–fluid levels and free air. When perforation is suspected and plain films are negative, abdominal CT scanning is a more accurate way to make the diagnosis. The chest x-ray can also help to diagnose pneumonia, pleural effusions, or other pulmonary causes of abdominal pain. The kidney, ureter, and bladder film in combination with ultrasound may be helpful in evaluating urinary stone disease, but this approach is less sensitive than helical CT.

Ultrasound can be used to image intra-abdominal organs such as the liver, spleen, pancreas, gallbladder, kidneys, uterus, and ovaries. It is the imaging modality of choice in the patient with RUQ pain or presumed pelvic pathology. Other conditions that ultrasound can detect include aortic aneurysm, pancreatic pseudocyst, and ureteral obstruction. Transvaginal ultrasound can help determine intrauterine versus ectopic pregnancy and other pelvic pathology. Appendicitis can be diagnosed with good accuracy in the hands of an experienced ultrasonographer, though its utility decreases in patients with a large body habitus and CT remains the modality of choice in making this diagnosis unless radiation is a concern (e.g., children and pregnant women). In many hospitals, emergency physicians perform goal-oriented ultrasonography in an attempt to reduce time to diagnosis and improve patient care for patients with abdominal pain. Emergency physicians can accurately diagnose cholelithiasis (7), as well as ectopic pregnancy, abdominal aortic aneurysm, and hydronephrosis as an indicator of ureteral colic.

CT has become a mainstay in diagnosing many diseases presenting with abdominal pain. Helical CT can identify kidney

stones, abdominal aortic aneurysm, appendicitis, diverticulitis, splenic or liver lacerations or infarctions, intra-abdominal abscesses, bowel obstruction, and free air. Although many of these diagnoses can be made without using contrast, IV contrast is helpful for detecting mesenteric ischemia and oral contrast for diagnosing intra-abdominal abscesses. In patients with adequate body fat stores, the stranding associated with appendicits is usually easily seen without oral contrast. However, in patients with little body fat, oral contrast may be necessary to increase the accuracy of CT in making this diagnosis. In stable patients with suspected abdominal aortic aneurysm, CT without oral or IV contrast should be performed, as it is a fast, accurate method of identifying the pathology. Such patients can be transported to the radiology suite without waiting for the creatinine to return or oral contrast to be administered. In addition, CT to diagnose ureteral stone does not require contrast administration. CT is now considered the imaging procedure of choice for patients with suspected mesenteric ischemia (8). Although angiography remains the gold standard for diagnosing thromboembolism, it is an invasive, time-consuming, potentially nephrotoxic, and costly procedure and should be performed only when acute mesenteric ischemia cannot be established by noninvasive modalities (8). It should be emphasized that although modern CT scans are increasingly sensitive, they may still be falsely negative in a significant minority of patients, and their results should not be used to trump physician judgment in cases where there is a high degree of suspicion for infectious or surgical pathology.

Patients presenting with epigastric pain and a nontender abdomen who are older than the age of 50 or have cardiac risk factors should have an electrocardiogram. In addition, unstable patients and the elderly should have an electrocardiogram as part of their workup for abdominal pain. Relief of pain after “GI cocktail” does not preclude myocardial ischemia and should not be used to rule out cardiac disease.

CRITICAL INTERVENTIONS

In patients presenting with acute abdominal pain the major goals are as follows:

- Stabilize the patient, replenish volume loss, and transfuse if necessary
- Treat the pain and control emesis
- Treat the pain
- Administer antibiotics when indicated
- Obtain surgical or obstetric consultation if necessary

If ruptured ectopic pregnancy is suspected:

- Emergent gynecology consultation should be obtained.
- If available, a bedside FAST ultrasound should be performed to look for free fluid in the abdomen.
- A blood type should be drawn and at least two large-bore IVs should be started.

In the hemodynamically unstable patient, life-threatening conditions should be rapidly ruled out.

- These include ruptured abdominal aortic aneurysm, myocardial infarction, ruptured ectopic pregnancy, adrenal insufficiency, perforated viscus, mesenteric ischemia, and sepsis.

Immediate resuscitation should start with the airway, breathing, and circulation first.

- This includes supplemental oxygen, IV access with two large-bore IVs and continuous cardiac monitoring.
- Volume resuscitation should begin with crystalloid infusion and then packed red blood cell transfusion if bleeding is suspected.
- If the patient remains hypotensive, vasopressors may be necessary.

In the hypotensive patient who does not respond to volume replacement, acute adrenal crisis may be the cause. If adrenal insufficiency is suspected:

- A stress dose of IV steroids (hydrocortisone 100 mg or dexamethasone 10 mg) should be administered; dexamethasone may be preferable, as using it will not interfere with diagnostic testing for adrenal insufficiency.

Medications are indicated to treat pain and nausea and vomiting.

- Multiple studies have shown that treating undifferentiated abdominal pain with judicious amounts of narcotic analgesia does not affect diagnostic accuracy.
- Morphine in 2- to 5-mg increments or fentanyl in 50- to 100-μg increments can be titrated to the desired effect.

When infections are a consideration, appropriate antibiotics should be initiated early.

- If sepsis from an undifferentiated abdominal source is a concern, then broad-spectrum antibiotics should be started, covering gram-positive, gram-negative, and anaerobic bacteria.

Management of porphyria is largely supportive.

- IV glucose infusion may abort attacks.
- IV hematin also may be helpful, although its efficacy has not been proven (2).

In patients with angioedema, because the upper airway can be involved acutely, a major clinical concern is sudden upper airway obstruction:

- Management may call for epinephrine administration, intubation, or cricothyrotomy.
- Treatment is otherwise supportive.

DISPOSITION

Patients with surgical or gynecologic disease should be evaluated by a surgeon or gynecologist and may require admission for treatment and operative intervention. The more challenging dispositions arise in patients with abdominal pain of unclear etiology. If possible, it is prudent to observe these patients for 6 to 12 hours before discharge, particularly if they are elderly. Observation may be helpful in differentiating surgical from nonsurgical disease. Patients with abdominal pain of uncertain cause that improves while in the ED can be discharged to home with close follow-up. In these patients, the most accurate and appropriate discharge diagnosis is abdominal pain of unclear etiology; it is important to resist labeling these patients with a more specific and sometimes speculative diagnosis.

Common Pitfalls

- Failure to obtain a thorough and accurate history and physical examination.
- Failure to diagnose an abdominal aortic aneurysm in patients who present with flank pain and hematuria.
- Failure to order a pregnancy test in all women of childbearing age to rule out the possibility of ectopic pregnancy.
- Relying on a normal white blood cell count to rule out the diagnosis of appendicitis or other infectious causes of abdominal pain, particularly in the elderly.
- Failure to recognize that the urinalysis may be abnormal in patients with processes that inflame the ureters, such as appendicitis or salpingitis.

CHAPTER 8
Shortness of Breath

C. Keith Stone

Shortness of breath refers to difficult, labored, or uncomfortable breathing. Shortness of breath results when ventilatory demand exceeds respiratory function. A mismatch between supply and demand of oxygen and failure of CO_2 elimination is the mechanism that produces the sensation of shortness of breath. Table 8.1 details the most frequently encountered causes and the most common etiologies of acute shortness of breath seen in the emergency department (ED).

TABLE 8.1
Causes of Acute Shortness of Breath

Alcohol	Imatinib mesylate
Barbiturates	Mephenytoin
Carbamazepine	Meprobamate
Chloroquine	Methyprylon
Chlorpropamide	Metoclopramide
Clonazepam	Phenytoin
Danazol	Progestins
Diclofenac	Pyrazolones
Ergots	Rifampin
Estrogens	Succinimides
Ethchlorvynol	Sulfonamide
Glutethimide	Valproic acid
Griseofulvin	

CLINICAL PRESENTATION

Patients commonly present to the ED complaining of shortness of breath. The clinical evaluation is guided by the history—is the shortness of breath new onset without any previous determination of the underlying cause or is the patient experiencing an acute exacerbation of a chronic respiratory, cardiovascular, or neuromuscular condition (1)? Once the initial assessment ensures that the airway is patent and oxygenation is adequate, a thorough history should be obtained. The duration and onset of the sensation of shortness of breath; associated chest pain or palpitations; precipitating factors such as exertion, exercise, or anxiety; associated paresthesias of the mouth and fingers; the number of pillows the patient uses to sleep; concomitant coughing or sputum production; exercise tolerance; tobacco use; recreational drug use; and occupational history are several important factors that can help narrow the differential diagnosis. Past medical history of asthma, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), coronary artery disease, and valvular heart problems should be sought. Paroxysmal nocturnal dyspnea (PND), breathlessness that occurs while sleeping, is usually associated with left ventricular failure. Orthopnea, the presence of shortness of breath in the recumbent position, is also associated with left ventricular failure but can be associated with COPD.

On physical examination, the patient's vital signs, mental status, body position, use of accessory muscles, conjunctival and mucous membrane color, skin and nail bed color, upper airway examination, neurologic examination, cardiovascular and pulmonary examinations may give valuable clues to the etiology.

DIFFERENTIAL DIAGNOSIS

Anaphylaxis

Anaphylaxis is a severe allergic reaction involving one or more body systems that produces signs and symptoms such as hives, flushing, pruritus, angioedema, stridor, shortness of breath, bronchospasm, tachycardia, and hypotension. Death from anaphylaxis usually results from respiratory obstruction or cardiovascular collapse.

Symptoms typically occur within 2 minutes of exposure to the triggering antigen but occasionally may occur as late as 2 hours (2). See Chapter 175 for further discussion.

Upper Airway Obstruction

Obstruction of the upper airway may be the consequence of foreign body aspiration, epiglottitis, croup, angioedema, peritonsillar or retropharyngeal abscess, or neuromuscular dysfunction. The nature of the presenting picture depends on the site and degree of the obstruction as well as the underlying cause. Cough, stridor, shortness of breath, aphonia, or hoarseness may be present. These conditions may not cause complete airway obstruction, but rapid deterioration is possible in these patients, and the emergency physician must be ready to provide immediate airway intervention. Alternative techniques to conventional direct laryngoscopy may be necessary; these include fiberoptic-guided intubation/video-assisted devices, bougie-assisted endotracheal intubation, blind nasotracheal intubation, lighted or optical stylets, flexible or rigid fiberoptic scopes, supraglottic airway devices (LMA, intubating LMA, PLMA), retrograde intubation, percutaneous transtracheal jet ventilation, and surgical airways (3). See Chapter 1 for further discussion.

Pulmonary Embolism

Pulmonary embolism (PE) is an obstruction of the pulmonary artery or one of its branches by an embolus, usually a blood clot derived from the deep venous system of the leg or pelvic veins. The diagnosis of PE is often subtle and may be difficult to make. The actual incidence of PE in the United States is unknown, but it is estimated to be greater than 650,000 cases annually and estimates are that the diagnosis is missed more than 400,000 times each year (4).

The classic findings of chest pain, shortness of breath, and hemoptysis are found in fewer than 20% of patients with a PE (4). Common complaints in addition to the classic symptoms include malaise, weakness, extremity discomfort, dizziness, or syncope (4).

Clinical suspicion plays a key role in the decision to pursue an evaluation for acute PE. Patients at high risk include those who have had a previous PE or deep vein thrombosis (DVT), surgery within the last 3 months, travel more than 4 hours in the past month, trauma to lower extremity and pelvis during the past 3 months, malignancy, cardiopulmonary disease, and women during pregnancy or in the postpartum period (4).

A ventilation–perfusion scan, spiral computed tomography scan, and pulmonary angiogram, used in conjunction with the clinical pretest probability, D-dimer assay, and duplex Doppler evaluation of the lower extremities, will help the physician determine the likelihood of PE and the necessity of anticoagulation and admission. See Chapter 79 for further discussion.

Myocardial Ischemia

Patients with myocardial ischemia classically present with chest pain. However, a significant number of patients present with symptoms other than chest pain, termed *anginal equivalents.*

Shortness of breath either new onset or associated with exertion, is the most common anginal equivalent symptom, particularly in the geriatric patient (5). Patients with known coronary artery disease or those with significant risk factors for coronary artery disease who present to the ED with shortness of breath in the absence of chest pain should be evaluated for myocardial ischemia. See Chapter 82 for further discussion on the evaluation of coronary syndromes.

Congestive Heart Failure

CHF is a complex clinical syndrome resulting from either a structural or functional disorder of the heart that restricts the ventricular filling or the ejection of blood (6). Acute precipitating factors of CHF include increased sodium intake, noncompliance with medications, acute myocardial infarction, dysrhythmia, or anemia. The most common causes of CHF are coronary artery disease and hypertension, valvular heart disease, and cardiomyopathy.

Pertinent information obtained on history includes the presence of dyspnea, orthopnea or PND, peripheral edema, exercise intolerance, and fatigue. The physical examination may reveal jugular venous distention, rales, cardiac S3 gallop, hepatojugular reflux, ascites, and peripheral edema (6). Pulmonary edema may also lead to bronchospasm and wheezing, often termed *cardiac asthma*. Chest radiography may reveal cardiomegaly, pulmonary vascular redistribution, Kerley B lines, pleural effusion, and peribronchial cuffing. The measurement of B-type natriuretic peptide (BNP) has become a useful tool for the diagnosis of CHF in patients presenting to the ED with acute shortness of breath. BNP is synthesized as preproBNP in the cardiac ventricles and is released as a result of left ventricular wall stress (7). See Chapter 83 for further discussion.

Chronic Obstructive Pulmonary Disease

Although COPD is a chronic disorder, acute exacerbations of diminished respiratory function often bring patients to the ED. Exacerbations are usually caused by a worsening of airflow obstruction due to increased bronchospasm, increased sputum production from superimposed respiratory infection, environmental irritants (such as tobacco smoke), or cardiovascular deterioration. The patient may present with progressive shortness of breath, increased sputum production, and audible wheezing. Hypoxemia, tachypnea, cyanosis, and agitation may be seen. Signs of hypercarbia such as confusion, stupor, inadequate respiratory effort, or apnea may be seen and indicate severe compromise with impaired gas exchange. Findings on physical examination may include a barrel chest, pursed lips breathing, cyanosis, tripoding, and use of accessory muscles (8). Auscultation may reveal a combination of diminished breath sounds, a prolonged expiratory phase, wheezes, or rales (8). The chest radiograph may reveal an increased anterior–posterior diameter, flattened diaphragms, hyperinflated lungs, attenuation of the peripheral lung markings, and, in cases of superimposed infection, an infiltrate. See Chapter 77 for further discussion.

Asthma

Asthma is a chronic inflammatory condition resulting from bronchial hyperresponsiveness and airway obstruction leading to the clinical manifestations of recurrent episodes of wheezing, chest tightness, shortness of breath, and cough (9). The physical examination may reveal an increased AP diameter of the chest due to air trapping, tachypnea, wheezing, and mild-to-severe respiratory distress. Auscultation may be misleading in the case of severe obstruction; wheezing may be absent, as bronchial airflow is diminished to such an extent that no sound is audible. Chest radiographs may be normal, demonstrate a pneumothorax (PTX) or pneumomediastinum or, in the case of a precipitating infection, reveal an infiltrate. See Chapter 76 for further discussion.

Pneumonia

Pneumonia classically presents as an acute febrile illness with cough and purulent sputum production. Pneumonia should be suspected in patients with newly acquired lower respiratory symptoms (cough, sputum production, or shortness of breath), especially if these symptoms are accompanied by fever, altered breath sounds to include bronchial breath sounds, egophony, or rales.

Classification of pneumonia is based on the environmental contact where the infection was acquired. This classification can then be used to guide the clinician to the likely offending agent and choose the appropriate treatment (10). For ED patients, pneumonia is classified as either community-acquired or healthcare-associated pneumonia (HCAP). *Streptococcus pneumoniae* remains the most common etiology of community-acquired pneumonia (10). HCAP is typically caused by *Pseudomonas aeruginosa, Klebsiella pneumoniae, Legionella,* and methicillin-resistant *Staphylococcus aureus* (10). Immunosuppressed patients may present with staphylococcal pneumonia or pneumonia caused by opportunistic organisms such as *Pneumocystis carinii,* mycobacteria, or fungal organisms.

A chest radiograph may demonstrate lobar consolidation, as in bacterial pneumonia; patchy infiltrates, suggesting staphylococcal

pneumonia, *Haemophilus influenzae,* or gram-negative pneumonia; interstitial infiltrates, suggesting *Mycoplasma, Legionella,* or *Pneumocystis;* or cavitary lesions, as in tuberculosis. However, there is considerable clinical overlap among these entities. Early recognition is important, so that appropriate empiric antibiotic treatment can be administered promptly. See Chapter 74 for further discussion.

Pneumothorax

PTX, or air in the pleural cavity, can occur spontaneously or as the result of trauma (see Chapter 31). Spontaneous PTX typically occurs in tall, thin, young males, and smoking greatly increases the likelihood (11). The cause of the spontaneous PTX is the rupture of a subpleural bleb or bullae, which is usually apical in location in 90% of cases (11). Spontaneous PTX also may be seen in patients with asthma, COPD, and tuberculosis and in AIDS patients with *P. carinii* pneumonia. Traumatic PTX results from blunt or penetrating trauma to the chest. Concomitant hemothorax, pulmonary contusion, and bronchial rupture may be present.

Patients may present to the ED in obvious respiratory distress or may complain of shortness of breath and pleuritic chest pain. Auscultation may reveal unilateral diminution of the breath sounds associated with increased tympany on percussion. Subcutaneous emphysema also may be present. Signs of imminent cardiovascular collapse such as hypotension, mediastinal shift, and the aforementioned findings may herald a tension PTX, prompting swift needle chest decompression prior to any further examination or diagnostic studies. Chest radiography may reveal an obvious PTX or may only show subtle findings. In the supine patient, the only sign of a PTX may be an abnormally prominent costophrenic angle on the AP or PA view. Ultrasonography at the bedside is a sensitive and specific imaging modality for the diagnosis of PTX. The anterior, lateral, and posterior lung should be scanned from the apex to the base with the patient in either supine or sitting position. If the scan

reveals the lung sliding effectively, there is no PTX with a negative predictive value of 100% (11).

Observation is indicated in a patient with a small PTX if there is no significant dyspnea. Patients, who meet this criterion, may be observed in ED for 3 to 6 hours on oxygen. If the PTX does not progress on chest radiograph at the end of the observation period, they may be discharged home with close follow-up within 24 hours (11). Patients with a large PTX, a small PTX but with significant dyspnea, or those that fail observation should undergo invasive management with either aspiration of the pleural space or small bore chest tube placement.

DIAGNOSTIC APPROACH

The most important initial step in the management of shortness of breath is to secure the airway and ensure oxygenation and circulation. The physician should then perform a rapid, complete history and physical examination to elucidate the cause of the shortness of breath and formulate a diagnostic plan if the etiology is not readily identified (12).

Pulse oximetry is an easy, noninvasive monitoring technique that allows low-cost, continuous, reliable measurements of oxygen saturation (12). Every person who presents to the ED complaining of shortness of breath should have his or her oxygen saturation measured. Pulse oximetry may be inaccurate in reflecting oxygen saturation in the presence of high carboxyhemoglobin levels, methemoglobinemia, and low-perfusion states (12), and it does not relay any information about PCO_2.

Arterial blood gas measurement may be necessary in evaluating patients who present with shortness of breath. Blood gases demonstrate the severity of gas exchange impairment and are useful as diagnostic tools as well as for establishing a baseline for monitoring therapy. The physician should use discretion, however, when obtaining blood gases. In cases of mild shortness of breath with a normal oxygen saturation on room air, blood gases are not needed.

The chest radiograph is a valuable diagnostic tool in elucidating the cause of shortness of breath and should be obtained in most all cases. Diagnostic radiographic findings can be expected in certain entities, such as pneumonia, PE, and PTX. However, the chest radiograph may be entirely normal, even when significant illness is manifested by shortness of breath. Special views of the chest may be helpful in certain circumstances. The lateral decubitus view may confirm the presence of a pleural effusion. Inspiratory–expiratory or positional films may indicate a bronchial foreign body.

The measurement of BNP can play an important role in the diagnosis of undifferentiated dyspnea. A BNP of 100 pg/dL or greater is consistent with the diagnosis of CHF with a sensitivity of 90%, specificity of 76%, and an accuracy of 81% for differentiating CHF from other causes of dyspnea (7). In addition, BNP has been shown to be useful to predict outcomes for CHF patients to include hospital readmission, and mortality (7). Other diagnostic studies may be helpful when evaluating a patient with shortness of breath. An electrocardiogram (ECG) can show abnormalities of heart rate and rhythm or evidence of ischemia, injury, or infarction. An ECG may also be helpful in evaluating patients with a suspected pulmonary embolus, although suggestive changes are present in only a minority of patients. Anemia is an important cause of shortness of breath, and a check of the patient's hemoglobin or hematocrit may be useful as part of the workup. Rarely, bedside laryngoscopy or bronchoscopy may provide a definitive diagnosis, especially in the case of upper airway obstruction or suspected foreign body.

CRITICAL INTERVENTIONS

- If the clinical condition warrants consideration of mechanical ventilation, the physician should determine whether the patient is a candidate for noninvasive positive pressure ventilation (NIV) (13). Evidence-based guidelines recommend the use of NIV in patients with severe COPD exacerbations with a pH <7.35 and relative hypercarbia, respiratory failure caused by cardiogenic

pulmonary edema with no evidence of shock, and acute coronary syndrome requiring urgent coronary revascularization (13). Contraindications include acute lung injury, cardiorespiratory arrest, severe encephalopathy, severe upper gastrointestinal bleeding, hemodynamic instability, unstable cardiac rhythms, facial or neurologic surgery, facial trauma or deformity, upper airway obstruction, the inability to cooperate or protect the airway, the inability to clear secretions, and patients who are at high risk for aspiration (13). Endotracheal intubation should be performed if any of these contraindications are present.

- In patients with anaphylaxis, a patent airway must be established and maintained. Immediate treatment with epinephrine (1:1,000 dilution in a dose of 0.3–0.5 mL intramuscularly) repeated every 5 to 15 min as needed (2). Intravenous epinephrine is reserved for patients in shock. The typical dose is 5- to 15-μg/min continuous infusion titrated to effect (14). Additional treatment includes antihistamines, to block both H1 and H2 receptors, and steroids. Observation after treatment is needed owing to a delayed, second phase of reactivity that may occur; a period of 24 h of observation in a monitored setting is prudent.
- Once a preliminary diagnosis is made, treatment should be appropriately tailored to alleviate the patient's shortness of breath. Specific therapies can be found in the chapters devoted to each of the differential diagnoses.

DISPOSITION

The disposition of the dyspneic patient depends on the cause of the respiratory difficulty, the severity of the respiratory compromise, and the success of the ED treatment. Any patient with continuing shortness of breath despite treatment should be admitted for further evaluation and treatment. Depending on the clinical condition and diagnosis, the patient may need observation on the general ward, on telemetry, or in the intensive care unit. The patient may be safely discharged home if he or she has improvement in or resolution of shortness of breath and an appropriate diagnosis, such as an asthma

exacerbation, has been made. When considering discharge in dyspneic patients, it is important to ensure that they are back to their baseline respiratory status, will be able to obtain the medications prescribed, are capable of caring for themselves at home, and will have adequate, prompt follow-up care.

Common Pitfalls

- Relying on pulse oximetry alone to gauge a patient's respiratory status (gives no information about PCO_2)
- In patients with clinical signs of a tension PTX, waiting for radiographic confirmation before decompressing the pleural space
- Withholding oxygen for fear of blunting the hypoxic respiratory drive in a patient with COPD; correcting hypoxia takes precedence
- Failing to realize that the absence of wheezing in a patient with asthma or COPD in respiratory distress indicates severe airway obstruction

CHAPTER 9
Syncope

Shamai A. Grossman and Christopher M. Fischer

Syncope is a sudden and transient loss of consciousness that is associated with a loss of postural tone and that resolves spontaneously and completely without intervention. In the United States, syncope accounts for an estimated 740,000 emergency department (ED) visits annually. This represents approximately 0.8% of all ED visits nationally. Nationally, approximately one-third of all ED patients with syncope are admitted, representing approximately 2% of all admissions from the ED (1). Although the pathophysiology of syncope is related to a transient decrease in cerebral blood flow, the etiologies of syncope are myriad and range from the benign to the life threatening. This range of severity contributes to the problematic nature of the ED evaluation of the patient with syncope. In addition, the lack of accurate historical information and the fact that patients are usually asymptomatic when evaluated combine to fuel diagnostic uncertainty and often leads to extensive testing in the ED. Annual healthcare costs associated with syncope in the United States exceed $3.8 billion, an amount comparable to the total annual hospital costs of asthma, chronic obstructive pulmonary disease, and HIV (2). The emergency physician is faced with the challenge of identifying those patients with potentially life-threatening processes (e.g., dysrhythmias, pulmonary embolism, subarachnoid hemorrhage, acute coronary syndromes), other patients who may require hospitalization and intervention (e.g., patients with bradycardia or medication-induced orthostatic hypotension), and those patients who have a more benign cause of syncope. When the initial ED evaluation of a patient

presenting with syncope does not reveal a clear etiology, the emergency physician must determine which patients require further diagnostic evaluation and monitoring and which patients can be safely discharged home.

CLINICAL PRESENTATION

A detailed history and thorough physical examination remain the cornerstone of accurate diagnosis of syncope in the ED. However, even with a thorough initial evaluation, a definitive etiology of syncope is often difficult to establish. Historical information should focus on the events and symptoms before, during, and after the episode, as well as on the past medical and medication histories. Certain elements of the history of the episode may direct the emergency physician toward possible causes of syncope. Tongue biting, the presence of a postictal period, or urinary incontinence may suggest that seizure rather than syncope caused the patient's symptoms (3). Syncope occurring while the patient is seated or reclining is more likely to have a cardiac etiology (4), whereas syncope that occurs after standing may suggest orthostatic hypotension (5). Exertional syncope, especially in younger patients, raises concerns about structural defects producing fixed cardiac output, such as hypertensive cardiomyopathy. Absent or brief preceding symptoms, including palpitations and dizziness, may be associated with dysrhythmias, whereas longer prodromes, often including nausea or vomiting, more commonly accompany neurally mediated syncope, also known as *vasovagal syncope* or *neurocardiogenic syncope.* Obvious precipitating events or stresses may lead one to consider the diagnosis of neurally mediated syncope, but caution should be exercised, because these prodromal symptoms are often subjective and agreement on the presence of "vagal" symptoms and the eventual diagnosis is inconsistent among physicians (6).

Corroborating history from witnesses and prehospital care providers is a vital source of information and should be obtained whenever possible. These individuals are often able to provide

information that the patient is unable to provide, including estimation of duration of loss of consciousness, evidence of seizure activity, and duration of confusion or lethargy after the episode.

A detailed medication history should also be obtained. Vasoactive medications, including antihypertensive agents, antianginal medications, and medications used to treat erectile dysfunction, may lead to syncope because of their vasodilatory effects. Medication interactions may prolong the QT interval and lead to potentially life-threatening dysrhythmias. Elderly patients in particular are more susceptible to medication effects that may cause syncope, and close attention should be directed to potential medication interactions in these individuals.

The role of patient age in the diagnostic evaluation of syncope is not clearly defined. Some studies have demonstrated the importance of age as a predictor of poorer outcome in patients with syncope of any cause, but other studies suggest that age is not an independent predictor of adverse outcome in syncope (7,8). Clearly, there is no single age that places a patient at higher risk for serious outcomes. It should be recognized that while syncope in younger patients is often caused by a single pathologic process, in older patients it is often multifactorial. Older patients are especially prone to syncope as a consequence of a combination of age-related alterations in the cardiovascular system, multiple comorbidities, and the use of numerous medications (9).

The medical history should focus on predisposing conditions that place patients with syncope at a higher risk for serious outcomes. Of particular note, attention should be paid to any history of cardiovascular disease. A history of coronary artery disease places patients at greater risk (10), and a history of poor left ventricular function or heart failure is consistently predictive of a greater risk of sudden death (6,11). Syncope in the patient with heart failure is a poor prognostic sign, and patients with impaired left ventricular function may be at higher risk for sudden death, even when they are diagnosed with a noncardiac etiology for their syncope (12).

Physical examination should focus on vital signs, a careful cardiovascular examination, and a detailed neurologic evaluation.

Vital sign abnormalities, including persistent tachycardia or hypotension, are of concern and must prompt a search for an underlying cause. Orthostatic hypotension (usually defined as a decrease in systolic blood pressure with standing of 20 mm Hg or greater) may identify some patients with syncope related to volume depletion, autonomic insufficiency, or medications. However, it is a common finding in up to 40% of asymptomatic patients older than 70 years and 23% of patients younger than 60 (13). The diagnosis of orthostatic hypotension as a cause of syncope should be approached with caution and should probably represent a diagnosis of exclusion in low-risk patients, because many high-risk patients also have orthostasis.

Physical examination findings of congestive heart failure, including elevated jugular venous pressure, dependent edema, and rales are concerning predictors of sudden death after syncope. Murmurs that may be indicative of valvular heart disease or outflow obstruction should prompt further evaluation for structural heart disease, usually with echocardiography.

Abdominal pain or tenderness associated with syncope must be investigated, with close attention to possible intra-abdominal pathology or hemorrhage. Rectal examination, with testing of the stool for blood, is recommended if gastrointestinal hemorrhage is suspected.

A detailed neurologic examination should be performed. Because syncope is associated with complete and spontaneous return to normal neurologic function, focal neurologic deficits should raise concerns for other diagnoses including stroke and transient ischemic attack (TIA), and prompt further investigation, including brain imaging, Although objective evidence of seizure activity is difficult to ascertain, lateral tongue biting and signs of urinary incontinence suggest seizure, although the absence of either of these does not exclude the diagnosis. Some studies have suggested that anterior tongue biting is more commonly associated with syncope, whereas lateral tongue biting is more suggestive of seizure (14). Seizures classically present with a prodromal aura or “warning” symptoms and are typically followed by a postictal period in which the patient

is often lethargic, agitated, or confused, with a gradual return to full consciousness. More than 5 minutes of loss of consciousness and rhythmic movements can be seen in both seizures and syncope but are far more common in patients who have had a seizure.

DIFFERENTIAL DIAGNOSIS

The transient reduction in cerebral blood flow that is responsible for most causes of syncope results in temporary underperfusion of both cerebral hemispheres simultaneously or sections of the brainstem thought to be responsible for the conscious state (the reticular activating system). Transient reversible underperfusion in the brain may also be caused by a sudden increase in intracranial pressure from trauma or other brain injuries that limit cerebral blood flow (Table 9.1).

TABLE 9.1
Differential Diagnosis of Syncope (From Higher to Lower Risk)

Cardiac Causes

Arrhythmias

Bradyarrhythmias: Second- and third-degree heart block, sinus node dysfunction, pacemaker malfunction

Tachyarrhythmias: Ventricular tachycardia, ventricular fibrillation, supraventricular tachycardia, torsades pointes

Pump failure

Myocardial infarction or ischemia

Valvular disease

Aortic or mitral stenosis, acute aortic, mitral, or tricuspid insufficiency

Outflow obstruction

Hypertrophic cardiomyopathy, pulmonary hypertension, pulmonary embolism, atrial myxoma, prosthetic valve dysfunction

Impairment of venous return

Pericardial tamponade

Other cardiovascular causes

Aortic dissection, Brugada syndrome

Neurologic

Subarachnoid hemorrhage, vertebrobasilar disease, peripheral and autonomic neuropathies, seizure

Systemic Hypotension

Hypovolemia, acute blood loss, dehydration, medications

Endocrine

Hypoglycemia

Medications

Vasodilators, calcium channel blockers, β-blockers, nitrates, diuretics, antiarrhythmics, angiotensin-converting enzyme inhibitors

Reflex Mediated

Neurally mediated syncope

Carotid sinus hypersensitivity, situational syncope (micturition, defecation), vasovagal syncope

Psychiatric Disease

Major depression, somatization disorder, panic disorder, substance abuse

Dysrhythmias produce syncope by decreasing ventricular filling and stroke volume, resulting in hypotension and diminished cerebral blood flow. Loss of consciousness may also occur as a result of transient bradyarrhythmias. In pacemaker-dependent patients,

pacemaker malfunction may produce syncope as a result of bradyarrhythmias or pacemaker-induced tachycardia.

Syncope can also be a manifestation of an obstruction to blood flow in the heart. Exertional syncope may be because of aortic stenosis or hypertrophic cardiomyopathy, both of which are also associated with tachyarrhythmias. Other valvular diseases, such as severe mitral stenosis, may also cause syncope. Mitral stenosis is most commonly associated with syncope during periods of atrial fibrillation.

Acute pulmonary hypertension can cause a functional obstruction to pulmonary flow, abruptly decreasing left ventricular preload and thus cardiac output. This is most likely the mechanism of syncope associated with massive pulmonary embolism. In patients with chronic pulmonary hypertension, activities that acutely raise intrathoracic pressure, such as coughing or Valsalva during defecation, can produce the same phenomenon.

Other causes of cardiac-related syncope include sudden left ventricular dysfunction or ventricular dysrhythmia associated with myocardial ischemia or infarction. Patients with pericardial tamponade, constrictive pericarditis, and constrictive myocardial disease may develop impairment of venous return, leading to decreased left ventricular output and resulting in syncope.

Reflex-mediated syncope is a common cause of syncope in all populations. Neurally mediated syncope (including vasovagal syncope) can be precipitated by painful or emotional situations. Other types of neurally mediated syncope include carotid sinus hypersensitivity and situational syncope (with micturition or defecation), which may share components of a common pathophysiologic mechanism. Most patients with vasovagal syncope have normal baseline vital signs and hemodynamics, and have immediate return to normal vital signs after their syncopal episode (15).

Syncope may be a manifestation of psychiatric illness. Studies have documented a high prevalence of psychiatric illness among patients with syncope, particularly patients with syncope of unknown origin (16). Psychiatric disorders include somatoform

disorders, mood disorders (including major depression), anxiety disorders (including panic attacks), and substance abuse (17).

Seizures also can cause a transient loss of consciousness. Although syncope may be associated with generalized shaking movements ("convulsive syncope"), seizure is usually associated with postictal disorientation, may be preceded by sensory auras, and may be accompanied by lateral tongue biting and urinary incontinence.

TIAs and stroke rarely cause syncope. For cerebrovascular disease to cause a loss of consciousness, either both cerebral hemispheres or the brainstem must be deprived of blood flow. In a patient with a prior hemispheric infarction, marked ischemia or infarction on the contralateral side may cause a loss of consciousness, but it is unlikely that this alteration in consciousness would be transient and resolve spontaneously. Similarly, vertebrobasilar ischemia may cause syncope, but it is usually associated with other manifestations of brainstem dysfunction such as diplopia, vertigo, or nausea.

Subarachnoid hemorrhage can produce syncope, presumably as a result of a sudden increase in intracranial pressure. The complaint of headache or the appearance of focal neurologic findings in a patient with syncope should raise this possibility.

Medications can produce syncope by several mechanisms. Certain medications result in volume depletion, orthostasis, gastrointestinal hemorrhage, or depressed left ventricular function. Other medications have a proarrhythmic effect that may result in syncope.

Endocrine causes of syncope include hypoglycemia, which is easily recognized by blood glucose testing and is easily treated by administration of supplemental glucose.

Other causes of syncope include hypotension secondary to acute blood loss, dehydration, and disorders of autonomic function, including peripheral neuropathies and central nervous system disease.

DIAGNOSTIC APPROACH

The history and the physical examination may identify an underlying cause of syncope in nearly half of the patients (18).

Although the electrocardiogram (ECG) provides diagnostic or clinically useful information in only approximately 5% of patients with syncope, a 12-lead ECG should be obtained to help identify myocardial infarction or life-threatening dysrhythmias. An ECG may also aid in the identification of a prolonged QT interval or other potentially life-threatening conditions, including Brugada syndrome and pre-excitation syndromes, as the cause of syncope. Although the definition of *abnormal* ECG varies among the many studies examining their role in the diagnosis of syncope, particular attention should be paid to any nonsinus rhythm, signs of ischemia, or conduction abnormalities.

If a significant dysrhythmia is suspected, cardiac monitoring for up to 72 hours may be warranted. However, many dysrhythmias discovered in the 24- to 72-hour window are asymptomatic. The diagnostic yield of longer-term monitoring is higher, and thus its utilization is justified if there is clinical suspicion of dysrhythmia. This is also true for patients with recurrent syncope of unknown etiology (19).

Brain imaging with noncontrast head computed tomography (CT) may be useful and appropriate in a patient population with syncope and concomitant signs of trauma above the clavicles, a history consistent with a seizure, symptoms of neurologic disease such as headache, or focal neurologic findings. Head CT should be routine in patients taking warfarin (20). However, the yield of head CT in other patient populations is low, and this test should be employed judiciously (21).

The utility of routine blood tests is limited. Blood tests are commonly ordered but often do not yield diagnostically useful information (22). Measurement of blood glucose is a simple test that may be of benefit, especially in patients with diabetes or in whom seizure, rather than syncope, is suspected. If blood loss is suspected, hemoglobin or hematocrit may be useful, although it should be recognized that they may be normal in the early stages of blood loss. Women of childbearing age who experience syncope should be evaluated with a pregnancy test. However, a physician should not automatically interpret pregnancy as the sole cause of a syncopal

episode. Rather, a complete evaluation should be performed to search more closely for an etiology. Growing evidence suggests that cardiac enzymes may be of little value if drawn routinely on patients with syncope unless they have other signs or symptoms suggestive of myocardial ischemia (23,24). Psychiatric evaluation should be considered in patients with known psychiatric illness, no organic heart disease, and recurrent syncope.

The most recent clinical policy from the American College of Emergency Physicians recommends that patients with syncope should receive a 12-lead ECG (Level A recommendation—generally accepted principles for patient management that reflect a high degree of clinical certainty). The policy also recommends that laboratory testing and advanced investigative testing such as echocardiography or cranial CT scanning not be routinely performed unless guided by specific findings in the history or physical examination (Level C recommendation—based on preliminary, inconclusive, or conflicting evidence, or in the absence of any published literature, based on panel consensus) (25).

CRITICAL INTERVENTIONS

- Goal of initial evaluation is identification and treatment of cause of syncope, if possible.
- As with all patients, assessment of the adequacy of the patient's airway, breathing, and oxygenation must be assessed immediately.
- Pulse oximetry and cardiac monitoring should be instituted in all ill-appearing patients and in patients in whom a cardiac etiology of syncope is considered.
- Bedside determination of the patient's blood glucose level should be performed at presentation.
- Intravenous (IV) access should be established in patients with hypotension, tachycardia, evidence of hypovolemia, or significant blood loss.
- Immediate resuscitation with crystalloid solutions and packed red blood cells, as clinically indicated, in patients with hypotension,

or evidence of hypovolemia.
- Emergent consultation with the appropriate services should be obtained when the clinical picture is consistent with a life-threatening emergency such as a ruptured abdominal aortic aneurysm, ruptured ectopic pregnancy, or pericardial tamponade.

DISPOSITION

It is often the case that despite a thorough history and physical examination, no obvious cause of syncope is identified. In these cases, the emergency physician must determine which patients require further diagnostic evaluation and monitoring and in what setting. As with the evaluation of chest pain, the role of the emergency physician in evaluating syncope has moved from the goal of determining a specific etiology of syncope to one of risk stratification, identifying those patients at highest risk of serious short-term outcomes.

A number of recent studies have attempted to identify predictors of short-term adverse outcomes in ED patients whose initial workup did not reveal an obvious cause of syncope (Tables 9.2 and 9.3) (6,10,26,27). However, there is no set of objective criteria that is 100% sensitive for determining which patients are at risk for serious outcomes and would benefit from admission to the hospital for further diagnostic evaluation. Moreover, the value of hospital admission in preventing a subsequent adverse outcome has not been demonstrated.

The San Francisco Syncope Rule

CHESS Mnemonic
C: History of congestive heart failure
H: Hematocrit <30%
E: Abnormal ECG
S: A patient complaint of shortness of breath
S: A triage systolic blood pressure <90 mm Hg

From Quinn JV, Stiell IG, McDermott DA, et al. Derivation of the San Francisco Syncope Rule to predict patients with short-term serious outcomes. *Ann Emerg Med.* 2004;43(2):224–232.

TABLE 9.3
The Boston Syncope Criteria

The modified Boston Syncope Criteria state that if syncope is clearly dehydration or vasovagal in etiology and the ED workup at physician discretion is otherwise normal, then these patients may be discharged even with risk factors.

Syncope Risk Factors for Adverse Outcome:

I. Signs and symptoms of acute coronary syndrome

1. Complaint of chest pain
2. Ischemic ECG changes (ST elevation or deep ST depression)
3. Other ECG changes (any abnormal atrial heart rhythm) or new STT wave change
4. Complaint of shortness of breath

II. Worrisome cardiac history

5. History of CAD, hypertrophic or dilated cardiomyopathy
6. History of congestive heart failure or LV dysfunction
7. History of or current ventricular tachycardia, ventricular fibrillation
8. Pacemaker
9. ICD
10. Antiarrhythmic medication not including digoxin, b blockers, or cc blockers

III. Family history of sudden death

11. Family history (first-degree relative) with sudden death, HOCM, Brugada syndrome, or long QT syndrome

IV. Valvular heart disease

12. Significant heart murmur by history or heard in the ED

V. Signs of conduction disease

13. Multiple syncopal episodes within the last 6 months
14. Rapid palpitations
15. Syncope *during exercise*
16. QT interval >500 ms
17. High grade or complete heart block

VII. Volume depletion

18. Gastrointestinal bleeding
19. Hematocrit <30
20. Dehydration not corrected in the ED

VI. Persistent abnormal vital signs in the ED

21. Respiratory rate >24
22. O_2 saturation <90
23. Sinus rate <50 or sinus rate >100
24. Blood pressure <90

VIII. CNS

25. Primary CNS event (i.e., SAH, stroke)

From Grossman SA, Fischer C, Lipsitz LA, et al. Predicting adverse outcomes in syncope. *J Emerg Med*. 2007;33(3):233–239.

Patients who are judged to be at risk for dysrhythmia or sudden death should be admitted to an inpatient unit, observation unit, or other monitored area. Although the definition of high-risk patient is not consistent across the studies to date, certain clinical and diagnostic features appear to indicate a high risk of dysrhythmia; these include older age with associated comorbidities, an abnormal ECG, hematocrit $<30\%$ (if obtained), and history or presence of heart failure, coronary artery disease, or structural heart disease. Patients with near syncope (patients who feel like they are going to pass out but do not) have similar risks for adverse outcome when compared to patients who actually do have transient loss of consciousness and should be treated similarly (28,29). Patients presenting to the ED with syncope determined to be of benign etiology (clearly vasovagal or dehydration related) with a negative ED workup should be considered for discharge regardless of the presence of other risk factors (30).

Common Pitfalls

- Discharging a patient without performing a complete history and physical examination
- Failure to obtain an ECG and measure the blood sugar
- Failure to utilize outside resources such as family, ambulance crews, and bystanders in obtaining a complete history of events surrounding the syncopal episode

CHAPTER 10

Fever

Sarah A. Sterling and Alan E. Jones

Fever is one of the oldest and most widely recognized signs of disease and accounts for numerous adult and pediatric visits to the emergency department (ED). Although the exact temperature that constitutes a fever is debatable, most consider a rectal temperature of 38°C in children and a temperature of 38.3°C in adults to represent a fever.

Body temperature is regulated by the preoptic area of the anterior hypothalamus. This area acts like a thermostat, continuously balancing heat production versus heat loss. Heat production is controlled by altering the basal metabolic rate by varying the level of circulating thyroxin, which in turn increases cellular metabolism. In addition, body heat is produced by increasing muscle activity (shivering when cold or the shaking chill of a fever), the fastest and most sensitive means of heat production. The principal method of adjusting body heat loss is to vary the volume of blood flowing to the skin's surface through vasoconstriction and vasodilation, decreasing and increasing heat loss, respectively. The exocrine sweat glands also contribute to heat loss, cooling the body by vaporization.

The hypothalamic thermostat has an inherent set point of about 37°C but ranges from 36° to 37.8°C. This set point is affected by the normal daily circadian rhythm, with temperatures lowest around 4 AM and gradually increasing throughout the day to peak between 6 and 10 PM. This diurnal pattern is often apparent in clinical practice with most fevers lower in the morning and higher in the evening.

The phenomenon of night sweats, most commonly related to tuberculosis or lymphoma, represents a nocturnal fluctuation in the hypothalamic set point, causing a slight rise in body temperature that leads to reactive perspiration.

Not all elevations of body temperature necessarily constitute a fever. A true fever is an elevation in body temperature caused by a change in the hypothalamic set point. This new higher set point causes the body to engage its normal heat-generating mechanisms, like shivering or shaking, to raise the body temperature until the new set point is reached. In hyperthermia, however, the body attempts to maintain a normal temperature but its homeostatic mechanisms (i.e., vasodilation, increasing sweat production) are insufficient to reduce body temperature and eventually become overwhelmed. Temperatures $>41^{\circ}C$ ($106^{\circ}F$) almost always represent hyperthermia and not a true fever (1,2).

Elevation of the hypothalamic set point appears to be mediated by cytokines, which are released from lymphocytes, monocytes, and macrophages in response to exogenous and endogenous pyrogens. Exogenous pyrogens include microorganisms and their metabolic by-products, drugs, and other toxins, and endogenous ones include neoplasms and metabolic processes. Cytokines travel via the bloodstream to the hypothalamus, where they act to increase prostaglandin synthesis, primarily prostaglandin E2 (PGE2). This causes an elevated cyclic adenosine monophosphate (cAMP) level, which raises the hypothalamic set point by affecting peripheral vasoconstriction and internal heat production. Fever is maintained until pyrogen levels fall or until prostaglandin production is inhibited. Aspirin, ibuprofen, and acetaminophen exert their antipyretic effects by blocking central hypothalamic prostaglandin synthesis, but have no effect on circulating pyrogens. Corticosteroids can block the release of endogenous pyrogens as well as inhibit prostaglandins but are relatively weak antipyretics, nevertheless.

Other cytokines produced in response to pyrogens include interleukins (ILs), tumor necrosis factor (TNF), and interferons (IFNs). It is generally believed that bacteria and their products of metabolism typically provoke release of IL-1. In contrast, viral

proteins appear to stimulate IFN. IL-1 induces the liver to produce acute phase reactants, including C-reactive protein (CRP), which are responsible for the elevated erythrocyte sedimentation rate (ESR) associated with some fevers. Although IFN is a potent pyrogen, it does not enhance production of acute phase reactants. Though not yet clearly supported by data, this is the rationale behind the expectation of an elevated ESR and CRP level with a bacterial fever but not with one of viral etiology. Procalcitonin, the precursor to calcitonin produced in the thyroid, rises from undetectable in well individuals to measurable levels within 2 to 3 hours (peaking in 24 hours) in patients with sepsis. Some studies have suggested this marker, rather than the later rising CRP, may be more specific for infection. Several studies have examined the use of CRP and procalcitonin as potential biomarkers of sepsis, which could be used in clinical practice to differentiate patients with bacterial versus nonbacterial infections; however meta-analyses suggest that procalcitonin is not yet ready to be deployed into routine clinical practice (3). While the use of these biomarkers appears promising, research is ongoing to determine their clinical utilization.

Many metabolic abnormalities are associated with the febrile state. Fever increases both the oxygen tension (PO_2) and the carbon dioxide tension (PCO_2) and shifts the oxyhemoglobin dissociation curve to the right, resulting in lower oxygen saturation. Fever also seems to lower the seizure threshold, which can result in seizures in children who do not have a predisposition to epilepsy (febrile seizures). Fever can also cause reactivation of latent herpes simplex infections and other chronic viral conditions.

Although higher metabolic demands are placed on the febrile patient, evidence suggests that fever has some physiologic benefits and protective effects as well. Neutrophils, macrophages, and lymphocytes are most active at elevated temperatures. In addition, higher temperatures decrease the level of serum iron, a substrate needed by many bacteria to replicate. Fever also seems to inhibit certain viruses, such as Coxsackievirus and poliovirus (1,4).

Despite this, many patients and parents, as well as practitioners, believe that fever is harmful or likely to cause harm. Many studies have shown that "fever phobia," initially described in the 1980s, persists. A recent study in a pediatric ED showed that more than 50% of caregivers would define fever at $<37.8^{\circ}C$ ($100^{\circ}F$) and a large majority would treat a fever $<37.8^{\circ}C$ (5). Despite these beliefs, no studies have shown true fevers to be harmful. In addition, research has shown that the response to antipyretics does not allow the differentiation between serious (e.g., bacterial) and nonserious (e.g., viral) infections (2). Fever anxiety can be greatly reduced when patients and caregivers are educated on the risks and benefits of fever and its proper management.

CLINICAL PRESENTATION

Though most febrile patients present to the ED with a chief complaint of fever, many present with more generalized complaints. Elderly patients, or their caregivers, may complain of generalized weakness, malaise, or a change in mental status. Parents may bring in infants who are eating poorly or appear lethargic. In these patients, fever may be an incidental finding, discovered only on review of systems or review of vital signs.

In children, a fever documented at home should be treated as real, even in the absence of a documented fever in the ED. One study found that while children referred to an ED by a general practitioner were more severely ill, approximately one in four children who self-reported with parents required extensive diagnostic testing, intravenous (IV) or aerosolized medications, or hospital admission (6). Studies have also found parents can correctly detect fever by palpation alone with sensitivities and specificities as high as 91% and 79%, respectively, reported in one study (7). Further, although bundling of infants can affect skin temperature, research has shown it has no effect on the rectal temperature of a healthy infant; so elevated rectal temperatures should not be attributed to bundling (8).

In the elderly, fever may be more difficult to detect and define. Previous studies have shown that while mean rectal temperature was similar to younger patients (37˚C), elderly patients had less diurnal variation (9). Another study found that lowering the definition of fever to 37.8˚C (100˚F) increased the sensitivity of predicting an infection to 70% (vs. 40% if 38.3˚C is used), while the specificity remained at 90% (10). Elderly patients may also have an impaired ability to mount a fever response altogether, with 20% to 30% of elderly patients who had a serious bacterial or viral infection having a decreased or absent fever response in some studies. To complicate the evaluation of this patient population more, the elderly may have a delayed fever response as well, which can be delayed more than 12 hours in 12% of patients despite known infection (9).

Similarly, immunocompromised patients with a low-grade fever may suffer from an acute, life-threatening condition, but may be unable to mount a febrile response. These findings highlight the importance of a high index of suspicion for infection in the setting of functional decline in the elderly or immunocompromised patient, and the need for reassessment after initial physical examination and evaluation.

History

Important points to address in the history include the following:

- Duration and magnitude of fever
- Associated symptoms
- Close contacts with similar illness
- Past medical history associated with immunocompromise
  - For example, HIV, diabetes, chronic renal failure, blood dyscrasia, alcohol or drug abuse
- Recent hospitalizations
- Presence of medical hardware
  - For example, prosthetic valves, ventriculoperitoneal shunts
- Current medications
  - Recent antibiotics or chronic steroid use

    - Serotonergic or neuroleptic drug
    - Last time and dose of antipyretics
- Recent travel
    - Areas with endemic malaria, parasitic, or fungal infections
    - Prolonged immobility or symptoms concerning for venous thromboembolism
- Occupational exposures
    - For example, medical personnel or postal worker/governmental official with possible biologic weapon exposure

Physical Examination

The most important observation during the physical examination is the patient's overall appearance and mental status. Specifically, does the patient look well or toxic? Does the patient have an altered mental status, which might indicate infection or sepsis, especially in the elderly? The overall impression of the patient and their general well-being is vital in determining pretest probabilities which will guide and direct the patient's workup.

The importance of reviewing vital signs cannot be overstated. Tachycardia and hypotension should not be ignored or attributed solely to a febrile response or faulty reading. One study found that hypotension, even if it is transient, significantly increases mortality in patients admitted to the hospital with sepsis (11). In the presence of a fever, the pulse can be expected to increase by approximately 18 beats/min for each 1°C increase in temperature. However, some diseases are associated with relative bradycardia for the degree of fever (pulse–temperature dissociation). This dissociation is classically seen with typhoid fever, but may also be seen in Legionnaires' disease, mycoplasmal infections, drug fever, factitious fever, and some viral syndromes. In addition, patients taking β-blockers may be unable to increase their pulse in response to a fever.

Tachypnea may also be an important indicator of significant infection or acid–base disturbance. Tachypnea and dyspnea are

often suggestive of pulmonary disease, whereas tachypnea without dyspnea may indicate sepsis or metabolic acidosis of any cause. In a study of nursing home patients, tachypnea >25 was the highest predictor of disease, with a sensitivity of 90% and a specificity of 95% for pneumonia (12).

The history will usually direct the physician to the most likely source of infection, though this may be challenging in patients with an altered mental status. In the absence of localizing symptoms, a thorough examination should be undertaken. The entire body should be examined for rashes, decubitus ulcers, cellulitis, track marks (needle marks), or lymphadenopathy. Rashes may suggest a viral exanthem, vasculitis, meningococcemia, tick-borne infection (e.g., Rocky Mountain spotted fever or Lyme disease), or toxic shock syndrome (staphylococcal or streptococcal). Lymphadenopathy associated with fever may suggest malignancy, autoimmune disorders, or infection. Tender, localized adenopathy is usually associated with an infection in the region drained by the involved nodes, whereas malignant nodes are usually painless, rubbery, and firm. The most common cause of acute generalized adenopathy is infectious mononucleosis.

The head and neck examination may also offer important clues to the source of infection. Nuchal rigidity or meningismus may indicate meningitis; however, these signs are often absent, particularly in the elderly or children. The eyes should be examined for scleral icterus, which could indicate hepatitis, cholecystitis, or ascending cholangitis. Examination in and around the ears may reveal otitis externa or media or may suggest mastoiditis. The oropharynx may show evidence of pharyngitis, peritonsillar or retropharyngeal abscess, or periodontal infection. Purulent rhinorrhea may suggest sinusitis or, in children, a nasal foreign body. Sore throat, drooling, and fever may suggest epiglottitis. It is important to remember that patients may not present classically, so airway edema, stridor, or hoarseness should be taken seriously as they could indicate significant infection and a potential airway emergency.

The chest should be examined for indications of a pulmonary or cardiac cause of fever. Localized rales or rhonchi suggest pneumonia. As x-ray findings can lag behind physical findings, an early pneumonia may not be visible on x-ray. A pericardial rub is indicative of pericarditis, and a new heart murmur suggests endocarditis, especially in IV drug users. However, functional murmurs may increase because of fever-induced tachycardia.

The abdomen should be examined for signs of peritoneal irritation or ascites. Localized pain may suggest cholecystitis, appendicitis, pancreatitis, or diverticulitis. Suprapubic pain suggests a urinary tract infection (UTI), and should prompt an evaluation for costovertebral angle (CVA) tenderness, which could indicate pyelonephritis. A rectal examination may demonstrate evidence of a perirectal abscess or prostatitis. In male patients with a urethral discharge, a sexually transmitted infection is likely and a swollen or painful testicle suggests epididymoorchitis. In females, a pelvic examination can be performed to evaluate for vaginal and cervical discharges and/or cervical motion tenderness suggestive of pelvic inflammatory disease, tuboovarian abscesses, or a retained vaginal foreign body. In neonates, examination of the periumbilical area is necessary to evaluate for omphalitis.

Examination of the musculoskeletal system is often overlooked in febrile patients, but examination of the spine may reveal tenderness suggestive of osteomyelitis, discitis, or epidural abscess (especially in IV drug users). A detailed examination of the extremities may demonstrate a septic or inflamed joint, or it may suggest osteomyelitis, myositis, or deep vein thrombosis (DVT). In addition, any retained catheters, such as peripherally inserted central catheter (PICC) lines or hemodialysis (HD) ports, should be evaluated for erythema, rubor, or discharge surrounding the catheter and regarded as a potential source of infection.

DIFFERENTIAL DIAGNOSIS

Infection

Infection is the most common cause of fever. Infection may originate in any portion of the body and lead to a febrile response, whether from bacterial or viral etiology. Fever may indicate localized infection, or may indicate a more significant systemic process, like sepsis. One of the more challenging aspects of practicing emergency medicine is determining the significance of infection and identifying patients early in the spectrum of sepsis.

Systemic Inflammatory Response Syndrome and Sepsis

Systemic inflammatory response syndrome (SIRS) indicates that the body has initiated a global inflammatory/immune response. SIRS is associated with a higher likelihood for organ dysfunction and organ failure. Although SIRS can result from noninfectious etiologies, in the setting of suspected or confirmed infection, if a patient has two or more SIRS criteria (Table 10.1), they meet the definition of sepsis (13,14).

TABLE 10.1
SIRS Criteria

Temperature	≤36°C or ≥38°C
Heart rate	≥90 beats/min
Respiratory rate	≥20 breaths/min or $PaCO_2$ <32 mm Hg
White blood cell count	≥12,000 or ≤4,000 cells/mm^3 or >10% bands

Severe Sepsis and Septic Shock

According to consensus definition, severe sepsis is sepsis, or suspected infection with systemic manifestations, and evidence of organ dysfunction. Septic shock is sepsis-induced hypotension (systolic blood pressure [SBP] <90 mm Hg or mean arterial pressure [MAP] <70 mm Hg, or an SBP 40 mm Hg below the patient's baseline) that does not respond to IV fluids. In addition, patients may have evidence of tissue hypoperfusion as indicated by an elevated blood lactate level, oliguria, renal failure, coagulopathy, or acute lung injury (15). Despite much attention to this area and aggressive treatment strategies, once septic shock occurs, the mortality rate remains high.

Drug-Induced Hyperthermia Syndromes

Drug-induced hyperthermia syndromes include neuroleptic malignant syndrome (NMS), malignant hyperthermia (MH), and serotonin syndrome (SS). Because all three syndromes have similar presentations, with severe muscle contraction and hyperpyrexia, they share common complications of rhabdomyolysis, myoglobinemia, and intravascular hemolysis. Temperatures $>42^{\circ}C$ cause central nervous system (CNS) damage, initially to the more sensitive cerebellum and eventually to the cerebral cortex, brainstem, and spinal cord. Patients may also develop pulmonary embolism, cardiovascular collapse, myocardial infarction, and acute respiratory failure.

NMS is a rare idiosyncratic reaction to neuroleptic medications. It has also been reported in patients taking lithium. NMS is thought to result from dopamine depletion in the brain, possibly in combination with increased anticholinergic activity. NMS presents with fever (temperature in excess of 41°C has been reported), muscle rigidity, and elevated creatine phosphokinase (CPK). Other findings may include altered mental status and autonomic instability. Symptoms develop rapidly over 1 to 3 days. Muscular rigidity of the thorax may impair breathing. Autonomic dysfunction may cause severe variations of both blood pressure and pulse, and some patients may develop seizures (eTable 10.1).

eTABLE 10.1
Diagnostic Criteria for NMS

History of neuroleptic medication use PLUS:

- Fever
- Muscle rigidity
- Elevated CPK

OR two of the above, PLUS four of the following:

- Tachycardia
- Abnormal blood pressure
- Tachypnea
- Altered mental status
- Diaphoresis
- Leukocytosis

MH is a rare, genetically determined reaction to inhaled anesthetic gases, depolarizing muscle relaxants (e.g., succinylcholine) and other agents. Succinylcholine is more likely to cause MH than inhaled anesthetic gases. The offending agent triggers the release of calcium by the sarcoplasmic reticulum resulting in increased muscle contraction and oxygen consumption. Masseter muscle spasm is generally noted initially, and then generalized muscle rigidity leads rapidly to hyperpyrexia. Symptoms typically develop as soon as 30 minutes following administration, though initial or recurrent symptoms may be delayed up to 48 hours later.

SS is a reaction to serotonin-active agents and most commonly occurs after a dosage increase of a serotonergic drug or with the addition of a potentiating drug to a serotonin-active agent. Common drugs that may cause SS are listed in eTable 10.2. Of particular note, the combination of triptans and serotonergic drugs has recently been shown to be a major cause of SS. SS involves an alteration in mental status, autonomic dysfunction, and increased neuromuscular activity, the latter causing a rise in temperature. Diagnostic criteria for SS are presented in eTable 10.3. Symptoms can be seen within 15 minutes of ingestion and can last for up to several hours. The duration of symptoms in other cases is dependent

on drug half-life, but, in severe cases, symptoms can persist for weeks.

TABLE 10.2
Surviving Sepsis Campaign Guidelines

To be completed within 3 hrs:

- Measure lactate level
- Obtain blood cultures prior to administration of antibiotics
- Administer broad-spectrum antibiotics
- Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L

To be completed within 6 hrs:

- Start vasopressors to maintain an MAP ≥65 mm Hg if hypotension does not respond to initial fluid bolus
- With persistent hypotension despite volume resuscitation or initial lactate ≥4 mmol/L:
  - Measure central venous pressure (CVP)[a]
  - Measure central venous oxygen saturation (ScvO2)[a]
- Repeat lactate if initial lactate was elevated[a]

[a]Targets for resuscitation: CVP of ≥8 mm Hg, ScvO2 of ≥70%, normalization of lactate.

eTABLE 10.2
Drugs Associated with Serotonin Syndrome

Selective inhibitors of serotonin uptake:
- Fluoxetine
- Paroxetine
- Fluoxetine/Olanzapine
- Sertraline
- Trazodone
- Meperidine
- Dextromethorphan
- Citalopram
- Escitalopram
- Fluvoxamine

Specific serotonin agonists:
- Buspirone
- LSD, Mescaline
- Triptans

Nonspecific serotonin agonists:
- Bromocriptine
- Bupropion
- Phenytoin
- Tryptophan
- Levodopa
- Lithium

Nonspecific inhibitors of serotonin reuptake:
- Clomipramine
- Venlafaxine
- Duloxetine
- Sibutramine
- Nefazodone

Agents that increase serotonin release:
- Amphetamine
- MDMA (Ecstasy)
- Cocaine
- Codeine
- Reserpine

Monoamine oxidase inhibitors:
- Pargyline
- Phenelzine
- Isocarboxazid
- Procarbazine
- Tranylcypromine
- Isoniazid
- Moclobemide
- Selegiline

Other drugs:
- Chlorpheniramine
- Brompheniramine
- Ginseng
- St. John's wort
- Tramadol

eTABLE 10.3
Diagnostic Criteria for Serotonin Syndrome

TABLE 10.3
Treatment of Malignant Hyperthermia

- Discontinue precipitating agent
- Administer dantrolene 2.5 mg/kg IV, up to 10 mg/kg/day
- Infuse D5W with sodium bicarbonate to maintain urinary output
- Monitor systemic pH to prevent alkalosis
- Cool patient with cooling blanket, ice packs, or evaporation
- Monitor for electrolyte imbalance and cardiac dysrhythmias
- Avoid the use of calcium antagonists or digoxin
- Agents safe for use in patients with MH: Vecuronium, pancuronium, etomidate, propofol, opiates, barbiturates, and benzodiazepines

The addition OR increase in dosage of serotonergic agent, PLUS three of the following:

- Fever
- Mental status changes (drowsiness, agitation, confusion, seizure, coma)
- Diaphoresis
- Diarrhea
- Myoclonus (lower more than upper extremities)
- Mydriasis
- Tremor
- Incoordination
- Hyperreflexia
- Autonomic dysfunction (hypertension, tachycardia, tachypnea)

Other Drug-Related Causes

Although any drug can cause a febrile reaction, penicillin and penicillin analogs are the most frequent causative agents. Many of the herbal and naturopathic supplements used by patients may interact with other medications causing fever as well. Drugs that are commonly associated with a drug fever are listed in eTable 10.4; however, drug fever should always be a diagnosis of exclusion.

eTABLE 10.4
Drugs Commonly Associated with Fever

Antibiotics
- Amphotericin
- β-Lactams
- Cephalosporins
- Isoniazid
- Nitrofurantoin
- Penicillins
- Rifampin
- Sulfonamides
- Vancomycin

Anticancer Drugs
- Bleomycin
- Streptozocin

Anticonvulsants
- Carbamazepine
- Phenytoin
- Barbiturates

Cardiac Drugs
- Hydralazine
- Methyldopa
- Nifedipine
- Procainamide
- Quinidine

Nonsteroidal Anti-Inflammatory Drugs
- Ibuprofen
- Salicylates

Others
- Cimetidine
- Iodides
- Interleukin

Some drugs used recreationally or as toxic ingestions (overdoses) are associated with elevated temperature, including cocaine, amphetamines, belladonna alkaloids, tricyclic antidepressants, and monoamine oxidase inhibitors. Salicylates as acute overdoses or in chronic poisoning may also cause fever. Chronic salicylate

intoxication may present similarly to sepsis, particularly in the elderly.

Venous Thromboembolism

Research using patient data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study found, after eliminating other sources of fever, 24% of patients with a pulmonary embolus were febrile. Although the fever in the majority of these patients was low grade, 6% had a temperature of at least 38.3˚C and 2% had a temperature of at least 38.9˚C (16).

A recent study of more than 14,000 patients found that almost 5% of patients who had a DVT presented with a fever. They also found that in patients with a DVT, those who were febrile on presentation had a twofold higher mortality rate than those who were afebrile (17).

Central Nervous System Lesions

Structural lesions, head trauma, and strokes can cause elevated temperature either by direct destruction of the hypothalamic thermoregulatory center (hypothermia is more likely) or, more commonly, by blood irritating the central receptors in the preoptic area. Acute subdural hematomas may elevate body temperature, and therefore nonaccidental trauma should be considered in the differential diagnosis of an irritable infant with unexplained fever.

Rheumatologic and Connective Tissue Disorders

Fever may be the initial manifestation of many connective tissue and rheumatologic disorders. In systemic lupus erythematosus (SLE), fever is the initial symptom in 5% of cases. In older patients, temporal arteritis may present as recurrent fevers with no identifiable source.

Neoplastic Diseases

Although many different malignancies and tumors may produce fever, the most common are leukemia, Hodgkin disease and nonHodgkin lymphoma, hepatoma, and atrial myxoma. However, since the underlying disease and/or its treatment often leaves the patient immunosuppressed, it is important to eliminate occult infection as the etiology of the fever.

Inherited Diseases

Patients with familial Mediterranean fever have recurrent fevers of variable intervals, symptoms of polyarthralgias, and chest (pleural) and abdominal pain; however, this is a diagnosis of exclusion.

Endocrine Disorders

Thyroid disorders, including hyperthyroidism and subacute thyroiditis, and adrenal disorders, especially adrenal insufficiency (Addison disease), often include findings of fever.

DIAGNOSTIC APPROACH

An accurate temperature measurement is of utmost importance when approaching a patient with a report of fever. This is particularly true in the case of the very young, very old, or immunosuppressed patient, yet is often omitted for the sake of convenience. Recorded temperatures may vary widely depending on the method used to obtain them. Rectal temperatures have long been the gold standard, but because of the invasiveness and relative difficulty in obtaining them, easier methods are often employed. Newer generation urinary catheters allow for bladder temperature measurement, which is also an accurate method of core temperature measurement. Multiple studies have shown that none of these alternative methods consistently provides a reliable measurement of core temperature that is comparable to the rectal temperature. In addition, there appears to be no standard correction factor that may be used to improve their accuracy.

The rectal temperature tends to be 0.7°C higher than a simultaneously obtained oral temperature, although oral

temperatures can vary more than 1.6°C, depending on where the probe is positioned in the mouth, the respiratory rate (an increase in respiratory rate results in decreased oral temperature), and the recent consumption of cold or warm foods or liquids.

Many studies have shown axillary, tympanic, and temporal artery temperatures are poorly sensitive for detecting fevers and that no reliable conversion factor to determine rectal temperature exists. While study results for pacifier thermometers have shown good correlation with rectal temperatures, poor sensitivity remains an issue. In addition, due to the need for patient cooperation (sucking the pacifier) and relatively long time periods for readings to results (several minutes), they have little practical use in the ED (7).

Laboratory Evaluation

While no test exists that easily identifies patients with serious infections, a thorough understanding of certain basic laboratory tests can greatly enhance patient evaluation. Although the WBC count is the oldest and best known screening test used to differentiate serious bacterial infections from other disorders, it is not specific or sensitive in either adults or children. Though still commonly used in clinical practice, a recent large systematic review found leukocytosis had a sensitivity and specificity of only 58% and 73%, respectively, for predicting serious bacterial infection in children (18). In a study of adults with unexplained fever after careful physical examination, only 15% had a WBC count $\geq$15,000/μL, and only 56% of those patients were subsequently shown to have a bacterial source (19). Several noninfectious processes including burns, fractures, steroids, diabetic ketoacidosis, and Addison disease can increase the WBC count. Patients with low WBC counts ($<$1,000/μL), however, are at significant risk for occult bacterial infections.

A “left shift” is only slightly more useful. Neutrophilia may occur secondary to emotional or physical stress, acute or chronic inflammation, benign or malignant tumors, myeloproliferative disorders, asthma, seizures, or medications such as steroids, lithium,

or epinephrine. Neutrophil counts >30,000/μL have been reported secondary to strenuous exercise, seizures, and lithium use. In addition, a total neutrophil band count >1,500/μL was found in approximately one-third of adult patients with unexplained fever, of which only half proved to have bacterial infections (19).

The occurrence of thrombocytopenia in septic patients has been recognized for many years. Studies have shown longer stays in the intensive care unit and a higher mortality rate in patients with thrombocytopenia. Acute phase reactants, ESR and CRP, are often used to help recognize patients with serious occult infections, though both of these tests lack sensitivity and specificity. The ESR is often used as a screening test for temporal arteritis, bacterial endocarditis, tuberculosis, osteomyelitis, septic joints, and occult bacteremia in children.

CRP is more sensitive and specific and rises faster than the ESR, but is not particularly useful in the ED currently. Procalcitonin is another biomarker of interest for differentiating those patients with significant infections. A large systematic review looking at the diagnostic value of laboratory tests in identifying serious bacterial infections in children found that both CRP and procalcitonin had potential diagnostic value; however, there was no consensus on what cutoff values should be used for ruling in or out serious infections (18). Though both CRP and procalcitonin appear promising, further studies are needed to improve sensitivity and specificity before they can be used consistently in the ED.

Elevated lactate levels reflect tissue hypoxia and decreased global perfusion in the seriously ill patient and are associated with mortality in sepsis that is independent of organ dysfunction (20). In the most recent update to the Surviving Sepsis Guidelines, sepsis-induced hypoperfusion was defined as hypotension after fluid bolus or a lactate ≥4 mmol/L (15). In addition, research has shown that even moderate elevations in lactate (2 to 4 mmol/L) are associated with worse clinical outcomes (21). Further, a previous study has also shown that septic patients with an elevated lactate (≥4 mmol/L) who were normotensive, had a mortality rate similar to septic patients who were hypotensive (20% and 19%,

respectively) (22). A point-of-care lactate can easily and quickly be obtained from a venous or arterial blood gas sample and rapidly help to risk stratify the patient and direct their care and disposition.

A urinalysis may also identify an infectious source of fever and indicate a UTI or pyelonephritis. In uncomplicated UTIs, urine cultures are probably not necessary at the time of initial diagnosis, though in elderly women, men, children, or patients who are pregnant or have comorbid diseases, and in cases resistant to therapy, urine cultures are recommended. In adults in whom there is a high clinical suspicion but a negative urinalysis, urine cultures should be obtained and treatment initiated. The formation of significant levels of nitrites or leukocytes in the urine occurs over time (up to 6 hours), and therefore, patients with urinary frequency may have a falsely negative urinalysis. Conversely, 10% to 50% of nursing home patients have chronic asymptomatic bacteriuria (essentially 100% in those with indwelling catheters), so the diagnosis of UTI as a cause of fever or mental status changes should be made with some caution (12).

Like many laboratory tests, there is no consensus on the value of routine blood cultures in febrile patients. The incidence of bacteremia in the ED has been reported to vary from 2.6% to as high as 10.7% of febrile patients. Mortality from bacteremia ranges from 20% to 40%; there are no data, however, on mortality for clinically unsuspected bacteremia.

Sklar and Rusnak (23) examined the value of outpatient blood cultures in febrile adults discharged from the ED. In this study, 5 of 86 patients subsequently proved to have positive blood cultures; 4 were subsequently admitted. No long-term morbidity was noted. Of these patients, 3 were diagnosed with endocarditis and 1 with pyelonephritis. The fifth patient, who refused to return for admission, had presumed pneumococcal endocarditis. Each of the patients with endocarditis had identifiable risk factors (2 with murmur and a history of rheumatic fever, 1 on dialysis and with a murmur, and 1 IV drug abuser). Other studies have shown that patients with underlying illnesses, most commonly diabetes, are at greater risk for bacteremia, and this study seems to support those

findings. Therefore, it is prudent to limit outpatient blood cultures to febrile patients who have underlying diseases or risk factors (e.g., murmurs, IV drug use, immunosuppression, diabetes).

For inpatients, the current recommendations are to obtain cultures in patients who are septic, have an altered mental status, are ill appearing with unexplained leukocytosis, or are immunocompromised. In addition, some recommend blood cultures to identify the causative organism in pneumonia, osteomyelitis, meningitis, or septic arthritis, but in general it is preferable to obtain cultures directly from the infected site. Blood cultures are rarely helpful adjuncts in the management of immunocompetent patients with simple infections.

Laboratory studies, such as liver function tests or thyroid function tests, may identify a potential etiology for fever (such as hepatitis or thyroid storm) and should be directed based on historical clues and physical examination findings. Serologic testing may confirm the presence of other entities causing fever, such as amebiasis, mononucleosis, toxoplasmosis, chlamydial infections, cytomegalovirus (CMV), brucellosis, and HIV/AIDS. Specific studies on stool or cultures of the oropharynx could also be ordered when the history supports their consideration.

Cerebrospinal fluid (CSF) analysis can be obtained in patients with fever, headache, photophobia, and signs of meningeal irritation such as nuchal rigidity, Kernig sign (with the thigh flexed at the hip, there is pain or resistance with knee extension), or Brudzinski sign (passive flexion of the head onto the chest induces flexion of the lower limbs). The CSF should be routinely analyzed for protein, glucose, Gram stain, and cell count with differential. In selected cases, a venereal disease research laboratory (VDRL)/rapid plasma reagin (RPR) for syphilis, viral cultures, or tests for bacterial antigens should be added. Indwelling ventriculoperitoneal (VP) shunts may be accessed for obtaining CSF in the patient with symptoms of fever and meningitis with or without hydrocephalus.

Various antigenic tests are available; they have the advantage of identifying a specific organism when positive. Latex agglutination is rapid, economical, and noninvasive. Better results are obtained with

urine than with serum or CSF, presumably because the antigens are more concentrated in urine. Unfortunately, these tests historically have had a high specificity (>99%) but a low sensitivity. Enzyme-linked immunosorbent assay (ELISA), an immunologic test, is much more sensitive in detecting pneumococci than latex agglutination. An ELISA assay is also used to detect West Nile virus IgM, but this test may be falsely negative if tested too early because IgM takes time to develop.

Quicker means of identifying organisms grown in blood cultures are also available. DNA probes have been developed that, when mixed with the growth from positive blood culture bottles, directly and rapidly identify *Staphylococcus aureus, Streptococcus pneumoniae, Escherichia coli, Haemophilus influenzae, Enterococcus* sp., and *Streptococcus agalactiae.* Polymerase chain reaction (PCR) is useful in diagnosing viral meningitis and has a high sensitivity and specificity for herpes simplex type I, Epstein–Barr virus, *Enterovirus,* and *Cytomegalovirus* (considered the gold standard for CMV). PCR can also detect tuberculosis and acute neurosyphilis.

For discussion on the workup and management of fever in infants and children, see Chapter 222.

Neutropenic Cancer Patients

The management of neutropenic cancer patients (absolute neutrophil count <500 cells/mm^3 or a count <1,000 cells/mm^3 with a predicted decrease to <500 cells/mm^3) presenting with a fever is evolving. Whereas previous guidelines recommended admission and IV antibiotics for all of these patients, recent strategies focus on early oral therapy, outpatient management, and discontinuation of antibiotics in low-risk patients. Recommended evaluation of febrile neutropenic patients includes a thorough history and physical examination to localize a source of fever; CBC with differential, liver, and renal function tests (necessary for antibiotic choices); and blood cultures for bacteria and fungi (one set from any central venous access device and one peripheral set). Urinalysis should be performed, but urethral catheterization is discouraged in this patient population. Urine culture should be

obtained if the urinalysis is abnormal, if there are signs or symptoms of a UTI, or if there is an indwelling catheter. Chest radiography should be obtained only if indicated by respiratory signs or symptoms or if there is consideration of outpatient therapy. Site-directed studies based on history and physical examination (e.g., lumbar puncture [LP], aspiration, and culture of abscesses) are also recommended. In addition, caution should be used in obtaining rectal temperatures in neutropenic patients due to the risk of causing occult bacteremia from rectal probe insertion.

Because neutropenic patients with bacterial infections cannot reliably be distinguished from noninfected patients at presentation, empiric IV antibiotics should be administered promptly. After evaluation, patients who look well, have no focus of bacterial infection (including vomiting or diarrhea), and are felt to be at low risk for severe infection may be considered for outpatient antibiotic therapy if they can be carefully observed at home and have prompt access to health care 24 hours a day. Factors favoring a low risk of infection in adults are listed in eTable 10.5.

eTABLE 10.5
Factors Favoring Low Risk of Infection in Adults with Febrile Neutropenia

- Age <60 yrs
- Absolute neutrophil and monocyte counts ≥100 cells/mm^3
- Normal chest radiograph
- Normal/near normal hepatic and renal function tests
- Outpatient status at time of fever onset
- Duration of neutropenia <7 days or expected resolution in <10 days
- No evidence of IV catheter site infection
- Early evidence of bone marrow recovery
- Malignancy in remission
- Peak temperature <39°C
- No prior history or treatment of fungal infection
- Asymptomatic or does not appear ill
- Absence of neurologic or mental status changes
- Absence of abdominal pain
- No comorbid conditions or complications (e.g., diabetes, hypotension)

From Mellors JW, Horwitz RI, Harvey MR, et al. A simple index to identify occult bacterial infection in adults with acute unexplained fever. *Arch Intern Med.* 1987;147(4):666–671.

For discussion of the workup and management of infants and children, see Chapter 222.

Imaging Studies

A chest radiograph should be obtained in patients with lower respiratory complaints and examination abnormalities, or any patient who is at high risk for aspiration, such as an elderly patient with altered mental status or a patient with a history of alcohol abuse. Routine chest radiographs are commonly obtained in patients who present with fever without an obvious source as well. This practice is probably based on studies that show a lack of auscultatory findings in patients with infiltrates on chest radiographs. In one study, physical examinations performed by an experienced internist, pulmonologist, and infectious disease subspecialist were only 47% to 69% sensitive in detecting radiographically proven pneumonia. However, all of these patients

had symptoms suggestive of pneumonia and did not represent patients with a fever and no source (24).

Signs or symptoms should guide the need for other imaging studies. Plain films may reveal osteomyelitis in patients with fever and bone pain, but bone scans and magnetic resonance imaging (MRI) are more sensitive. Abdominal radiographs may identify free air (bowel perforation), appendicoliths (appendicitis), or "thumbprinting" or gas in the bowel wall (mesenteric ischemia). Patients with fever and abdominal pain may benefit from an ultrasound to evaluate for the presence of cholecystitis or tuboovarian abscess. Ultrasound may also be of use in localizing soft tissue abscesses as fever source, especially in the IV drug user. Computed tomography (CT) scans should be used in selected patients to evaluate for appendicitis, abdominal abscess, or diverticulitis. MRI is the study of choice to rule out epidural abscess. Echocardiography (particularly transesophageal echocardiography [TEE]) should be used to evaluate suspected endocarditis patients for valvular disease. It may also be used in the patient with suspected pericardial effusion from inflammatory, malignant, or infectious processes.

CRITICAL INTERVENTIONS

- Initiation of antibiotics as appropriate
  - Should be based on the type and site of infection if possible
  - Send appropriate cultures prior to antibiotics if possible
- Do not delay antibiotics for LP in suspected meningitis
- Check lactate in patients with suspicion of infection and SIRS criteria
- A protocolized, quantitative resuscitation in severe sepsis and septic shock
  - See Table 10.2 for treatment recommendations
- Antipyretics for patient discomfort or tachycardia
  - Acetaminophen: 15 mg/kg in children, 650 to 1,000 mg in adults
    - May repeat every 4 to 6 hours depending on dose

- Maximum dose: 90 mg/kg/day or 4 g/day
- Ibuprofen: 10 mg/kg in children, 400 to 600 mg in adults
  - May repeat every 6 to 8 hours depending on dose
  - Maximum dose: 40 mg/kg/day or 2.4 g/day
    - Should not be used for more than a few days at max dose
  - Not approved for infants <6 months old
- Repeat vital signs and reassess patient frequently
- Drug-related fever
  - Stop offending agent
  - MH: See Table 10.3 for treatment recommendations
  - SS: Supportive care is the mainstay of treatment
    - Benzodiazepines may help with hyperactivity
  - NMS: Specific treatment not well established
    - Dantrolene: Most useful in patients with prominent muscle contraction
    - Bromocriptine mesylate: Use alone or in combination with dantrolene
      - Most useful when dramatic muscle rigidity is not present
    - Levodopa and carbidopa–levodopa: Useful in many patients
      - Particularly useful in cases associated with medication withdrawal
- Aggressive cooling measures in hyperthermia
  - If temperature >41°C, cool to 39°C within 30 minutes
  - Use cool water spray with fans or cooling blankets
  - Control shivering with benzodiazepines or chlorpromazine
    - Avoid phenothiazines in NMS
  - Monitor for rhabdomyolysis, electrolyte abnormalities, and disseminated intravascular coagulopathy (DIC)
  - Remember: This is not a true fever, so antipyretics are typically ineffective

DISPOSITION

When considering the disposition of the febrile patient, the most important considerations are age and general health. Infants who are younger than 90 days old or incompletely immunized require a

more extensive evaluation and may require admission or discharge with close follow-up.

For a discussion of the management of infants and children with a fever, see Chapter 222.

Patients who appear nontoxic and have no medical problems have a very slight chance of developing a serious infection (with the exception of IV drug abusers). As the age and presence of underlying medical problems increase, the chance of serious occult infection increases and makes admission advisable. Keating et al. (25) found that 95% of patients who were older than 60 years and had a temperature >38.3°C (101°F) on admission to the ED had a serious infection, and 92.5% required admission.

Most patients with unexplained fever and neutropenia or malignancy should be admitted for further workup. Patients with diabetes are at special risk, as are patients who are taking corticosteroids. Alcoholics are also considered to be immunosuppressed and at increased risk for complications. Also, pregnancy-related immunosuppression increases morbidity and mortality in pregnant females and may necessitate admission for infections that would otherwise be handled on an outpatient basis.

The postsplenectomy patient is at special risk for developing clinically unapparent bacteremia, usually from *S. pneumoniae.* These patients often have fever and a flu-like syndrome as their only complaints. Even when promptly diagnosed and started on antibiotics, the mortality rate remains high (50% to 75%). Although most postsplenectomy patients should be immunized against *S. pneumonia,* it is important to approach these patients cautiously and keep a high level of suspicion.

If good follow-up can be arranged, specimens for cultures can be obtained in the ED, and the nontoxic, low-risk patient can be discharged and rechecked in 24 hours when initial culture results become available. Continued follow-up or contact is necessary until cultures are confirmed to be negative.

Common Pitfalls

- Failure to obtain a rectal temperature, especially in the elderly or immunosuppressed
- Discounting parental reports of fever in infants who are afebrile in the ED
- Attributing fever in infants to overbundling
- Failure to check a lactate when clinically appropriate
- Relying on the WBC count or the response to antipyretics to determine the presence or seriousness of an infection
- Disregarding (even transient) hypotension
- Failure to perform a protocolized, quantitative resuscitation in septic patients
- Failing to reassess patient's response to treatment and repeat vital signs
- Failure to immediately and aggressively cool patients with severe hyperthermia (>41°C)

CHAPTER 11

Altered Mental Status and Coma

J. Stephen Huff and Marcus L. Martin

Viewed from a physiologic perspective, consciousness is the sum of the activities and interactions of the reticular activating system and the cerebral cortex. A useful model is to think of the general state of alertness and wakefulness as arising in the reticular activating system, a group of neurons in the brainstem. Cognition, language, personality, and higher awareness of the environment are functions of the cerebral cortex. Coma results from the dysfunction of either the reticular activating system, the bilateral cerebral cortices, or both the reticular activating system and the cerebral cortices.

CLINICAL PRESENTATION

A patient with an altered mental status presents along a spectrum of consciousness. In the drowsy or lethargic state, there is slightly decreased wakefulness and interaction with the environment, but the patient may be aroused by verbal stimuli or light touch. Coma is the state in which the patient cannot be fully aroused to normal alertness by any environmental stimuli. The deeply comatose patient has failure of the arousal system and is unable to be awakened by vigorous sensory stimulation. Obtundation and stupor are intermediate states where the patient may be awakened only briefly by energetic stimulation. Rather than using clinical terms that are sometimes inexact, a simple description of the patient's

response to the examiner's stimulus is preferred for clarity in communication.

Some other disorders of consciousness include the recently described "minimally conscious state" in patients with inconsistent but discernible evidence of partial consciousness; these patients may demonstrate sustained visual fixation and limited motor function including localizing stimuli and automatic movements such as scratching. The *persistent vegetative state* is characterized by complete absence of self or environmental awareness but with preserved capacity for stimulus-induced or spontaneous arousal. Sleep–wake cycles are preserved. The *locked-in syndrome* is a mimic of altered consciousness. Because of damage to efferent motor tracts, patients appear to lack responsiveness but have preserved consciousness, cognition, and emotion; they are tetraplegic and are unable to speak. Sometimes vertical eye movements are the only remnant of voluntary motor activity. This syndrome is often due to pontine infarction, but high cervical spinal cord injuries and severe drug-related dystonias may simulate the syndrome. Clinicians may underestimate the degree of awareness in patients with altered mental status and it is best to assume that some element of comprehension is preserved.

Pathophysiologic causes of coma may range from dysfunction at the cellular level to grossly visible pathologic changes of the brain. Impairment at the larger structural level includes focal injury to central nervous system (CNS) structures, which may result from increased intracranial pressure, reduction in cerebral perfusion pressure, or from direct destruction due to tumors, trauma, stroke, or hemorrhage. Dysfunction of many of the body's organ systems may impair CNS function at a cellular level. This may occur with hypothyroidism or adrenal insufficiency, with disturbances of electrolyte regulation such as hypo- or hypernatremia, hypercalcemia, or other metabolic disturbances, such as hypoglycemia or hyperosmolar states. Illnesses resulting in renal or hepatic damage may cause encephalopathies with impairment of neurotransmitters likely being the mechanism. Hypoxia from pulmonary or cardiac etiologies may also affect CNS function.

Hypotension with decreased cerebral perfusion may result from a primary cardiac etiology, sepsis, or volume loss from gastrointestinal (GI) bleeding or trauma. External environmental or toxic insults may also cause CNS depression through a direct effect at the cellular level or secondarily through damage to specific organ systems.

In general, when the CNS function is impaired at the cellular level, global CNS dysfunction follows and focal clinical findings such as hemiparesis or abnormal extraocular movements are not present on examination. Some notable clinical exceptions are hypoglycemia, hyperglycemia, and hepatic failure where focal findings may be seen. Pupillary light reflexes generally remain intact with toxic and metabolic causes of altered mental status, except when the CNS depression is caused by certain toxins that affect pupillary size, such as anticholinergics or opiates.

There are often focal findings on examination when a destructive process causes structural damage to a specific area of the CNS. Localized lesions of the CNS may also induce an additional injury process such as cerebral edema secondary to a tumor or hemorrhage, or vasospasm following aneurysmal subarachnoid hemorrhage.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of coma is extensive (Table 11.1). In the emergency department (ED), history and physical examination will help narrow the possibilities. History will often suggest a likely cause and all sources—family, witnesses, emergency medical service (EMS) providers, and medical records—should be considered. The emergency physician must identify reversible causes and remediate injury when possible while simultaneously pursuing a strategy to sort the patient with altered mental status into structural, metabolic, infectious, toxic, environmental, or other etiologies. An organized approach is necessary to detect easily remedial cause, prevent ongoing neurologic injury, and determine a diagnostic strategy.

TABLE 11.1
Differential Diagnosis of Altered Mental Status and Coma

Metabolic Causes
Electrolyte disorders
Hypernatremia
Hyponatremia
Hypercalcemia
Hypoglycemia
Hypermagnesemia
Diabetic ketoacidosis
Hyperglycemic hyperosmolar states
Hypothyroidism
Thyrotoxicosis
Adrenal insufficiency
Hepatic encephalopathy
Uremia
Thiamine deficiency (Wernicke encephalopathy)

Infectious Etiologies
Meningitis
Encephalitis
Intracranial abscess
Sepsis

Vascular Causes
Hypertension
Hypotension
Vasculitis
Cerebrovascular accident (thrombotic or hemorrhagic)
Subarachnoid hemorrhage (aneurysm or AVM)

Neurologic Structural Etiologies
Tumor
Hydrocephalus
Intracerebral hemorrhage

Seizures
Status epilepticus

Trauma
Subdural hematoma
Epidural hematoma
Cerebral contusion
Diffuse cerebral edema

Toxicologic Etiologies
Carbon monoxide
Ethanol, methanol, isopropyl alcohol, ethylene glycol
Drug abuse and overdose

Environmental Etiologies
Heatstroke
Hypothermia
High-altitude cerebral edema (HACE)
Near drowning
Dysbarism

Hypoxia and Hypoglycemia

In the evaluation of any patient with mental status changes or coma, failure of substrate supply necessary for neuronal function (oxygen, glucose) must always be considered. After briefly evaluating for hypoxia and initiating oxygen supplementation, hypoglycemia, another common cause of altered mental status that is readily

detectable and reversible, must be considered. Hypoglycemia is most common in patients on insulin therapy. It may be due to dosage errors, missed meals, a change in exercise pattern, or erratic absorption from injection sites. Interaction with other drugs, such as β-blockers or salicylates, may potentiate hypoglycemia. The oral hypoglycemic agents may also produce hypoglycemia. Many of these agents have a long duration of action, and pharmokinetics may change with overdosage, so the patient should be carefully observed for recurrent hypoglycemia or admitted. Hypoglycemia may also occur with alcohol intoxication and some other toxins. Renal or hepatic disease and other processes such as sepsis also increase the risk that a patient will develop hypoglycemia.

When blood glucose levels fall to a level of 50 to 70 mg/dL, symptoms of CNS excitation may appear; these may include anxiety, tremor, sweating, and occasionally hallucinations. As the glucose level falls further, progressive CNS depression and coma occur. Brainstem reflexes are preserved until late. Loss of consciousness is usually preceded by a period of confusion but may happen suddenly. Hypoglycemia may also cause focal neurologic signs including hemiparesis and should be considered early in the differential diagnosis of stroke. Other described signs of hypoglycemia include hyperreflexia, pupillary dilation, tachycardia, and primitive movements such as sucking movements of the lips, forced grasping, and extensor plantar responses.

Hyperglycemia

At the other end of the glycemic spectrum are the hyperglycemic conditions that may also cause altered mental status. Diabetic ketoacidosis (DKA) may be seen as the initial presentation of new-onset juvenile diabetes, in a known diabetic with poor compliance, or in a diabetic with a precipitating stressful event such as infection. A history of polyuria, polydipsia, nausea, vomiting, or abdominal pain may be obtained. Acetone-tinged breath or Kussmaul breathing may be present. Hyperosmolar hyperglycemic nonketotic coma typically occurs in an older patient with undiagnosed diabetes or

type II diabetes experiencing another intercurrent illness. Gram-negative pneumonia, uremia with vomiting, or acute viral illnesses are the most commonly reported predisposing conditions. In contrast to DKA, the patient often has a longer period of symptoms before presentation.

Adrenal and Thyroid Emergencies

Though unusual in clinical practice, adrenal and thyroid emergencies are important to consider in the differential diagnosis of coma since treatment may be lifesaving. In a patient with suspected myxedema coma, history may reveal symptoms or prior treatment of hypothyroidism. Radioactive iodine treatment is associated with a relatively high incidence of delayed hypothyroidism. A history of noncompliance with thyroid medications may be obtained. Clinically, mild hypothermia, hypotension, and bradycardia may be present as well as periorbital and pretibial nonpitting edema. On neurologic examination, the muscle relaxation phase of the deep tendon reflexes is often described as delayed. Laboratory studies may reveal hyponatremia, hypo-osmolarity, and an elevated creatine phosphokinase as well as abnormalities in the thyroid laboratory panel.

Thyroid storm rarely presents as coma. Confusion, agitation, or occasionally hallucinations are more common. Temperature above 38°C (hyperthermia), tachycardia, and cardiac failure may be present. Often there is a precipitating event such as trauma or infection.

Acute adrenal crisis may occur because of an acute exacerbation of chronic adrenal insufficiency, rapid cessation of chronic steroid medications, or adrenal hemorrhage. Physiologic stressors such as infection, trauma, or surgery may all precipitate an adrenal crisis. Nausea, vomiting, abdominal pain, and fever may be present. Hypovolemic shock may develop and the mental status may deteriorate into lethargy or coma. A patient with known adrenal insufficiency or who is taking glucocorticoid replacement

medication may not develop dehydration and hypotension until late in the course of adrenal crisis.

Hypertension

There is no distinct level of hypertension that correlates with mental status changes. In a patient with altered mental status and severe hypertension, possible causes include intracerebral hemorrhage or hypertensive encephalopathy. Hypertension is often present in subarachnoid or intracerebral hemorrhages. Hypertension, headache, altered mental status, and focal findings such as hemiparesis or aphasia are consistent with intracerebral hemorrhage. Subarachnoid hemorrhages may present with diffuse neurologic findings on examination and mental status changes range from confusion to coma. The classic history is the sudden onset of a severe headache associated with nausea and vomiting. A patient may give a history of prodromal headaches in the preceding weeks. In a small number of patients with subarachnoid hemorrhage, the computed tomography (CT) scan is normal. If a subarachnoid hemorrhage is suspected and the CT scan is negative, a lumbar puncture must be performed. Hypertensive encephalopathy is a diagnosis of exclusion. Funduscopic changes such as papilledema or hemorrhages will be present. Posterior reversible encephalopathy syndrome (PRES) is associated with uncontrolled hypertension and visual changes. MRI is the confirmatory procedure showing changes suggesting white-gray matter edema involving the posterior cerebral regions.

Toxic Causes

There are a wide variety of medications and illicit substances that may produce mental status changes. Correct diagnosis requires obtaining an adequate history and recognizing the toxidromes that appear in some specific toxic exposures.

High doses of benzodiazepines may produce sedative–hypnotic effects. Cardiac depression is usually minor, as is respiratory depression. However, respiratory depression may become severe if

benzodiazepines are combined with other CNS depressants, in the elderly, or in patients with underlying respiratory disease.

Opiates and barbiturates may produce severe respiratory depression and hypotension. Miosis is usually present with opiates (exceptions are meperidine, propoxyphene, and tramadol, with which pupils may be of normal size). Pulmonary edema is most commonly seen with intravenous (IV) heroin overdose but may occur in other opiate or barbiturate intoxications. Cutaneous bullae and hypothermia may occur with sedative–hypnotic overdoses and are associated with prolonged unresponsiveness.

Ethanol intoxication may produce a somnolent, difficult-to-arouse patient with varying degrees of respiratory depression. Ingestion of ethanol substitutes such as methanol, ethylene glycol, or isopropyl alcohol also occurs in the alcoholic or with intentional overdoses. Isopropyl alcohol can present as stupor in a known alcoholic or as an encephalopathy of unknown cause in persons with hidden addictions. In addition to CNS depression, GI effects (abdominal pain, gastritis, nausea, or vomiting) and cardiac toxicity can occur. The major metabolite of isopropyl alcohol is acetone; as such, the severe anion-gap metabolic acidosis seen in methanol and ethylene glycol poisoning is not seen with isopropyl poisoning. In methanol intoxication, the patient may present with visual changes ranging from blurred vision to blindness. Calcium oxalate crystals may be present in the urine of patients who have ingested ethylene glycol. The osmolal gap should be calculated and any discrepancy that cannot be attributed to ethanol ingestion alone should prompt consideration of ingestion of other osmotically active substances.

Ingestion of tricyclic antidepressants may produce rapid mental status changes, coma, seizures, and cardiovascular effects. Sinus tachycardia is most commonly noted. The QRS complex may become widened and atrial or ventricular dysrhythmias may occur. Anticholinergic effects such as delayed gastric emptying, decreased bowel sounds, and mydriasis may be present.

A history of tinnitus and vomiting may lead the clinician to suspect salicylate intoxication. Chronic salicylism in the elderly is often subtle. Respiratory alkalosis in adults or metabolic acidosis in

children may be seen. Acetaminophen and salicylate levels should be obtained in the patient suspected of an intentional ingestion. Carbon monoxide or cyanide toxicity should be suspected if the patient has been in a fire. Carbon monoxide poisoning should also be suspected in colder weather, particularly if the patient or others in the household have experienced flulike symptoms. Arterial blood gas levels may show a normal PO_2, but the measured hemoglobin saturation may be low. Arterial blood co-oximetry should be performed to quantitate carboxyhemoglobin and to look for other abnormal hemoglobin complexes.

Seizures

Convulsive seizures are easily recognized. The clinician must remember that the seizures may be a symptom of a disease process, injury, ingestion, or withdrawal, and that epilepsy (unprovoked recurrent seizures) is largely a diagnosis of exclusion. Following generalized convulsions, patients often have altered mental status. Patients are frequently described as *postictal,* yet there is no definition or test for this condition or any consensus as to the duration. However, the clinician must always consider a broad differential diagnosis of altered mental status or complications of the seizures, particularly if the patient does not have improvement of level of consciousness over 20 to 30 minutes following cessation of the convulsive activity. Should the patient's mental status not improve following cessations of generalized convulsions, the possibility of subtle status epilepticus must be considered. Subtle status epilepticus, also known as *epileptic encephalopathy* and by other terms, is present when the abnormal electrical seizure activity is continuing in the absence of motor movements. Nonconvulsive status epilepticus, sometimes used as a synonym, may also present with prolonged confusion or altered mental status. These uncommon nonconvulsive seizures with clouded consciousness or confusion require a high level of suspicion for recognition. Typically there is a history of seizures. Neurology consultation with electroencephalographic evaluation may be required for recognition.

DIAGNOSTIC APPROACH

The initial assessment of a patient presenting with coma or transient loss of consciousness should be performed in a relatively short time and combined with stabilization procedures. The state of consciousness is determined by assessing functions of both cerebral cortical and the ascending reticular activating system. Key observations will often help determine whether the disease is of the brainstem or cerebral hemispheres.

Before the unresponsive patient arrives in the ED, field personnel should assist with airway support and administer oxygen. The spine is immobilized and stabilized if there is the possibility of trauma. IV access is obtained, and cardiac monitoring is initiated. Point-of-care glucose testing should be performed if possible, and the patient should receive glucose if hypoglycemic or if there is suspicion of hypoglycemia. Support procedures not performed by field personnel should be quickly initiated in the ED.

The history, physical examination, and serial neurologic examinations are all of importance. However, life-threatening and reversible processes causing coma or altered level of consciousness should be considered before detailed history and physical examinations are performed; these include hypoxia, hypoglycemia, poisoning, infections, and increased intracranial pressure. Evaluation of the cardiorespiratory status and blood glucose takes precedence over investigation of other potential etiologies. Glucose administration to a patient with stroke or other brain injury may theoretically worsen the injury process and should be avoided when possible by using reliable point-of-care testing.

Obtaining historical information proceeds with patient stabilization. Information should include the abruptness of change in mental status, preceding events, medical history, current medications, and use of toxic agents. The clothing should be checked for suicide notes and drug bottles, and any medical alert tags should be noted. After the ABCs have been addressed, the patient is evaluated for signs of injury, including pupillary asymmetry and reactivity, hemotympanum, and other signs of head

trauma. Assess vital signs including a core body temperature. The level of consciousness is documented, and the Glasgow Coma Scale is usually used to roughly quantify the patient's condition though limitations of the scale have been noted (see Chapter 22). Recently the FOUR score has been validated for use in comatose patients. The FOUR score includes some assessment of brainstem reflexes and may find use in the ED (Table 11.2).

TABLE 11.2
The Four Score

Eye Response
4 = eyelids open or opened, tracking, or blinking to command
3 = eyelids open but not tracking
2 = eyelids closed but open to loud voice
1 = eyelids closed but open to pain
0 = eyelids remain closed with pain

Motor Response
4 = thumbs-up, fist, or peace sign
3 = localizing to pain
2 = flexion response to pain
1 = extensor response to pain
0 = no response to pain or generalized myoclonus status

Brainstem Reflexes
4 = pupil and corneal reflex present
3 = one pupil wide and fixed
2 = pupil or corneal reflex absent
1 = pupil and corneal reflex absent
0 = absent pupil, corneal, and cough reflex

Respiration
4 = not intubated, regular breathing pattern
3 = not intubated, Cheyne–Stokes breathing pattern
2 = not intubated, irregular breathing
1 = breaths faster than ventilator rate
0 = breathes at ventilator rate or apnea

Adapted from Wijdicks EF, Bamlet WR, Maramattom BV, et al. Validation of a new coma scale: The FOUR score. *Ann Neurol.* 2005;58:585–593.

Respirations should be briefly observed before deciding if ventilatory support is necessary. Apneustic breathing, characterized by deep inspiration followed by a long apneic phase and only a few breaths per minute, suggests brainstem failure. Irregular ataxic breathing is an ominous sign of brainstem failure. Cheyne–Stokes respirations may be due to bilateral dysfunction of structures deep in the cerebral hemispheres, bilateral cerebral infarctions, congestive heart failure, hypertensive encephalopathy, or other systemic causes.

Examination of the patient's eyes may be the single most important assessment in the evaluation of coma. Coma by definition is an eyes-closed unresponsive state. An unresponsive patient who has open eyes may actually be in a persistent vegetative state or have the locked-in syndrome. The fundi are examined for evidence of papilledema or lack of venous pulsations, which might suggest increased intracranial pressure.

The shape and size of pupils and their reactions are recorded. Reactive asymmetric pupils differing in size by 1 to 2 mm (physiologic anisocoria) may be seen in 10% of normal people. In cases of toxic or metabolic coma, pupils are likely to remain small, equal, and reactive. A fixed, unilaterally dilated pupil in an unresponsive patient suggests a structural cause of coma and uncal herniation. Local trauma or topical mydriatics can also cause unilateral pupillary dilation. Stimulation of the cornea tests another brainstem reflex arc and will cause an eye to blink if the fifth and seventh cranial nerves are intact.

The patient with a possible head or neck injury presents a problem in testing doll's eye maneuvers (oculocephalic reflex) because the neck should not be manipulated. Cold water caloric testing (oculovestibular reflex) may be performed without moving the neck if additional testing for unresponsiveness or testing for additional brainstem reflexes is needed. The slow phase of caloric eye movements tests brainstem functions, and the fast phase tests cerebral functions. The rapid eye movements of nystagmus are present only in an awake patient with functioning cerebral cortices. The presence of nystagmus in an apparently unresponsive patient

indicates cortical functioning and in fact suggests psychogenic or pseudocoma. Caloric testing, performed correctly in a comatose patient, may help differentiate a brain stem lesion from a hemispheric lesion. If the brainstem is functioning normally in a comatose patient, the eyes will deviate conjugately toward the side where ice water is flushed into the ear and nystagmus will be absent. Cold calorics involve the vestibular system, the afferent functions of cranial nerve VIII, brainstem interneurons, and efferent functions of cranial nerves III (abduction of eyes) and VI (abduction).

The neck is flexed to check for nuchal rigidity if there is no contraindication or possible injury. Rigidity of the neck or resistance to flexion suggests meningeal inflammation due to meningitis or subarachnoid hemorrhage. However, the absence of nuchal rigidity cannot reliably exclude meningitis or other processes of meningeal irritation.

The patient's posture is observed, and the response to stimulation is noted. Decorticate and decerebrate posturings are abnormal postures that may be present in the deeply comatose patient. *Decorticate* or *flexor* posturing is characterized by flexion of the upper extremities with extension in the lower extremities and suggests injury to the brain above the level of the midbrain. *Decerebrate* or *extensor* posturing is characterized by arms that are extended, adducted, and hyperpronated, and legs that are extended with feet plantar flexed. Decerebrate posturing occurs in patients with infarcts of the brainstem above the level of the midpons and also in patients with large cerebral hemorrhages that destroy or compress the lower thalamus and midbrain. This motor pattern typically emerges with lesions of the internal capsule or cerebral hemisphere that interrupt the corticospinal pathways. Clinical disease patterns often cloud the demarcation between flexor and extensor posturing, and motor responses may shift back and forth depending on the location of the lesion and pressure effects on the upper brain stem.

The diagnostic approach to patients with coma or alterations in consciousness must be systematic. Orderly evaluation, with

simultaneous stabilization, is of the utmost importance. Early recognition and correction of reversible causes and prevention of further brain damage by definitive intervention are the basic principles of treatment in patients with altered consciousness. There are three primary pathologic processes that produce coma: expanding mass lesions that secondarily destroy the reticular activating system; brain stem lesions that directly damage the reticular activating system; and diffuse toxic, metabolic, or infectious processes that disrupt brain function globally. CT scanning will aid in identifying lesions that need neurosurgical treatment. In carbon monoxide poisoning, patients immediately receive high-flow oxygen. Patients suspected of meningitis receive IV antibiotics promptly when the diagnosis is considered. Patients intoxicated with ethanol receive supportive care and careful observation, and clinical determination that head injury or methanol, ethylene glycol, or isopropyl alcohol is not responsible for their presentation. In addition to general supportive care, metabolic causes, such as hypothyroidism, adrenal insufficiency, and electrolyte abnormalities receive specific treatment.

CRITICAL INTERVENTIONS

- Suggested steps in the management of the comatose patient are as follows:
- Assess the ABCs, establish and maintain the airway, and protect the patient from aspiration.
- Administer oxygen and provide ventilation as needed.
- Establish IV access and support circulation.
- Draw blood for rapid glucose determination. Other laboratory evaluation may include electrolytes, calcium, and renal and liver function; drug screen; arterial blood gas determination; complete blood count; thyroid function studies; or platelet count, depending upon the clinical situation.
- Interventions are tailored to the individual patient. If indicated by the rapid glucose determination, glucose should be administered as 25–50 mL of 50% dextrose solution to adults

and 2 mL/kg of 25% dextrose solution to children. In patients with possible thiamine depletion (alcoholics and those with other causes of chronic malnutrition), 100 mg thiamine should be administered intravenously. If a narcotic toxidrome is present or if a narcotic overdose is suspected, 2–4 mg of naloxone should be given intravenously in adults (0.01–0.1 mg/kg in children). In cases of suspected elevated intracranial pressure, measures to transiently decrease intracranial pressure including hyperventilation to reduce pCO_2 to about 35 mm Hg and administration of IV mannitol (0.5–1 g/kg) should be performed. Fluid restriction may be necessary; cerebrospinal fluid may need to be drained by intraventricular catheter by consultants. Empiric antibiotic coverage should be promptly administered in cases highly suspicious of meningitis. Antibiotic coverage should not be delayed by the diagnostic workup (i.e., inability to perform lumbar puncture due to delay in obtaining a head CT). If generalized seizures are present, a benzodiazepine (lorazepam or diazepam) is considered the initial drug of choice (see Chapter 156). The Glasgow Coma Scale, FOUR score, or other assessments are recorded.

- An electrocardiogram should be obtained, pulse oximeter applied, and a Foley catheter placed. If extreme hypothermia or hyperthermia is present, the cause of this should be sought and appropriate environmental issues initiated bring the temperature toward normal. An exception to this is the patient with return of spontaneous circulation after cardiac arrest: Institution of therapeutic hypothermia may be indicated. After the initial treatment of reversible causes and stabilization, definitive workup and therapy are instituted to prevent further CNS damage. In addition to diagnostic laboratory studies, plain radiographs (cervical spine series, chest x-ray), and head CT scan may prove helpful. CT scanning has assumed a prominent role in the evaluation of the comatose patient because of its accessibility and the ability to detect hemorrhage, edema, and masses. Lumbar puncture should be performed in suspected cases of

meningitis, encephalitis, or subarachnoid hemorrhage; this typically follows a cranial CT. MRI may be useful in some cases but is typically not available on an urgent basis.

DISPOSITION

All patients with significantly altered mental status require admission for continued evaluation and treatment after diagnostic evaluation. Consultation is required on any potentially operable focal lesions, and immediate contact with a neurosurgeon or transfer to an appropriate facility is essential. When transferring comatose patients, it is important to provide advanced life support care. Such patients generally require definitive airway control before transfer. In patients in whom there is no surgically treatable disease, consultation with either a neurologist or internist for intensive care unit admission is indicated if a rapidly reversible cause of the coma is not identified.

Common Pitfalls

- Failure to check a bedside glucose level in all patients with altered mental status.
- Delaying neurosurgical or neurologic consultation in patients with a focal abnormality requiring immediate intervention.
- Delaying the establishment of an airway, cardiovascular support, and provision of adequate oxygen and glucose to the patient with severely altered mental status.
- Failure to reexamine the patient.
- Ascribing alteration in mental status to postictal state.

CHAPTER 12 Headache

Jonathan A. Edlow

CLINICAL PRESENTATION

Headache is the reason for approximately 2% of all emergency department (ED) visits (1). This large number of patients can be divided into two groups—those with benign causes (≥95%) and those with treatable illnesses that are life, limb, vision, or brain threatening (≤5%) (1,2). These two groups are not always easily distinguished, and delay in the diagnosis of meningitis and subarachnoid hemorrhage (SAH) is an important reason for malpractice payments in emergency medicine (3).

The brain parenchyma is insensate (4). Head pain results from tension, traction, distention, dilation, or inflammation of the pain-sensitive structures external to the skull, portions of the dura, and the blood vessels. Because all of these mechanisms are likely mediated by a final common biochemical pathway resulting in pain, a favorable response to analgesics, or even the more specific antimigraine agents, should not be used to judge the cause of an individual headache (5).

These basic facts highlight two points: Headache is common, and the potential for serious diagnostic error exists. Given that emergency physicians work under both time and resource utilization pressures, physicians must develop a logical, practical, and accurate approach to distinguish between the two groups of patients (6,7).

Physicians have three tools to make this critical distinction: The history, the physical examination, and diagnostic tests.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of headache can be organized in several ways. The International Headache Society method (Table 12.1), although comprehensive, is cumbersome for use in the ED. Another method of sorting the differential diagnosis is by temporal pattern. For example, is the current headache a chronic recurring one or is it a new-onset unusual event? Still a third method, and one that is consistent with the way emergency physicians work, is the division of headaches into the two groups listed previously. The problems that are life, limb, brain, or vision threatening are referred to as cannot-miss diagnoses (6,8). These disorders result in serious morbidity or mortality if untreated (Table 12.2).

TABLE 12.1
International Headache Society Classification

Diagnostic Group: Headache Associated with	Comments
Migraine	Requires five or more attacks of a specific nature. For migraines with neurologic deficits (e.g., ophthalmoplegic), other etiologies should be excluded
Tension type	Requires 10 or more attacks of specific nature. Absence of nausea, vomiting, and photophobia
Cluster and chronic paroxysmal hemicrania	Always unilateral. Periorbital location lasting minutes to hours. Associated with eye, nose, or face symptoms (e.g., rhinorrhea)
Miscellaneous headaches unassociated with structural lesions	This group includes a variety of brief (idiopathic stabbing headache), situational (cough, exertional, coital) headache syndromes
Head trauma	This group includes the minor postinjury headaches
Vascular disorders	A very important group for emergency physicians, which includes brain ischemia and infarction and all forms of intracranial hemorrhage, venous sinus thromboses, giant cell arteritis, arterial dissections, and hypertensive encephalopathy
Nonvascular intracranial disorders	Includes idiopathic intracranial hypertension, post-LP headache, and headaches from meningitis, encephalitis, and brain abscess and tumor
Substances or their withdrawal	Includes drugs and food additives (e.g., monosodium glutamate headache, or Chinese restaurant syndrome); also includes headache from carbon monoxide poisoning
Noncephalic infection	Includes pain due to febrile illnesses (e.g., pyelonephritis, pneumonia, and acute viral syndromes)
Metabolic disorder	Includes headaches from hypercarbia or high altitude illness
Disorders of HEENT-associated (includes dental)	Includes narrow angle closure glaucoma. Note that for sinus headache to be confidently diagnosed, specific criteria must be followed. Chronic sinusitis should not cause headache
Cranial neuralgias, nerve trunk and deafferentation pain	Most of these are cranial neuropathies and herpes zoster
Not classifiable	Others

TABLE 12.2
“Cannot Miss” Causes of Headache (see Text for Definition)

Diagnosis	Suggestive History and Physical Findings	Diagnostic Testing
Meningitis and encephalitis	Fever, stiff neck, jolt accentuation, altered mental status, seizure	LP (if preceded by a CT because of concern for raised intracranial pressure, give antibiotics before CT)
Subarachnoid hemorrhage	Abrupt onset of severe headache, stiff neck, third nerve palsy	CT scan LP if CT is nondiagnostic
Stroke (ischemic or hemorrhagic)	Abrupt onset and focal neurologic deficit conforming to an arterial territory	CT scan; MRI if available will give more information (should not delay thrombolytic therapy)
Dissection of craniocervical arteries	Neck pain, abrupt onset, variable presence of neurologic deficit	MRA (or conventional angiography)
Hypertensive encephalopathy	Severe (usually chronic) hypertension Often papilledema and other signs of end-organ damage	Careful, titratable lowering of BP to ~25% off the peak BP will decrease the headache
Idiopathic intracranial hypertension	Obese, female patient Papilledema, often sixth nerve palsy	LP (following an imaging study, that by definition will be normal)
Giant cell arteritis	Nearly always age >50 years Symptoms of polymyalgia rheumatica Abnormal scalp vessels on examination	ESR Temporal artery biopsy
Acute angle closure glaucoma	Painful red eye with midposition pupil and corneal edema	Tonometry
Intracranial mass (tumor, abscess, hematoma)	Any neurologic finding, focal or generalized	CT scan; if available, MR will give more information
Cerebral venous sinus thrombosis	Hypercoagulable state of any type	MRI and MRA with venous phase
Carbon monoxide poisoning	Cluster of cases, winter season	COHb level
Pituitary apoplexy	Visual acuity or field abnormalities Known pituitary tumor	MRI

Overall, primary headache disorders such as migraine, cluster, and tension headaches are by far the most common causes of headache (9). Detailed discussions of the primary headache syndromes and the other individual disease entities are discussed in other chapters (Chapters 156 and 157). This chapter focuses on strategies to avoid missing these cannot-miss diagnoses.

DIAGNOSTIC APPROACH

The physician has two parallel and related goals: Correct diagnosis and effective treatment, with the first goal facilitating the second. Not only is it perfectly acceptable to begin treating the pain before the diagnosis is made, but it is preferable. Faster pain control results in greater patient satisfaction and more rapid disposition, and if a subsequent lumbar puncture (LP) is needed, a more relaxed patient.

Because most patients have benign causes of their headaches, and because of the limiting issues of both time and cost, most patients do not require further evaluation beyond history and physical examination. Physicians must decide who requires further evaluation and who can be safely treated and discharged with appropriate follow-up.

All patients with acute headache associated with new neurologic deficits must be evaluated sufficiently to explain the cause of those deficits. The same is true for those with significant abnormalities in the head, eyes, ears, nose, and throat (HEENT) examinations and the vital signs. However, the more common and more difficult situation is the patient whose physical examination is normal. In this group of patients, physicians must use the history, past medical and family history, and other epidemiologic factors to decide upon further evaluation. As with any painful symptom, the standard attributes of the pain—location, severity, quality, onset, timing and duration, associated symptoms, alleviating and exacerbating factors—are used to try to make the distinction between benign and cannot-miss diagnoses. Each of these factors must be factored into the equation. There is no single response to any single question that automatically triggers a workup.

The *location* of pain is less helpful in making this distinction than it is with other types of pain; there is significant overlap between benign and serious causes (8). Some recommend working up patients whose headaches are consistently on the same side (10). *Severity* of pain also has limitations. Although the "worst-of-life" headache suggests a more serious problem, most severe headaches in the ED have benign causes (11,12). This is partly because of the variability of patients' pain thresholds and partly because overall, most headaches have benign causes. That said, increasing severity should lower one's threshold for further diagnostic testing, and most patients with the abrupt onset of a worst-of-life headache should be evaluated for SAH (8). Defining the *quality* of pain is crucial (8). It is important to ask in detail about the patient's prior headaches. A new headache that is qualitatively unique and unusual for the patient may be more significant than the "worst-ever" headache in another patient whose current headache is similar in quality to prior episodes, only more severe. *Onset* is another important feature that drives decision-making. Abrupt or "thunderclap" onset suggests intracranial hemorrhage or cerebral venous sinus thrombosis, although once again, there is a broad differential diagnosis, and most abrupt-onset headaches are benign (13). For abrupt-onset headaches, the activity at onset sometimes suggests the etiology, for example, in coital headache or benign exertional headache (14,15). However, although these activities are sensitive for the corresponding diagnoses, they are not specific; SAH must be ruled out. Importantly, many SAH patients develop their headache during quiet activity or even sleep (16).

Defining the *timing* and *duration* of the pain is useful. Worrisome features include new acute headache, or a subacute headache that is increasing in severity. Long-standing duration (years) of a headache or a similarly long history of intermittent headaches is less likely to be a cannot-miss cause, assuming that sufficient history is taken to ensure that there is nothing new or different to the prior headache pattern. Very fleeting headaches, termed *jabs and jolts,* that last seconds are generally benign (17).

Similarly, *associated symptoms* can be important. Nausea and vomiting occur with migraine but also suggest intracranial mass, blood, or infection. Again, comparison with prior headaches is important. The significance in a patient with migraines who always vomits with them is different from the migraineur who is now vomiting for the first time. The same is true of photophobia. Visual abnormalities suggest migraine, idiopathic intracranial hypertension, temporal arteritis, and pituitary apoplexy. Diplopia from a pupil-involving third nerve palsy suggests a cerebral aneurysm or other mass (18). Diplopia from a sixth nerve palsy is seen with elevated or abnormally low intracranial pressure of any cause, presumably due to stretching of the sixth cranial nerve. Associated syncope, seizure, or any focal neurologic symptoms associated with a new headache should generally prompt an evaluation.

Exacerbating and *alleviating* factors are less helpful with headache. For example, the classic history that a headache from brain tumor increases on awakening is neither specific nor sensitive (19). It is also seen in patients with chronic lung disease and hypercarbia (which worsens during sleep). Headache from intracranial hypotension, either spontaneous or post-LP tends to worsen on standing upright, and headache due to acute sinusitis often worsens on bending forward with the head dependent (20). In terms of alleviating factors, diagnostic significance should not be ascribed to pain relief, even with over-the-counter medications. New medications or the discontinuation of a medication may also be diagnostically relevant in some patients (21).

Patients frequently use the word *migraine* loosely to refer to any bad headache or *sinusitis* to refer to any frontal headache. Unless these diagnoses have been substantiated by a prior medical evaluation, it is preferable to simply use the less specific but more accurate word *headache* (6). Sinusitis is a relatively uncommon cause of headaches; many of these patients actually have migraines (22,23). Tension headaches and migraines are very common. The lifetime incidence of migraine is about 11% (24); therefore, even patients with true histories of tension headaches or migraines will occasionally develop new headaches of another cause. This fact

underscores the importance of carefully exploring the difference between a patient's prior headache and the one that led to the current ED visit.

The epidemiologic context is important. A family or past history of cerebral aneurysm increases the likelihood of an aneurysmal cause. Poorly treated hypertension may lead to hypertensive encephalopathy. Vascular risk factors can result in stroke. Hypercoagulability or a past or family history of thromboembolic events should raise the possibility of cerebral venous sinus thrombosis. Obesity increases the possibility of idiopathic intracranial hypertension (pseudotumor cerebri), especially in women. New-onset headache at older ages also suggests a secondary cause (1,2). Most migraine headaches begin before age 30, and very few begin after age 50. Therefore, physicians must have a lower threshold to work up older patients with new headaches. Specifically, giant cell arteritis, tumors, subdural hematoma, and medication-related headaches should be considered in this group. Patients who are HIV positive or have a history of cancer represent other groups in whom a lower threshold to pursue evaluation seems justified. Winter season and common source clusters are associated with carbon monoxide poisoning. Although migraine is the most common cause of headache in pregnancy, other disorders such as stroke, SAH, cerebral venous sinus thrombosis, and of course eclampsia must also be considered (25).

The International Headache Society definition of tension and migraine headaches requires multiple episodes to definitively diagnose migraine or tension headache (26). Migraine is defined by 5 or more episodes of a throbbing headache that has certain characteristics (7), and tension headache is defined as 10 or more episodes. Although all of these patients must have their first headache at some point in time, most do not present to the ED. Therefore, diagnosing a patient with a new, different headache with a primary headache disorder opens the door to misdiagnosis.

The physical examination starts with the general appearance and vital signs. General appearance can be deceiving and is, at least in part, a function of a given patient's pain threshold. Nevertheless, the

patient who is shielding the eyes from the light, while consistent with migraine, also suggests meningeal irritation. Fever is not a symptom of migraine and suggests infection or a several-day-old SAH.

Isolated hypertension is an uncommon cause of headache; however, it is a common result of headache. Patients with headache may have a high blood pressure reading due to the pain, stress, or the presence of underlying intracranial pathology. Reducing the blood pressure and treating the pain pharmacologically may make the patient look and feel better without identifying the underlying etiology. In some specific causes of headache, such as stroke, overzealous blood pressure reduction can be detrimental (27). On the other hand, in hypertensive encephalopathy (elevated blood pressure with signs of end-organ damage), the headache is directly related to the elevated pressure. In these cases, reduction of the blood pressure by about 25% of its peak value is usually followed by rapid improvement of the patient's symptoms. The emergency physician should have a low threshold for brain imaging (and possibly LP) in patients with hypertension and a headache that is otherwise worrisome based on onset, severity, quality, and associated symptoms.

The emergency physician should also look for signs of meningeal irritation. Meningismus, stiffness on passive flexion of the neck (to be distinguished from just pain without stiffness on neck flexion) results from infections (meningitis) or irritation (SAH). However, this finding is not reliably present, and its absence does not exclude either condition. The same is true of Kernig and Brudzinski signs (see Chapter 185). One physical finding that has been found to be more reliable in meningitis is jolt accentuation. This sign is positive if, when the patient is asked to turn their head horizontally (as if shaking their head "no") two to three rotations per second, the baseline headache increases (28).

The HEENT examination may reveal the headache's cause (Table 12.3). Vesicles on the scalp, tip of the nose, or external ear canal suggest herpes zoster. Scalp lesions suggest a first or second cervical root involvement; tip of the nose lesions suggest that the first

division of the trigeminal nerve is involved and should prompt a careful slit-lamp examination to detect corneal involvement. Vesicles in the ear canal are associated with the Ramsay Hunt syndrome (herpes zoster infection causing seventh nerve palsy). Temporal artery tenderness, nodularity, or thickening is seen with giant cell arteritis. A red eye with an edematous cornea and midposition pupil suggests narrow angle closure glaucoma. Proptosis or chemosis suggests a cavernous sinus thrombosis.

TABLE 12.3
Common HEENT Findings that Suggest Particular Diagnoses

Finding	Diagnosis	Comments
Vesicles on scalp	Herpes zoster of upper two cervical roots or V-1 root of trigeminal nerve	Usually unilateral pain Must examine scalp carefully
Vesicles on tip of nose	Herpes zoster of V-1 root of trigeminal nerve	Carefully examine the cornea with slit lamp
Vesicles in external ear canal	Ramsay Hunt syndrome	Carefully examine the seventh and eighth cranial nerves
Temporal artery nodules, tenderness or thickening	Giant cell arteritis	Ask patients about visual symptoms; consider empiric steroid use and arranging temporal artery biopsy
Red eye and corneal edema	Acute narrow angle closure glaucoma	Pupil is usually midposition Consult ophthalmology
Proptosis of eye Chemosis of conjunctiva	Cavernous sinus thrombosis	Neurosurgical consultation and MRA with venous phase

The physician should perform a complete neurologic examination on patients with headache. New neurologic abnormities should trigger a workup beyond the history and physical examination, although some migraine patients, specifically those with aura, will have neurologic deficits. An abnormal mental status with a new

headache always must be explained and suggests increased intracranial pressure or a diffuse process such as meningitis, encephalitis, or severe carbon monoxide poisoning. Several cranial nerve findings suggest particular causes of a headache (Table 12.4).

TABLE 12.4
Common Cranial Nerve Findings of Diagnostic Significance in Patients with Headache

Finding	Diagnosis	Comments
Decreased visual acuity	Giant cell arteritis Acute narrow angle closure glaucoma	Carefully examine the eye and the temporal arteries Send ESR in patients >50 years old
Visual field cut	Mass lesion Pituitary apoplexy	Location depends on the specific field cut (this may be a parenchymal problem rather than a cranial neuropathy)
Third nerve palsy	SAH Cavernous sinus thrombosis	Check the pupil (usually involved in SAH; usually spared in "diabetic" third nerve palsy)
Sixth nerve palsy	Any condition associated with increased or decreased ICP Basilar meningitis (e.g., Lyme, tuberculous, cryptococcal, etc.) Cavernous sinus thrombosis	Look for papilledema Consider pseudotumor or cerebral venous sinus thrombosis Consider LP if brain imaging is negative
Direction changing nystagmus	Cerebellar or brainstem stroke	This can occur with any central lesion causing vertigo
Lower motor neuron seventh nerve palsy	Bell palsy Ramsay Hunt syndrome	This may present with severe ear or retroauricular pain
Eighth nerve palsy (diminished hearing or vertigo)	Ramsay Hunt syndrome	See above; also look for vesicles in the external auditory canal

The remainder of the neurologic examination (power, sensation, cerebellar function, gait, and reflexes) should be performed. Abnormalities in these areas suggest a mass lesion or focal brain ischemia or infarction; the specific findings are a function of the location of the pathology. The ocular fundi should be inspected for signs of raised intracranial pressure, but the appearance of papilledema can be delayed and is not always present. Physicians should also look for venous pulsations in the retina. Their presence is strongly indicative of normal intracranial pressure, while the converse is not true. Two aspects of the neurologic examination that are frequently omitted are visual fields and gait testing. Both are important in that they cover a large amount of neuroanatomic territory. Field cuts are seen in patients with pituitary apoplexy (29). A new headache, especially occipital, associated with ataxia, nystagmus, or other cerebellar findings suggests a cerebellar stroke (30,31). Gait abnormalities may also have an impact on safe disposition from the ED.

Based on the history and physical examination, patients will fall into one of the three categories. The first is patients who have abnormal physical examinations in whom the need for further diagnostic testing is unambiguous. The second is patients whose examinations are normal and whose histories do not suggest the presence of a cannot-miss diagnosis. The last category is patients with normal physical examinations and worrisome histories that trigger further diagnostic testing (Table 12.5). Separating out these last two categories is largely a matter of experience, judgment, and meticulous attention to detail in the history and physical examination.

TABLE 12.5
Factors Suggesting Further Evaluation Should Be Pursued Beyond History and Physical Examination

Headache-Related or Patient-Related Factors	Diseases to be Considered	Evaluation
First or worst headache (HA)	All diseases in Table 12.2	Varies (Table 12.2)
Increasing frequency or severity	Mass lesion	Consider brain imaging
Associated with altered mental status	Elevated ICP	Brain imaging, LP if negative results of imaging, COHb level
	Encephalitis and meningitis	
	Carbon monoxide poisoning	
Associated with new neurologic deficits	Any of the intracerebral diagnoses	Varies, but includes brain imaging
Visual symptoms	Idiopathic intracranial hypertension, pituitary apoplexy, migraine with aura	Brain imaging
		LP for idiopathic intracranial hypertension
		(Note: If visual symptoms classic of migraine aura, other testing may not be necessary)
With fever and meningismus	Meningitis, SAH	LP (CT first in many cases—see text)
New onset after 50 years of age	Tumor, SDH, giant cell arteritis	Brain imaging
		ESR
New onset in HIV-positive patients	Meningitis, lymphoma, opportunistic infections	Varies, but usually includes both brain imaging and LP
New onset in patients with cancer	Tumor or cerebral venous sinus thrombosis	Brain imaging, ideally MRI but CT may suffice

Once the decision has been made to pursue other diagnoses, there are a limited number of tests to be performed. The choice of which tests, and what sequence, is partly a function of the specific differential diagnosis and the intrinsic limitations of the tests. This latter point cannot be overemphasized. Every test, including magnetic resonance imaging (MRI) in acute stroke (32), has some limitations that the physician must factor into the decision making. Again, the response to analgesics of any class must not be assigned any diagnostic significance.

Brain imaging has revolutionized the diagnosis of patients with headache. Computed tomography (CT) scanning and MRI allow diagnoses of conditions much earlier and with far greater precision. CT scanning is widely available and extremely rapid, and there is a great deal of experience with its interpretation among radiologists and emergency physicians. A noncontrast CT scan is extremely sensitive for acute intraparenchymal blood and very sensitive for subarachnoid blood, but small or older subarachnoid bleeds may not be visible. Physicians may miss subtle findings (33). Some tumors and abscesses will not show on a scan performed without IV contrast, although most masses large enough to cause a significant headache will be associated with some abnormality on a noncontrast head CT.

In general, MRI is superior to CT, especially in evaluating vascular and neoplastic lesions, infections, and pathology at the cervicomedullary junction and in the posterior fossa (10). MRI and CT have equivalent accuracy for imaging acute blood (34), but

specific imaging sequences are needed and communication with the radiologist is important. When MRI is required but unavailable, the emergency physician should consider transferring the patient, performing CT with IV contrast, or obtaining neurologic consultation to discuss other options.

MRI permits much greater detail of the brain anatomy and physiology than CT scanning. Blood vessels, both arterial and venous, can now be evaluated by magnetic resonance angiography (MRA). Brain tumor, abscesses, and pituitary apoplexy are easily visible. Carotid and vertebral artery dissections, cerebral aneurysms, and cerebral venous sinus thromboses are best diagnosed with MRA or MR venography. Although MRA is the preferred test, CT angiography (CTA) or venography are rapidly improving and are increasingly useful for diagnosing aneurysms, cervical artery dissections, and cerebral venous sinus thrombosis (35–37). However, no test is perfect. Cases have been described in which a cerebral aneurysm was missed by MRA, despite the fact that both patients presented with third nerve palsies, and the clinician expressed concern for a posterior communicating artery aneurysm to an experienced neuroradiologist, who carefully reviewed the films (38). This underscores the fact that even in the face of negative imaging studies, it is important to pursue hard physical findings. In some cases, the traditional gold standard for vascular pathology—catheter angiography—may be indicated, along with neurologic consultation.

Despite these sophisticated imaging tests, there is still a role for the LP. For cases of suspected SAH in which the CT scan is nondiagnostic, and for suspected meningitis, an LP will establish those diagnoses with nearly 100% sensitivity. However, like all tests in medicine, even the LP has limitations. Rare cases of meningitis can be associated with no white blood cells (39), and late-presenting cases of SAH may have no red blood cells (6,8). After 2 weeks, even xanthochromia may disappear. Measuring the opening pressure may help to distinguish traumatic LP from true SAH, as well as help with the diagnosis of idiopathic intracranial hypertension and cerebral venous sinus thrombosis (6,8).

Guidelines recommend that all patients with a thunderclap headache being evaluated for SAH with a negative CT have an LP (40). Recent studies suggest that sensitivity of CT done within 6 hours of headache onset approaches 100% sensitivity and that in this group of patients, LP may not be necessary (33,41). The best study was a prospective ED study of over 3,000 patients, 8% of whom had SAH (a typical ED population) (41). However, another retrospective article argues for caution; however, it is not clear that many of the patients labeled as having SAH actually had a true SAH (as opposed to an incidental unruptured aneurysm) (42,43). As of 2013, guidelines have not yet been changed. If physicians choose not to perform an LP in rule-out SAH patients who have a negative CT done within 6 hours, they must carefully understand the limitations in this group (classic thunderclap headache presentation, normal neurologic examination, CT interpretation by a competent attending level radiologist) (33,41,44).

On specific occasions, other tests may be diagnostic (e.g., the erythrocyte sedimentation rate [ESR] in giant cell arteritis, tonometry for acute narrow angle closure glaucoma, and carboxyhemoglobin levels in carbon monoxide poisoning, in whom standard pulse oximetry may be falsely normal).

Given the limitations of individual tests, it should be clear that sometimes a series of tests is necessary. For example, if a CT scan is negative in a possible SAH patient, an LP should be performed (see above). If an ESR is normal in an elderly patient with a new headache, the physician should consider performing brain imaging because giant cell arteritis is much less likely. If a CT scan is negative in a patient with a clear-cut focal neurologic finding, an MRI should be considered.

One other test to be considered is a neurologic consultation. Although the emergency physician should be able to diagnose the vast majority of patients with headache who seek care in the ED, there may be times when a neurologist can supply a useful perspective, either in real time or in follow-up. The timing of consultation is a function of the specific differential diagnosis, the pace of the patient's illness, and the availability of that service. In

patients with a new, definite neurologic finding on physical examination and normal results of brain imaging, the physician should strongly consider urgent or emergent consultation to sort out the possibilities.

CRITICAL INTERVENTIONS

- Although rarely required, patients with headache whose level of consciousness is declining should be intubated.
- Patients should be treated aggressively but the response to analgesics should not be used to conclude that the etiology is benign.
- In ill patients with possible bacterial meningitis, CT is not always indicated. However when the clinician decides to do a CT prior to LP, dexamethasone and antimicrobials should be administered and blood cultures obtained BEFORE the CT.
- When lowering the blood pressure in patients with hypertensive encephalopathy, the emergency physician should try to target a blood pressure of about 25% lower than the peak pressure on presentation.
- In pregnant or postpartum women with severe headache, although preeclampsia and eclampsia are the likeliest diagnoses, other possible causes such as posterior reversible encephalopathy, reversible cerebral vasoconstriction syndrome, and venous sinus thrombosis should be considered.
- In elderly patients with new headaches, an ESR should be sent when the diagnosis of giant cell arteritis is considered as it can lead to blindness if untreated.

DISPOSITION

Most patients with headache will be discharged after successful treatment of their acute pain. This includes patients with the diagnoses of primary headache disorders and those who have had a negative evaluation. For patients with suspected SAH, for example, many studies looking at outcomes after negative CT scans and normal spinal fluid examination have all found that these patients do

not develop SAH after this workup. However, because occasional patients are outliers and because abnormal tests are occasionally incorrectly interpreted as normal, follow-up is important.

Because time can sometimes be an effective diagnostic tool, arranging follow-up for patients with headache is important. This may be with their primary care physician or a neurologist. This does not pertain to patients with abnormal physical examinations, whose further evaluation should take place urgently, often in the hospital, and in consultation with the physician who will be doing the follow-up.

Common Pitfalls

- Failure to inquire about prior headache details and how they compare to the current one.
- Failure to understand that some patients with serious pathology will not appear very ill.
- Failure to critically consider patient-initiated words such as *migraine* and *sinusitis,* in the absence of a substantiated diagnosis.
- Failure to perform (and document) complete neurologic and HEENT examinations.
- Failure to realize that there is no diagnostic significance to successful treatment of headache pain with any kind of analgesic or antimigraine drug.
- Failure to perform an LP after a nondiagnostic head CT in patients being evaluated for possible SAH (see the text above regarding ultra–early-presenting patients).
- Failure to know that hypertension is not usually the cause of a new headache.
- Failure to explain new focal neurologic findings. If the first test (e.g., a CT scan) is negative, consider a second test (e.g., MRI or neurologic consultation), because the physical finding is still present and requires explanation.

CHAPTER 13 Weakness

Andy Jagoda

Patients presenting to the emergency department (ED) with a complaint of weakness pose a challenge because the complaint is often nonspecific and the differential diagnosis is large. Successful ED management depends on a systematic evaluation. Specific attention to potentially life-threatening etiologies is the principal focus, and diligence in data gathering is essential to the establishment of a diagnosis. A detailed history and physical examination guide the selection of appropriate diagnostic studies. Though rarely encountered, when approaching the patient with a complaint of weakness, consideration is given to disorders such as toxic exposures, metabolic abnormalities, botulism, myasthenia gravis, and Guillain–Barré syndrome because of their associated high morbidity and mortality. The emergency physician should consider these and all other disorders that can precipitously compromise the respiratory and functional status of the patient when approaching a patient with the chief complaint of weakness.

The complaint of "dizziness" may accompany that of "weakness," and, at times, patients use these terms interchangeably. There is considerable overlap in their etiologies. In the ambulatory care setting, dizziness is the most common presenting complaint in patients older than 75 years (1). *Weakness* is defined as a decrease in muscle strength or power. It may be a focal symptom, involving a single muscle group, or it may be generalized. Dizziness is imprecisely interpreted by patients and may be used to describe lightheadedness, disequilibrium, disorientation, confusion, or vertigo (see Chapters 14 and 70). The emergency physician must appreciate

the distinction between these symptoms and attempt to understand the patient's intended meaning. This chapter specifically addresses those patients who present with a complaint of "weakness."

CLINICAL PRESENTATION

The historical features that are important when assessing the patient with weakness are the acuity of onset and duration of symptoms, exacerbating and mitigating factors, presence of associated symptoms, and location is the weakness, focal or generalized (2). Sudden onset of weakness may suggest a metabolic derangement or infection: A slower progression of symptoms from days to weeks may suggest Guillain–Barré syndrome or myasthenia gravis, although these illnesses may also have accelerated courses. A history of symmetric ascending weakness in a patient with a recent respiratory illness or influenza vaccine will aid in the diagnosis of Guillain–Barré syndrome. The weakness of myasthenia gravis may fluctuate, and a careful history is needed to elicit a progression of symptoms throughout the day or an association with exercise or repeated activity, such as chewing or combing one's hair. Recent illness, other medical problems, recent vaccination, occupational history, travel history, history of tick bites, use of medications, and use of recreational drugs are important factors in assessing the patient complaining of weakness. A thorough review of systems includes inquiry about recent weight loss, fever or sweats, visual changes (including diplopia), difficulty swallowing, joint or muscle pain, palpitations, change in bowel habits, and skin rashes. Occupational or recreational exposures may indicate drug toxicity.

The patient's age is an important consideration in developing the differential diagnosis in a patient with weakness. The elderly have a higher incidence of comorbid medical conditions than their younger counterparts. The elderly are also at higher risk of acute central nervous system (CNS) and cardiovascular events. They are more likely to present with occult infections and metabolic disorders that are symptomatically manifested as weakness (1). In the pediatric age group, infantile botulism and intussusception are two rare but important considerations. Infantile botulism may be seen in children

days old to more than 1 year of age. This variant of botulism is much more common than food-borne or wound botulism; it presents with weakness, poor tone, poor suck, or constipation.

The physical examination in a patient complaining of weakness includes a full set of vital signs, orthostatic monitoring, oxygen saturation, and a finger blood glucose. Supplemental oxygen is indicated if hypoxemia is present; the airway must be secured if there is a potential for imminent compromise. Tachycardia, with or without hypotension, suggests volume depletion or toxic drug ingestion. Rectal temperature measurement is particularly important, because infection frequently presents with nonspecific complaints, such as weakness. A blood glucose level should be obtained early during the evaluation, as hypoglycemia may present with an array of symptoms, including weakness. The ears, sinuses, thyroid, and cardiac status should be assessed, as well as a careful evaluation for signs of trauma, which may suggest physical abuse. A rectal examination, including a guaiac test for occult blood, is recommended in select cases.

The neurologic examination begins early in the course of the patient's evaluation with an assessment of the mental status, for example, assessment of orientation and attention. Altered mental status, including confusion, slowness, or agitation, may represent underlying disease or toxic exposure such as in carbon monoxide poisoning and organophosphate exposure. Suspicion of cognitive defects may prompt a formal mental status evaluation depending on the clinical setting (3). Abnormal neuropsychiatric testing in a patient with carbon monoxide poisoning may indicate the need for hyperbaric oxygen therapy. Cranial nerve testing in the patient with a complaint of weakness focuses on the motor examination. Ptosis can be an early sign of myasthenia gravis, in which case it is usually symmetric (4). When myasthenia is a consideration, having the patient hold an upward gaze for several minutes is helpful in assessing for fatigue. Difficulty with accommodation can be the earliest sign of weakness due to botulism and does not occur with myasthenia. Diplopia due to weak oculomotor muscles should be assessed, with an emphasis on the evaluation of the sixth cranial nerve. The abducens is the longest intracranial cranial nerve and the

most sensitive to toxins such as botulism or to increased pressure from intracranial mass lesions.

The remainder of the neurologic examination in the patient complaining of weakness concentrates on motor strength, deep tendon reflexes, and assessment for muscle atrophy and fasciculations. Table 13.1 lists the motor strength grading system (from 0 to 5), which permits standardization of documentation of the motor examination among examiners. Deep tendon reflexes are graded on a scale from 0, indicating areflexia, to 4, signifying hyperreflexia, with 2 being normal. *Upper motor neuron* diseases, such as multiple sclerosis, will typically present with hyperactive reflexes in comparison to the diminished or absent reflexes seen in diseases of the *lower motor neuron,* as in Guillain–Barré syndrome. Acute spinal cord lesions, such as in a conus medullaris lesion or transverse myelitis, can often initially present with areflexia early in its course. Cauda equina syndrome is due to impingement of the lumbar and sacral nerve roots, commonly from a ruptured vertebral disk. These patients will present with distal motor weakness, areflexia, urinary retention, and anesthesia in the saddle distribution.

TABLE 13.1
Motor Strength Grading System (Medical Research Council Scale)

Grade	Definition
5	Normal strength
4	Active movement against gravity and resistance
3	Active movement against gravity (no resistance from physician)
2	Active movement with gravity eliminated (no resistance from physician)
1	Flicker or trace contraction
0	No visible or palpable contraction

Both upper and lower motor neuron diseases can initially present with the complaint of weakness. The important distinguishing characteristics are listed in Table 13.2. *Upper motor neurons* arise in the cerebral cortex, and their axons extend through the subcortical white matter, internal capsule, brainstem, and spinal cord, where

they synapse directly with lower motor neurons or interneurons, fine-tuning motor activity. *Lower motor neuron* cell bodies lie in the brainstem motor nuclei and anterior horn of the spinal cord. Their axons extend to the skeletal muscles they innervate.

TABLE 13.2
Upper Versus Lower Motor Neuron Weakness

Clinical	Upper Motor Neuron	Lower Motor Neuron
Weakness	Weakness greater in the arm extensors and leg flexors; weakness often unilateral	Weakness often in one muscle group; extensor same as flexor
Deep tendon reflexes	Increased	Decreased
Muscle tone	Increased	Decreased
Fasciculation	None	Present
Muscle atrophy	None	Severe
Babinski sign	Present	Absent

The weakness of *upper motor neuron* disease is generally unilateral, the Babinski sign is present, muscle tone is increased, deep tendon reflexes are increased, and no fasciculations are visible or palpable. In general, distal muscle groups are more severely affected than are proximal groups. *Lower motor neuron* disease affects single muscle groups. Flexors and extensors are equally compromised in an extremity. Deep tendon reflexes and muscle tone are decreased with lower motor neuron disease. Muscle atrophy and fasciculation are long-term results of lower motor neuron lesions.

Amyotrophic lateral sclerosis (ALS) is a combined upper and lower motor neuron disease that can clinically present as a mixed picture. The etiology of ALS is unclear but it is a disease involving the destruction of the anterior horn cells in the spinal column and the Betz cells in the motor cortex of the CNS. The clinical presentation is of asymmetric weakness in the distal motor groups with sensory sparing. Patients often have muscle fasciculations of lower motor neuron disease but associated positive Babinski signs and hyperreflexia as seen in upper motor neuron disorders.

Lower motor neuron diseases can arise from a muscle-based disorder, a neuropathic-based disorder, or a myoneural junction source. Table 13.3 illustrates several symptoms, physical signs, and

laboratory findings that distinguish the etiologies of lower motor neuron weakness. Weakness due to a myopathy tends to involve proximal muscle groups, whereas neuropathic disease (Guillain–Barré syndrome) affects distal muscle groups. Myoneural junction diseases have a more distal distribution and are particularly inclined to affect respiratory and bulbar muscle groups (myasthenia gravis and botulism).

TABLE 13.3
Myopathy Versus Neuropathy Versus Myoneural Junction Disease

Clinical	Myopathy	Neuropathy	Myoneural Junction
Distribution	Proximal > distal	Distal > proximal	Diffuse, especially bulbar and respiratory muscles
Reflexes	Decreased	Decreased	Normal
Sensory involvement	–	+	–
Atrophy	±	±	–
Fatigue	±	±	+
Serum CPK	Normal to elevated	Normal	Normal
Example	Polymyositis	Guillain–Barré syndrome	Myasthenia gravis

CPK, creatine phosphokinase.

Spinal cord disorders from compressive or traumatic injury can also present with weakness involving motor function distal to the defect, as well as sensory and autonomic nerve dysfunction. In comparison to atraumatic cord disorders, such as in multiple sclerosis, traumatic cord lesions generally present acutely with distinct sensory and motor findings, as seen with the saddle anesthesia in patients with cauda equina syndrome. Autonomic dysfunction is also seen more commonly in spinal cord injuries manifesting with hypotension or priapism. Detailed history (including anticoagulation, recent fall or trauma, immune status, fever, intravenous drug abuse, spinal procedure, or surgery) is often necessary to make the diagnosis. An uncommon and occasionally overlooked diagnosis of spinal epidural abscess can be made in the setting of a patient with a history of intravenous drug abuse presenting with severe back pain, fever, and progressive lower extremity weakness.

When psychogenic weakness is considered in the differential diagnosis, several maneuvers may be helpful. Weak muscles give way to pressure in a smooth fashion, but psychogenic weakness usually results in a jerking or sudden release. In a patient with upper extremity weakness from organic disease, making a fist should not result in wrist extension (unless there is an isolated lesion of the flexor tendons); in functional states, the wrist extends as the patient tries to make a fist. In patients with psychogenic bilateral lower extremity weakness, attempts to lift one leg against resistance result in the other leg firmly thrusting downward, whereas in patients with organic disease, the downward thrust is diminished or absent.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the weak patient is extensive. Division of the etiologies into broad categories, such as metabolic, toxic, infectious, structural, endocrinologic, cardiac, and rheumatologic, permits a more organized approach to this extensive list. In this section, the diagnoses are also presented in order from high risk to low risk. Detailed history taking and careful examination should direct the physician to one of these categories. Diagnostic testing may then be used to narrow the differential diagnosis and determine the management plan for the patient's condition.

Metabolic

Metabolic derangements that can present with weakness include hypoxia, hyperthermia, and alterations in serum glucose, potassium, sodium, phosphate, magnesium, and calcium (5). Severe hypokalemia presents with generalized weakness and paralysis due to a dysfunction of potassium regulation (6). This state may be induced by medications such as diuretics as well as gastrointestinal losses; it also rarely occurs in association with genetic disorders such as familial periodic paralysis. Hyperkalemia, though typically known for its effects on the myocardium, is a lesser known cause of weakness presenting with ascending paralysis, ultimately leading to respiratory failure (6). One of the most frequently seen causes of weakness in the ED is hypoglycemia, which accounts for an average of 380,000 ED

visits per year in the United States (7). During the summer, elderly patients with heat exhaustion will frequently present to the ED with weakness due to dehydration and inability to regulate their temperature.

Cardiovascular

Weakness may be the only complaint in the elderly patient with acute myocardial infarction (MI); this must be in the differential diagnosis for all geriatric patients presenting with nonspecific complaints. In one study of symptoms of MI in the elderly with autopsy-proven MI, 20% of the patients initially presented with weakness (8). As the population ages, more patients will present with atypical complaints of MI such as weakness or shortness of breath.

Myocarditis is another serious but often missed cause of weakness in a patient with a recent viral infection. Patients complain of weakness as part of a constellation of symptoms that includes cough, dyspnea, myalgias, fever, vomiting, or diarrhea. In one study, up to 60% of patients with myocarditis did not have chest pain (9).

Other cardiovascular causes of weakness associated with lightheadedness or presyncope are due to transient decreased cerebral perfusion. These disorders include postural hypotension, carotid and vertebral artery insufficiency, cardiac dysrhythmias, vasovagal events, and states of decreased cardiac output.

Central Nervous System Lesions

Structural lesions in the CNS generally present with focal weakness. Weakness, in association with changes in speech, visual loss, diplopia, paresthesias, and dizziness, are frequently associated with the diagnosis of stroke (10). Patients with brainstem infarcts can present with difficulty swallowing, talking, or breathing, in addition to weakness. Lesions in the frontal lobes, basal ganglia, and cerebellum can cause disequilibrium.

Lesions in the spinal canal such as epidural hematoma and abscess and metastatic cancer can result in weakness that is symmetric and distal to the site of compromise. Transverse myelitis is an infrequent

yet debilitating demyelinating disease of the spinal cord presenting with an acute onset of back pain, lower extremity weakness or paralysis, and sensory deficit below the level of involvement. The etiology is unknown but thought to be related to a recent viral infection or autoimmune disorder. The clinician should suspect this disease in a patient with a recent viral illness presenting with both weakness and sensory deficit below a cord level. This disease should not be confused with Guillain–Barré syndrome. Though also preceded by a viral syndrome, the physical examination findings of Guillain–Barré syndrome will typically demonstrate sparing of the anal sphincter and hyporeflexia with progressive weakness in an ascending pattern over days to a week. Clinical findings of transverse myelitis generally progress over 24 hours and include diminished or absence of strength and sensation below the level of involvement, sphincter dysfunction, hyperreflexia, and urinary incontinence or retention.

Specific Neuromuscular Diseases

The patient with myasthenia gravis will present with weakness of a specific muscle group associated with blurred vision, diplopia, and ptosis. Patients with Guillain–Barré present with generalized ascending paralysis with variable sensory deficits. ALS is a disease that affects both upper and lower motor neurons and can present with a mixed picture. Myopathies caused by metabolic derangements, medications, and inflammatory states may present with symmetric proximal muscle weakness with preservation of sensory function.

Infections

All infections can potentially cause weakness, either through nonspecific mechanisms, such as those seen with mononucleosis or hepatitis, or from specific toxins affecting neuromuscular function, such as poliomyelitis, botulism, Guillain–Barré, or tick paralysis. Sinus and ear infections can affect the labyrinthine system and produce lightheadedness or vertigo. The human immunodeficiency virus (HIV) can directly or indirectly cause the full spectrum of weakness, from nonspecific fatigue to neuropathies and myelopathies.

Chronic fatigue syndrome, thought to be viral in origin, requires an extensive workup to exclude all other processes before the diagnosis can be established. This diagnosis should not be made in the ED.

Medications and Toxins

Prescription mediations can produce generalized weakness (Table 13.4). There are usually no focal findings on examination. In one study of 106 patients with a chief complaint of weakness and dizziness, 9% of all patients and 20% of those older than age 60 had symptoms attributed to prescription medications (1). Drugs associated with vasodilatation, bradycardia, or diuresis can produce orthostatic blood pressure changes, often giving the patient the feeling of weakness.

TABLE 13.4
Commonly Used Drugs and Other Substances Associated with Weakness

Myopathies
Steroids
Alcohol
Heroin
Clofibrate
Epsilon-aminocaproic acid
Diuretics
Laxatives
Amphotericin
D-Penicillamine
Cimetidine
Procainamide

Neuropathies
Carbon monoxide
Heavy metals
Polychlorinated biphenyls
Isoniazid
Nitrofurantoin
Gold

Neuromuscular Junction Disease
Organophosphates
Carbamates

Certain toxins can present with the sudden onset of weakness, leading to acute respiratory compromise. Other toxins present with a slowly progressive course and subtle complaints. Organophosphates and carbamates act at the neuromuscular junction by inhibiting acetylcholinesterase. Patients present with a constellation of symptoms including lacrimation, defecation, salivation, and weakness, which can progress rapidly to paralysis and respiratory failure. The ability to recognize this toxidrome is critical to early medical treatment and public health intervention. In contrast, poisonings from heavy metals can be subtle and present with a slowly progressive course. In these cases, a thorough history is necessary to elucidate the cause of the patient's symptoms. Carbon monoxide exposure still remains the leading cause of death from poisoning in the United States. Patients may present with weakness and headache as their only complaints. The emergency physician should consider

this diagnosis in patients presenting with weakness especially during the winter months.

Endocrine

Hypothyroidism is the most common endocrine cause of weakness and is often initially misdiagnosed (see Chapter 206). Thyrotoxic periodic paralysis can present with weakness as a primary complaint, probably mediated through hypokalemia (5,11). Adrenal insufficiency, perhaps the most life-threatening endocrine etiology of weakness, may present with hypotension, hyperkalemia, and hyponatremia (see Chapter 207). It is a diagnosis that must be considered in weak patients on chronic steroid therapy. The diabetic patient with hyperglycemia can present with generalized weakness from diabetic ketoacidosis or nonspecific neurologic deficits secondary to hypoglycemia (Chapters 201 to 204). Cobalamin deficiency (vitamin B12), which is most commonly seen with pernicious anemia, is an important cause of lower extremity weakness and is infrequently considered in the emergency setting. In addition to lower extremity weakness, the patient often complains of paresthesias and tongue discomfort and has a macrocytic anemia on laboratory analysis.

Rheumatologic

Weakness is a prominent complaint of most rheumatologic diseases and occasionally is the primary presenting symptom. Systemic lupus erythematosus, polymyositis, dermatomyositis, polymyalgia rheumatica, and particularly myasthenia gravis must all be considered in patients presenting with symmetric weakness.

Psychogenic Weakness

This diagnosis should be made after an exhaustive search for the cause of weakness has excluded both metabolic and systemic diseases. Patients with conversion disorder may present with paralysis of a specific muscle group that is not anatomically consistent. The symptoms of these patients are subconscious, which is

in contrast to the malingering patient, whose actions are purposeful and often have secondary gain. Although the evaluation of this group of patients can often be difficult and resource consuming, the diagnosis of psychogenic weakness should be one of exclusion after other diagnoses have been considered (12).

DIAGNOSTIC APPROACH

An exhaustive history and physical examination should be performed to uncover the subtle details essential in establishing the cause of a patient's complaint of weakness. The patient's definition of *weakness* must first be clarified. Whether the weakness is focal muscle weakness or generalized fatigue must be determined early in the evaluation. If the patient complains of muscular weakness, then the clinician must determine whether it is focal or generalized, proximal or distal. The information gathered from the history and physical examination guides further testing. In general, a complete blood count, serum chemistry, and urinalysis should be obtained. A sedimentation rate may be helpful if rheumatologic disease is suspected. A monospot test, liver function tests, and thyroid function tests are sometimes indicated. Heavy metal screening and red blood cell acetylcholinesterase level are required in selected cases, but these are rarely available to the emergency physician while the patient is in the department. Carboxyhemoglobin is indicated in suspected cases of carbon monoxide poisoning. A serum creatine phosphokinase and aldolase are helpful in cases of suspected myopathy.

Pulse oximetry and arterial blood gas analysis are indicated in cases of suspected pulmonary dysfunction. Pulmonary function testing, including vital capacity and maximum inspiratory force, is recommended when respiratory muscle compromise is suspected, as in patients with myasthenia gravis and Guillain–Barré syndrome. An electrocardiogram and cardiac monitoring have a low diagnostic yield in patients with generalized weakness, though they may be helpful when dysrhythmias or electrolyte abnormalities are suspected. In the elderly patient without other sources of weakness, an electrocardiogram should be obtained to assess for a cardiac source. Rarely, more specialized laboratory testing is indicated in the

evaluation of the weak patient in the ED. Lumbar puncture (LP) and cerebrospinal fluid (CSF) analysis for Gram stain and culture can be a useful diagnostic tool when suspecting infection as a cause of weakness. In the setting of a fever and headache without a source or an immunocompromised patient with unknown fever and weakness, LP may be diagnostic. If there is a suspicion of increased intracranial pressure in a patient with fever and headache, a computed tomography (CT) scan, prior to LP, should be performed to exclude an intracranial mass. The LP can also aid in the diagnosis or exclusion of specific neurologic disorders. Multiple sclerosis will typically have a pleocytosis on CSF examination, and electrophoresis may demonstrate oligoclonal bands of IgG, which is highly suggestive of the disease. Guillain–Barré syndrome characteristically exhibits fewer than 50 lymphocytes per milliliter, a normal sugar, and an elevated protein. A Tensilon test should be considered in patients with suspected myasthenia gravis.

Computed axial tomography or magnetic resonance imaging (MRI) with intravenous contrast best evaluates structural lesions in the brain or spinal canal. The CT is a useful tool to diagnose intracerebral lesions and edema as a cause of weakness, such as in tumors, toxoplasmosis, cerebral bleeds, and infarcts. Clinical history and physical examination can be used to guide the clinician on this decision. If there are no focal neurologic findings in a patient with a normal mental status and a careful fundoscopic examination reveals no signs of papilledema with adequate venous pulsations, an LP can be performed safely without a CT. CT is also useful in patients with physical examination findings suggestive of upper motor neuron disease associated with symptoms such as headache, nausea, and vomiting. Unfortunately, the CT is not as sensitive in the evaluation of spinal cord lesions such as in spinal epidural hematomas and abscesses. If a patient presents with distinct weakness and sensory deficit below a cord level with associated back pain and the diagnosis of a spinal cord lesion is considered, MRI is the test of choice. MRI is also a useful imaging modality in the diagnosis of cauda equina syndrome as a cause of the lower extremity weakness in the setting of urinary dysfunction, saddle anesthesia, and impotence. If an MRI

cannot be obtained, the patient should be stabilized and consideration given to transfer to an appropriate facility.

CRITICAL INTERVENTIONS

- The focus of the emergency physician's approach to the patient complaining of weakness is to rule out the life-threatening diagnoses, specifically those that can progress to cardiopulmonary or respiratory compromise (Table 13.5). After airway patency is established, patients should be assessed for adequacy of respiration. Certain patients, based on the history and physical examination, must be assessed for hypoxemia, hypercapnia, or carboxyhemoglobinemia. Assessment of pulmonary function with measurements of tidal volume and vital capacity may be valuable, especially in patients with suspected myasthenia gravis or Guillain–Barré syndrome; patients with a vital capacity <1.5 L are possible candidates for intubation.

TABLE 13.5
Acute Life-Threatening Causes of Weakness

Cause	History	Physical	Laboratory	Treatment
Myasthenia gravis	Chronic weakness, improves with rest	Double vision, muscle fatigue, improves with rest	Positive Tensilon test	Thymectomy, AChE inhibitors
Guillain–Barré	Recent infection, progressive weakness distal to proximal	Distal motor with/without sensory loss, absent reflexes, no visual deficits	CSF with elevated protein, <50 WBCs	Supportive care, plasma exchange, gamma globulin
Botulism	Acute onset; canned, pickled, smoked food	Blurred or double vision	None	Supportive care, equine antitoxin
Adrenal insufficiency	Acute weakness associated with stress	Hypotension, hyperpigmentation	Hyperkalemia, hyponatremia	Hydrocortisone
Organophosphate poisoning	Occupational exposure, progressive weakening	Miosis, fasciculations, muscarinic dysfunction	Decreased RBC AChE	Atropine, pralidoxime
Carbon monoxide poisoning	Occupational or social exposure	Nausea, vomiting, coma, headache, dizziness	Elevated carboxyhemoglobin	100% oxygen, hyperbaric oxygen
Hypokalemia	Familial, GI, or renal loss	Diffuse weakness	Low serum potassium	Potassium

AChE, acetylcholinesterase; CSF, cerebrospinal fluid; WBCs, white blood cells; RBC, red blood cell; GI, gastrointestinal.

- Signs of respiratory compromise that may require intubation are declining oxygen saturations, increasing hypercapnea if capnometry is available, changes in mental status such as confusion or lethargy, and the increased use of accessory muscles for the work of breathing. Upon preparation for rapid sequence intubation, careful thought should be given to the medications used. If intracerebral mass lesion is suspected, premedication with

lidocaine and fentanyl should be considered. Organophosphates decrease the amount of plasma pseudocholinesterase and prolong activation of succinylcholine at the neuromuscular junction. Using a depolarizing agent in the paralysis of a suspected myasthenic patient should be attempted with caution because of increased sensitivity and possible exaggerated response to succinylcholine. Hyperkalemia can also result from using succinylcholine in patients with multiple sclerosis or ALS and should be avoided.

- Potentially unstable patients require intravenous access, pulse oximetry, and cardiac monitoring. Regular reassessment throughout the ED stay is necessary to avoid missing deterioration in the patient's status. Specific interventions depend on the diagnosis. Both plasmapheresis and intravenous IgG have been shown to improve outcome and shorten the course of disease in patients presenting with Guillain– Barré syndrome. Sedating drugs should be avoided in anxious patients who are hypoxemic. Drugs that interfere with myoneural junction function, such as the aminoglycosides, should be avoided in patients with suspected myasthenia gravis. Hypoglycemia is treated with dextrose and hypokalemia with potassium. Hydrocortisone, 100 mg intravenously, should be given to patients with suspected adrenal insufficiency. Patients with periodic paralysis do not have a total body deficit of potassium but instead have an alteration in intra- and extracellular potassium levels. Therefore, potassium should be corrected carefully to avoid inducing hyperkalemia. Patients who are weak because of toxins require specific antidotes when available. Significant carbon monoxide poisoning is an indication for hyperbaric oxygen treatment. Organophosphate poisoning requires the use of atropine and pralidoxime. Heavy metal poisoning is treated with chelation therapy.

DISPOSITION

Patients with progressive symptoms or those with a suspected or confirmed disease that has a progressive course or risk of respiratory compromise, such as myasthenia gravis, Guillain–Barré, or botulism, should be admitted to an intensive care setting regardless of their

initial appearance. Early consultation with a neurologist or neurosurgeon is recommended, and a comprehensive management plan should be determined. Laboratory tests should not be ordered unless the results will be available before ED discharge or careful follow-up has been arranged.

Common Pitfalls

- Failure to perform a detailed history and physical examination.
- Failure to diagnose an acute stroke in a timely manner.
- Failure to obtain a thorough drug and toxin exposure history.
- Failure to suspect drug-induced myopathy, drug-induced adrenal insufficiency, or overdose.
- Failure to detect an occupational exposure and properly decontaminate the patient.
- Diagnosing a psychogenic etiology or chronic fatigue syndrome in the ED.
- Failure to recognize absent reflexes as an early manifestation of the Guillain–Barré syndrome.
- Failure to distinguish periodic paralysis from hypokalemia induced by drugs, gastrointestinal loss, or other etiologies.

CHAPTER 14
Dizziness

Jonathan A. Edlow

CLINICAL PRESENTATION

Dizziness is one of the most common presenting symptoms in emergency medicine (1,2). Misdiagnosis is common, even when patients are evaluated by neurologists (3). Dizziness has numerous causes and the very word "dizziness" means different things to different people. Older dizzy patients, who are becoming increasingly common in the emergency department (ED), have a higher incidence of serious central nervous system (CNS) and cardiovascular causes (4–6). Furthermore, dizziness is often caused by a variety of non-CNS or cardiovascular symptoms such as toxic-metabolic and infectious disorders. For all these reasons, correct diagnosis is important, but can be challenging. The evidence base for our understanding of the diagnosis and treatment of dizziness is weak (7), but has increased substantially in the past several years (8,9).

The traditional diagnostic approach to dizziness is based on "symptom quality," a paradigm that was first published in 1972, based on limited data from a small number of selected patients evaluated in a specialty clinic (10). The "symptom quality" method is to ask the patient, "What do you mean dizzy?" and their response will place them into one of the four categories: vertigo, presyncope, disequilibrium, or "other" nonspecific dizziness. Implicit is that each category has etiologic significance: Vertiginous patients have vestibular causes (usually peripheral), presyncopal patients have cardiovascular causes, those with disequilibrium have neurologic issues whereas nonspecific dizziness is caused by psychiatric disease.

The “symptom quality” approach has fundamental problems. The first has to do with the methods of the original 1972 paper (10). Methodologic weaknesses include small number of patients enrolled, diagnosis assigned by a single neurologist without independent verification, no brain imaging nor any long-term follow-up. Furthermore, some diagnoses known now to be common causes of dizziness (e.g., vestibular migraine), had not yet been recognized as diagnostic entities. Nevertheless, when no tests identified a specific diagnosis, the type of dizziness was used to assign the final diagnosis (e.g., vertigo was assigned a peripheral vestibular cause if no other cause was found). The paradigm of “symptom quality” has never been prospectively and properly validated.

Most ED dizzy patients would never end up in an outpatient specialist-run dizziness clinic, including those with acute cardiovascular, cerebrovascular, metabolic, infectious, and other causes. The original study was done in an era of fewer medications (propranolol was the only beta-blocker, there were many fewer antihypertensive agents) and far less polypharmacy. Thus, the patients in that 1972 study were not at all representative of patients seen in an ED in 2014.

Sensory symptoms are difficult to describe. A recent study asked patients a series of questions designed at describing their dizziness type (11). Within 10 minutes, they were asked the same questions but given the answer choices in a different sequence. Half the patients changed the category of dizziness that they had initially endorsed just a few minutes before, and most endorsed multiple dizziness symptom qualities. This fact alone seriously undercuts the “symptom quality” paradigm.

Other recent research shows that patients with cardiac causes of dizziness often use the word “vertigo” to describe what they are feeling (12). In another study of older patients presenting to an ED with dizziness, the use of the word “vertigo” (as opposed to lightheadedness or dizziness) did not predict those who had a cerebrovascular cause (13). The converse is also true. Patients with clear-cut vestibular disease often complain of vague lightheadedness or nonspecific “dizziness.”

Taken together, this literature suggests that using the "symptom quality" paradigm for the diagnosis of unselected dizzy patients has serious shortcomings. As well, they begin to suggest an alternative paradigm based on "timing and triggers." In the study showing that patients change their "type" of dizziness, their responses to issues about dizziness timing and triggers were far more reliable (11). Because the type of dizziness may not be etiologically useful and because many of the major dizziness syndromes have reliable timing and triggers patterns, an alternative paradigm based on "timing and triggers" may be more useful to the clinician.

The "timing and triggers" paradigm can be summarized using the mnemonic of **ATTEST** (see Table 14.1).

TABLE 14.1
Attest—A Method for Diagnosing Dizzy Patients

A—Associated symptoms, signs, or basic test results
Using the history (especially the HPI, ROS, and medications), vital sign, physical examination, and basic labs (e.g., finger-stick glucose or ECG) search for abnormalities that suggest a specific diagnosis or group of diagnoses
T—Timing
Is the dizziness intermittent or persistent? Did it start gradually or suddenly? If persistent, how long has the dizziness lasted and if episodic, how long do episodes last?
T—Triggers
Is there anything that triggers the dizziness (e.g., turning one's head, starting a new medication, standing up, or is it spontaneous? That is, does it "just happen" out of the blue?); distinguish "triggers" from "exacerbating factors"
ES—Exam Signs
Apply several bedside tests that can be very helpful in clinically distinguishing some dangerous from some benign causes of dizziness (oculomotor testing in AVS; in PVS, positional tests)
T—Testing
After history and physical examination with the appropriate bedside testing, there will be instances in which there is still significant diagnostic ambiguity about serious diseases. Perform whatever confirmatory testing or consultation is needed to try to resolve the ambiguity, erring on the side of patient safety

A: Associated symptoms, signs, and basic testing (such as finger-stick glucose)
TT: Timing and Triggers
ES: Exam Signs
T: Testing (if needed to confirm the clinical diagnosis)

First, the emergency physician (EP) should ask about associated symptoms that suggest a particular diagnosis or group of diagnoses (Table 14.2). For example, dizziness associated with chest pain, or vomiting and diarrhea, or acute neck pain, or fever and cough, suggest obvious possible diagnoses. Has the patient started a new medication? It is important to establish what symptoms accompany the dizziness since a large proportion of ED patients have various medical (and not vestibular or neurologic) problems that cause their dizziness (4). This step will often lead to a clear-cut limited differential diagnosis and workup for many patients (e.g., a chest x-ray for a dizzy patient with fever, cough, and green sputum).

TABLE 14.2
Associated Findings (That May Suggest a Specific Diagnosis or Group of Diagnoses)

History

Has the patient started a new medication or changed the dose of an existing one?

Has there been any recent head injury?

Does the patient have vascular risk factors or history of prior stroke or TIA?

Are coincident symptoms present?

- Headache or neck pain
- Fever
- Ear pain or discharge
- Hearing loss or tinnitus
- Chest pain or palpitations
- Dyspnea or other acute respiratory symptoms
- Abdominal pain
- Gastrointestinal blood or fluid loss (vomiting, diarrhea)
- Acute neurologic symptoms—diplopia, dysphagia, dysarthria, weakness, and any other new neurologic symptom

Physical Examination

Abnormal vital signs

- Fever
- Bradycardia or tachycardia
- Hypotension or severe hypertension
- Tachypnea or hypoxia

New murmur or gallop

New rales or wheeze

Gastrointestinal blood loss

Any new abnormality in the neurologic examination

Basic laboratory testing (as indicated)

Finger-stick glucose testing

Pregnancy testing

Urinalysis

Electrocardiogram

Next, the EP should ask questions designed to place the patient into one of four "timing and triggers" categories (see Table 14.3). These include the acute vestibular syndrome (AVS), the episodic vestibular syndrome (EVS), the positional vestibular syndrome (PVS), and the chronic vestibular syndrome (CVS). The history can be used to define the onset, duration, constancy, and triggering or exacerbating features. Patients can generally describe these features

of their histories more reliably than the "type" of dizziness (11). Each of these four categories suggests a particular differential diagnosis (see Differential Diagnosis section and Table 14.3).

TABLE 14.3
Timing and Triggers Categories for Dizzy Patients (and Differential Diagnosis of More Common Causes)[a]

Acute vestibular syndrome: Rapid onset of dizziness that persists for days and is associated with nausea, vomiting, head motion intolerance, nystagmus, and gait disturbance

Benign causes: vestibular neuritis (no auditory symptoms) and labyrinthitis (with auditory symptoms)

Serious causes: cerebellar and brainstem infarction (far less commonly, hemorrhage)

Episodic vestibular syndrome: Episodes of dizziness lasting minutes to hours without obvious trigger (occasionally shorter spells)

Benign causes: vestibular migraine, Menière syndrome (with auditory symptoms), vasovagal near syncope

Serious causes: cardiac arrhythmias, low-flow states (including PE or ACS), posterior circulation TIA)

Positional vestibular syndrome: Brief episodes of dizziness that are triggered, often lasting only seconds

Benign causes: BPPV

Serious causes: Orthostatic hypotension from hypovolemia (any cause), central positional vertigo (e.g., cerebellar tumor)

Chronic vestibular syndrome: Prolonged dizziness lasting weeks to years

Benign causes: presbylibrium, chronic bilateral vestibular failure, poorly compensated unilateral vestibular failure

Serious causes: paraneoplastic syndrome (e.g., cerebellar degeneration), posterior fossa tumor

[a]This is not meant to be an encyclopedic list, but rather a list of the more common and more serious conditions that are seen in the emergency department; there are many other causes of dizziness.

BPPV, benign paroxysmal positional vertigo; PE, pulmonary embolism; ACS, acute coronary syndrome; TIA, transient ischemic attack.

Once the category is defined, then one uses bedside and other routine tests to further narrow the differential diagnosis. Some of this testing is part of a normal physical examination. Is the patient mentating normally? Is there obvious nystagmus on primary gaze

(staring straight ahead)? Is there a murmur or signs of heart failure? Is there melena or evidence of gastrointestinal bleeding? Some of the confirmatory tests are a more detailed bedside oculomotor examination that helps to distinguish central from peripheral vestibular disorders. These tests are easy to learn to do and interpret.

Confirmation with more sophisticated (nonbedside) tests is the final step. This might mean a computed tomography angiography (CTA) of the chest if pulmonary embolism (PE) is the target diagnosis or telemetry, serial cardiac enzymes, and electrocardiograms if an acute coronary syndrome (ACS) is the concern. Many patients will not need these tests because the bedside examination findings and basic tests can establish some diagnoses (e.g., vestibular neuritis or benign paroxysmal positional vertigo or a urinary tract infection).

The "timing and triggers" paradigm frequently leads to making a specific diagnosis compared to the traditional "symptom quality" approach. The approach to patients with AVS and PVS have been studied fairly extensively (8,9,14), but it is important to acknowledge that the "timing and triggers" or ATTEST approach has not been prospectively validated or systematically studied.

DIFFERENTIAL DIAGNOSIS

Without some type of diagnostic strategy or algorithmic approach, diagnosis of the dizzy patient is an exercise in futility since dozens, if not hundreds, of individual conditions as well as side effects from nearly every medication can produce dizziness. An approach based on "timing and triggers" also suggests a differential diagnosis based on various temporal categories (Table 14.3).

For patients with an AVS, the major differential diagnosis is a peripheral vestibular process (of the eighth nerve or its end organ) versus stroke. The eighth cranial nerve has two components, the vestibular and the cochlear, that can be affected together or individually. Patients with vestibular neuritis have dizziness (but no hearing loss) (15). Patients with acute sensorineural hearing loss have diminished hearing (and no dizziness) (16,17). The term labyrinthitis is often used when both systems are affected. Because the organs of balance and hearing are colocated peripherally,

coinvolvement of dizziness and hearing generally implicates a peripheral process, but there is an important exception.

The labyrinth is supplied by the labyrinthine artery, which is a branch of the anterior-inferior cerebellar artery (AICA—itself originating from the basilar). It is, therefore, possible that an AVS or an acute sensorineural hearing loss is due to a stroke. This is probably less common than benign peripheral causes; however, with AICA strokes, both balance and hearing are usually affected (18). Although "vertigo" has been reported in patients with supratentorial stroke (19), patients with dizziness or vertigo as a prominent presenting symptom of cerebrovascular disease usually have posterior fossa strokes (20). Although vestibular neuritis accounts for the majority of patients who present with the AVS, cerebellar (or brainstem) stroke is the other important possibility that is critically important for the emergency physician to consider (21). Bedside testing can help distinguish between these groups of patients, and within the first 48 hours, may actually be better than MRI (14).

Acute intracerebral hemorrhage is a very rare cause of the AVS; almost all such patients have other neurologic symptoms or signs (22). Some older patients with a toxic–metabolic or infectious problem could present with an AVS but the frequency with which this happens is probably low ($<1\%$) (9) and many of these patients will likely be identified by attention to associated symptoms. Multiple sclerosis can also present as the AVS.

Vestibular migraine is the most common cause of the EVS. Migraine is extremely common in the general population and in one series of dizzy patients older than 65 years, 13% were found to have vestibular migraine (23). However, the EP should be cautious in diagnosing migraine in elderly patients without a prior history of migraine. Dizziness from migraine can occur with or without headache (24). Duration of attacks is often minutes to hours to days but can last seconds in 10% of patients (24). Head motion intolerance is common (24). Meniére disease is another cause of the EVS and is associated with episodic dizziness and hearing loss, tinnitus and ear fullness that last between minutes and hours (25). Meniére disease is an uncommon cause in the ED.

The major serious diagnoses that present with the EVS are transient ischemic attack (TIA) of the posterior circulation, cardiac arrhythmias, and transient low flow states such as from a PE, an ACS, or aortic stenosis. As for posterior circulation TIA, classic teaching is that other brainstem symptoms are nearly always associated with dizziness, at least in patients presenting with episodes occurring over more than 3 weeks (26). Since 1975, when the NIH published its TIA classification system (27), many authorities have recommended this definition, which stated that patients presenting with isolated vertigo, general dizziness, diplopia, and dysarthria should not be diagnosed with posterior circulation TIA. Several authors report that TIA can present with isolated dizziness (28–30). Others have reported that spells of dizziness (even over months) can herald a subsequent basilar stroke (31). More recent data clearly suggests that the symptoms above (formerly thought not to represent TIA) in fact do (32). Patients presenting with these symptoms had an odds ratio of 15 for having a vertebrobasilar territory stroke, many within the 48 hours following the transient neurologic symptoms (32). Some of these patients had isolated vertigo. Patients with vertebral stenosis and posterior circulation symptoms are at particularly high risk for subsequent stroke (33).

Patients with the PVS have a narrower differential diagnosis. BPPV is the most common benign cause. These patients have very brief episodes lasting about 15 to 30 seconds that are triggered by head movement. It is important to note that many episodes occur at night in bed and therefore some patients have difficulty precisely fixing the duration of the spells. This is one instance in which a symptom waking a patient from sleep makes a benign diagnosis more likely than a serious one. Patients with BPPV may feel an anticipation of dizziness and will sometimes report “constant” dizziness for days, but a careful history will tease out the true episodic nature of the dizziness. It is important to note that many patients with BPPV do not endorse true vertigo (34). As well, BPPV may be less well recognized in elderly patients (35). It bears reemphasis that these patients may complain of vertigo or vague lightheadedness or

dizziness that can easily be mistaken for orthostasis if symptoms occur on arising in the morning, as is often the case. The two can usually be distinguished, however, by inquiring whether the symptoms also occur on reclining or rolling over in bed, which should not occur in those with orthostatic hypotension.

More serious diagnoses that present as the PVS include orthostatic hypotension of any cause and central positional vertigo. The former can be due to any dangerous cause of hypovolemia such as gastrointestinal bleeding, fluid losses from gastroenteritis, persistent vomiting, and others including medication side effects (36). Abnormal orthostatic vital signs are very common in elderly patients especially in those who live in extended care facilities (37); this means that orthostasis is a common cause of dizziness, but also that the presence of an orthostatic blood pressure drop may be an incidental finding in an elderly patient with dizziness of another cause.

Central positional vertigo is a very uncommon BPPV mimic that can be caused by tumors, strokes, and other CNS lesions (38–40). Most of these patients will have physical examination clues during positional testing (Dix–Hallpike) that typical BPPV is not the correct diagnosis: persistent symptoms or signs lasting longer than 1 minute, downbeat nystagmus, lack of latency to nystagmus onset, and lack of therapeutic response to an Epley or other canalith repositioning maneuver (41).

Patients with the CVS whose symptoms persist longer than weeks most commonly have polysensory dizziness, degenerative neurologic disease, psychiatric syndromes, drug side effects, or drug–drug interactions, although specific data about the relative frequency for various causes are lacking. Occasionally, a patient with a slow growing posterior fossa tumor can present with the CVS.

DIAGNOSTIC APPROACH

History

The history is of paramount importance. In addition to the usual history, the following steps may help focus and supply clues that

may help pinpoint a diagnosis or at least help to narrow the list of potential diagnoses.

The ATTEST (Table 14.1) mnemonic should be used to gather the important elements of the history. Associated symptoms should be identified that may supply clues of the underlying etiology (see Table 14.2). Antecedent medication changes or head trauma may suggest a drug side effect or posttraumatic BPPV. The clinician's focus will be different with a patient who presents with severe abrupt onset headache with dizziness than with a dizzy patient who reports abdominal pain and diarrhea as associated symptoms.

A distinction should be made between "triggering" the dizziness and "exacerbating" the dizziness. "Triggered" dizziness suggests that something made a patient dizzy when they started out not dizzy. An example is a patient who is lying on a stretcher completely asymptomatic and when a Dix–Hallpike is done, the patient becomes dizzy. "Exacerbated" suggests that something increased a dizzy patient's symptoms (but they were already dizzy to start with). An example of this would be a patient with vestibular neuritis who feels dizzy at baseline while lying still in the stretcher, but on head motion, the dizziness intensifies.

This is a very important distinction and highlights a common misconception about dizziness (42). The misconception is that a patient whose dizziness worsens with head motion has a peripheral vestibular cause of their dizziness. This is not true. A dizzy patient from a stroke, multiple sclerosis, or a cerebellar tumor, will develop worse dizziness with head movement. A hypovolemic patient will also have worse dizziness upon changing position (standing up).

Next, a "timing and triggers" category should be defined by asking questions such as the following.

- "When did the dizziness start?"
- "Did it begin suddenly or gradually?"
- "What were you doing when it started?"
- "How long does the dizziness last?"
- "Is it episodic or continuous?"
- "If it's episodic, how long do episodes last?"
- "Are the episodes triggered or do they occur without warning?"

• “If they are triggered, what seems to be the trigger?”

PHYSICAL EXAMINATION

Physical examination of the dizzy patient needs to be fairly comprehensive given the long list of possible causes but always starts with considering the vital signs (factoring in the specific chief complaint). For example, if a patient has dizziness with a new fever, then the source of the fever should be sought. If the fever is associated with cough, then a chest x-ray is likely indicated. Dizziness and tachycardia should raise the suspicion of a gastrointestinal bleed or PE or perhaps just dehydration from poor PO intake as a result of a vestibular disorder.

The EP should not pigeonhole the patient too early in the evaluation and certainly not based on which word the patient uses to describe their dizziness. A patient endorsing true vertigo “like the room is spinning around” might have rapid atrial fibrillation whereas another patient complaining of “lightheadedness” might have BPPV. With the caveat that the physician has done relatively thorough general and cardiac examinations and that the vital signs do not suggest anything obvious or catastrophic, special care should be taken on the examination of the ears, eyes, and nervous system. As for the neurologic examination, the EP should test the gait, and focus on the cerebellar and oculomotor examinations.

The tympanic membrane is inspected for signs of otitis. Unilateral new hearing deficit plus dizziness suggests a peripheral cause, since hearing and balance end organs are colocated peripherally. However, in the appropriate setting (abrupt onset of symptoms in a patient with vascular risk factors), a stroke involving the AICA or its labyrinthine branch can cause acute hearing loss and dizziness.

Gait should be tested. Patients who normally use a cane or a walker should be tested using those devices to allow for a meaningful comparison with their baseline. A new gait abnormality, especially the inability to walk without falling, should suggest a central cause of dizziness or severe volume depletion. In a patient who is vomiting, having the patient try to sit up in the stretcher without holding on to the side rails (e.g., with arms crossed across the chest) will also test

for truncal ataxia. In patients with the AVS, presence of severe gait instability or truncal ataxia strongly suggests a CNS cause (21,43).

As well, in patients with the AVS, three specific bedside oculomotor tests can identify posterior circulation stroke more accurately than MRI, at least in the first 48 hours from symptom onset (14). These three tests are the horizontal head impulse test (HIT), testing for direction-changing gaze-evoked nystagmus, and alternate cover test for skew deviation (14). An important caveat to this study is that it was done by trained neuro-otologists. However, from the perspective of a practicing emergency physician, these tests are relatively easy to learn to perform and interpret. In patients presenting with an AVS, the presence of any of the worrisome findings suggests stroke (or another central cause) whereas the absence of all the worrisome findings strongly suggests a peripheral problem.

The HIT was first described in 1988 (44). Figure 14.1 shows how the test is performed and interpreted. The presence of a corrective saccade of the eyes back toward the examiner's nose is a positive test and means that the lesion is likely in the peripheral labyrinth. The maneuver tests the vestibulo-ocular reflex (VOR), which does not loop through the cerebellum or lower brainstem, that is why it is negative (no corrective saccade) in patients with cerebellar or medullary strokes. Pooled results across four studies identified as part of a systematic review showed that a normal HIT was found in 85% of patients with stroke ($n = 152$) and only 5% of patients with a peripheral vestibular problem ($n = 65$) (9). However, the HIT will be positive in some patients with brainstem stroke that affects the vestibular nerve root entry zone in the pons. Most patients with these brainstem strokes will have one of the other two eye findings on examinaton that indicates the central nature of the lesion (14). The HIT is a safe test although a single case of transient complete heart block has been described (45).

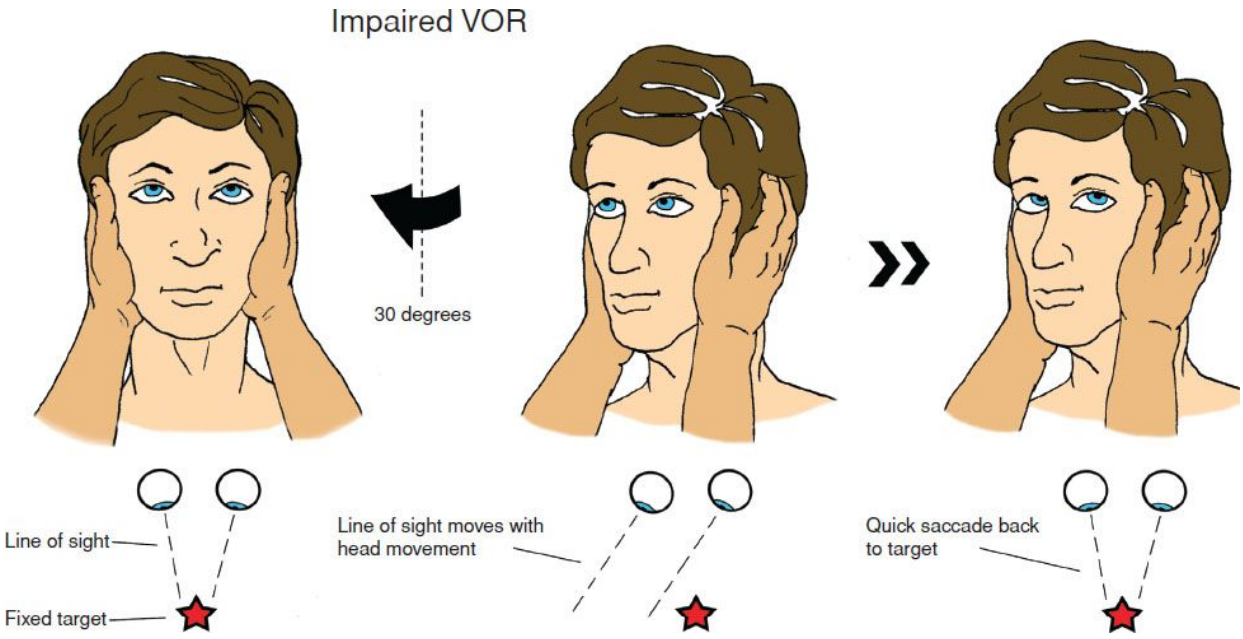

FIGURE 14.1 The head impulse test (HIT, sometimes referred to as the head thrust test) is a test of vestibular function that can be easily done during bedside examination. The HIT tests the vestibulo-ocular reflex (VOR), and can help to distinguish a peripheral process (vestibular neuritis) from a central one (cerebellar stroke). With the patient sitting on the stretcher, the physician instructs him to maintain his gaze on the examiner's nose. The physician holds the patient's head steady in the midline axis and then rapidly turns the head to about 20 degrees off the midline. **Panel 1:** The normal response (intact VOR) is for the eyes to stay locked on the examiner's nose. **Panel 2:** The abnormal response (impaired VOR) is for the eyes to move with the head, and then to snap back in one corrective saccade to the examiner's nose. The HIT is usually "positive" (i.e., a corrective saccade is visible) with a peripheral lesion (vestibular neuritis), and the test is normal (no corrective saccade) in cerebellar stroke. This occurs because the VOR pathway does not loop through the cerebellum. Occasional patients with small brainstem strokes may have a positive test because the VOR pathway does loop through the brainstem. Because it is the "positive" test that is reassuring with the head impulse test and the "negative" test that is worrisome, it is very important to only use the test in patients with the AVS. If one were to use the HIT in patients with pneumonia or with a fractured wrist, the HIT would be "negative" (worrisome for a

CNS event). Therefore, it is critical that it only be applied to patients presenting with an AVS.

There is one important issue with respect to the HIT that bears special emphasis. Because it is the "negative" or "normal" result (no corrective saccade) that is worrisome for a stroke etiology, it should only be done in patients with the AVS. For most elements of the physical examination, it is the abnormal result, which is the cause for concern, but for the HIT, it is the opposite. If one were to perform the HIT on normal individuals (or patients with pneumonia or sprained ankles), the result would be "normal" (and thus "worrisome"). Therefore, if one were to do a HIT on a patient with the EVS or the PVS, it would also be falsely "normal" and incorrectly suggest a central cause.

Nystagmus can be the clinician's friend. Patients with both vestibular neuritis and cerebellar stroke may have nystagmus. Merely reporting the presence or absence of nystagmus is not particularly useful and certainly does not distinguish benign peripheral etiologies from serious central ones. It is the nature of the nystagmus that can help to differentiate the two groups.

Patients with vestibular neuritis will have predominantly horizontal nystagmus, sometimes with a very slight torsional component (15,46). This may be present in primary gaze (patient looking straight ahead), and nearly always be present on gaze toward one side. When these patients look to the other side, they may still have nystagmus, but, if they do, the direction of the fast movement will be in the same direction as with the first side tested. The intensity of the nystagmus diminishes with fixation (46). In patients with CNS causes of dizziness, the nystagmus is usually still predominantly horizontal, but the direction of the fast component may "change direction." That is, when the patient looks to the left, the fast component beats to the left and when the patient looks to the right, the fast component beats to the right. Not very sensitive, this finding is found in approximately 20% to 50% of patients with central causes of dizziness (14,21); when present, however, it is very specific. Importantly, some normal patients will have slight

direction-changing nystagmus on extreme end gaze both right and left that resolves after a few beats and is symmetric; this is physiologic nystagmus.

Skew deviation is another relatively insensitive, but very specific finding indicating a CNS lesion in dizzy patients (14). Skew deviation is tested by performing the “alternate cover” test. With the patient instructed to focus on a fixed point, each eye is alternately covered over and then uncovered sequentially. This forces the patient to take up visual fixation first with one eye and then the other, which allows the examiner to assess whether the eyes are completely aligned. The examiner looks at the eyes to see if there is an upward or downward (hypertropia or hypotropia) correction as the eye is uncovered. This vertical misalignment is termed skew deviation. The presence of a horizontal misalignment (esophoria or exophoria) does not convey the same meaning.

Most patients with the EVS will usually be asymptomatic by the time they present to the ED; however if they are not, these same tests as above may be useful. Note however that a central localization does not necessarily mean a serious diagnosis. Migraine is a central phenomenon and patients with vestibular migraine may have findings that localize to the CNS.

In patients with the PVS, the Dix–Hallpike should be performed to test for BPPV of the posterior semicircular canal (the most common form). If this is negative and the history is strongly suggestive of BPPV, then the horizontal canal should be tested by the supine roll test (8). The Dix–Hallpike test is considered positive when there is reproduction of symptoms after several seconds of latency, with a burst of upbeat-torsional nystagmus and spontaneous resolution within 45 seconds, usually less. It should generally be positive on one side and negative on the other.

Torsional nystagmus is expected for BPPV (PVS) but pathologic in patients with the AVS. This illustrates how the “timing and triggers” category informs the “rules of nystagmus.” As well, patients with any cause of persistent dizziness, including CNS ones, will feel worse on head movements so tests producing only additional symptoms or

exacerbating pre-existing horizontal nystagmus should not be interpreted as positive.

DIAGNOSTIC TESTS

Unless a diagnosis is totally clear based on history and physical examination, and many times it will be (such as a patient with BPPV, vestibular neuritis, or hypovolemia), some basic testing probably makes sense. This is particularly true in elderly patients since the incidence of other diseases becomes increasingly common. Performing an electrocardiogram (ECG) may be useful in the dizzy geriatric patient and no obvious cause by history or physical examination. Checking the hematocrit, a basic metabolic profile including creatinine, and a stool guaiac may also be helpful. Beyond these basics, diagnostic should be targeted rather than "shotgun." If PE is the suspect diagnosis, a CT angiogram of the chest might be the best first test. If drug toxicity in a heart failure patient taking digoxin is considered, then a serum digoxin level might be an appropriate first test.

The less well a patient is able to communicate the details about their dizziness, the less well this system (or any other) will allow the physician to tailor their differential diagnosis and therefore, the subsequent testing. The important goal is to try to make a specific diagnosis. Because medication side effects are an important cause of chronic dizziness, an outpatient trial of stopping a medication might be the appropriate "test"; of course this should be coordinated with the primary care doctor.

It is very important to know the limitations of commonly used tests, especially computed tomography (CT) of the head for posterior circulation stroke (47). A recent study estimated the sensitivity of CT for acute posterior fossa stroke to be 42% (48), but studies with direct comparison to MRI scans suggest it could be as low as 16% in the first 24 hours (49). If stroke is a serious consideration, MRI with diffusion-weighted imaging is needed. Since hemorrhage is a rare cause of isolated dizziness, physicians should strongly consider starting with MRI (22). However the clinician must also be aware that even MRI is imperfect, and may miss up to 20% of posterior

circulation strokes in the first 24 to 48 hours after symptom onset (9,14).

CRITICAL INTERVENTIONS

- The treatment for BPPV is a canalith repositioning maneuver, most commonly the Epley maneuver if the BPPV is of the posterior semicircular canal (~85% of cases) (50,51). In elderly patients, one ought to make sure that the neck is sufficiently mobile to safely move the head and neck as needed; in these patients a different "side-lying" (Semont) maneuver may be used (34,52). Some patients with a typical history of BPPV will have a negative Dix–Hallpike and will not respond to an Epley maneuver. Many of these patients will have horizontal (lateral) canal BPPV diagnosed by supine roll test and can be treated with a Lempert barbecue roll maneuver (8). If a patient does not respond as expected (e.g., they have sustained nystagmus, downbeat nystagmus, no latency, bilateral positive positional test, or other new neurologic signs), the clinician should consider a rare BPPV mimic, which can be due to various CNS lesions (39).
- Patients with vestibular neuritis who present within 72 hours of symptom onset should probably be treated with steroids unless there is a contraindication (46,53). Although a vestibular "sedative" such as meclizine may be useful, its use should be limited to several days beyond which time it can impair vestibular compensation (46). As well, meclizine should not be used for BPPV, for which it has no therapeutic effect and can only potentially worsen symptoms due to its sedating side effects.
- With any peripheral cause of dizziness, it is important to ensure that the patient is well hydrated as there is a tendency for them to have become dehydrated because of nausea and decreased oral intake.
- Patients who have a posterior circulation stroke or TIA or high risk for one should be admitted to the hospital for further monitoring, vascular workup, and treatment. Treatments should be applied to prevent secondary progression or complications or

cerebellar stroke such as obstructive hydrocephalus or brainstem compression, as appropriate.

- Treatment for other specific diagnoses made are obviously based on the diagnosis made (heparin for PE, endoscopy and/or transfusion for a GI bleed, etc.).

DISPOSITION

The disposition is a function of two issues—specific diagnosis and general environmental safety. A patient with an AVS due to an ischemic cerebellar stroke requires admission both to diagnose and treat the underlying vascular lesion as well as to observe for deterioration from posterior fossa edema. Another patient with the exact same presentation but which is due to vestibular neuritis can be sent home with oral steroids and meclizine for symptomatic control. Therefore, disposition is partly a function of the underlying diagnosis. Although vascular risk factors may help stratify those at highest risk for TIA and stroke (e.g., using the ABCD2 rule) (54), care should be taken not to rely too heavily on age or related risks to exclude vascular disease—it is well documented that younger patients with vertebral artery dissection may present with dizziness or vertigo due to TIA or stroke (9) and are most likely to be misdiagnosed with dangerous consequences (55,56).

Simultaneously, the second issue is ensuring environmental safety. This is especially important in elderly dizzy patients. Dizzy patients may become dehydrated, worsening their symptoms, whatever their initial cause. Therefore, even the patient with vestibular neuritis might require admission if they are dehydrated and still sufficiently symptomatic such that they cannot keep up with fluids. Most patients with BPPV can safely go home after canal-repositioning treatment. However an elderly BPPV patient who is somewhat dehydrated, volume sensitive, and lives alone may need to some slow intravenous fluids as an inpatient prior to safe discharge. An elderly patient who has a few steps to get to the bathroom or lives with a healthy spouse may need a different disposition than another who normally has to climb a flight of stairs to do the same or lives alone.

Common Pitfalls

- Failure to identify timing and triggers to best define the category into which a patient falls.
- Failure to recognize that use of the word “vertigo” or “near fainting” does not necessarily signify a vestibular or CNS cause in the first case or a cardiovascular one in the second.
- Failure to recognize that peripheral causes of the AVS (vestibular neuritis) can closely mimic central causes (posterior circulation stroke). Posterior circulation TIA is becoming increasingly recognized.
- Failure to use bedside physical examination including gait testing and a focused oculomotor examination to differentiate peripheral from central causes of AVS. The HIT will be falsely worrisome if it is performed in patients who do not have AVS.
- Failure to categorize nystagmus differently based on syndromic category. Direction-changing horizontal nystagmus on gaze testing or predominantly vertical or torsional nystagmus is due to CNS disease in AVS, but not necessarily in PVS.
- Failure to focus more on the syndrome and examination findings than on the patient’s age or vascular risk factors—young patients have strokes too, and these are most likely to be missed.
- Failure to understand the limitations of CT scanning for cerebellar and brainstem infarction.

SECTION III
Pain Management and Procedural Sedation

Section Editor: CARLO L. ROSEN

Medical Foramen

CHAPTER 15

Acute Pain Management

Steven Rosenzweig, Bernard L. Lopez, and Glenn Oettinger

Acute pain is the most common symptom for which patients seek emergency care, and analgesics account for one-third of all medications prescribed in US emergency departments (EDs). Studies consistently document that pain is often inadequately treated by physicians in the ED and other settings (1). Expediting appropriate and compassionate pain relief remains one of the greatest challenges in the practice of emergency medicine today (2).

Drugs used to treat pain act by reversing the underlying cause of pain (e.g., nitrates for angina) or by suppressing the symptom (i.e., the perception of pain). This chapter focuses on drugs used to treat the symptom of acute pain. Other medications that reverse the underlying cause of pain are discussed elsewhere in this book. Related discussions include the chapters on conscious sedation (Chapter 17), and chronic pain syndromes (Chapter 16).

PAIN ASSESSMENT

Current practice standards include pain assessment as the fifth vital sign. However, many challenges exist to the accurate assessment of pain in the ED.

Subjective Nature of Pain

Pain is an experience that has both physical and nonphysical dimensions. Physiologically, pain is mediated by a set of neurochemical events. At the level of consciousness, it is an event of personal suffering. The perception of pain and severity of suffering is

highly individual. These are affected by an individual's psychological and cultural conditioning, cognitive appraisal of pain, emotional state, and coping style.

The *language of pain* presents a challenge to clinical assessment. It can be very difficult for anyone to find words to convey either the quality of pain or its severity. Descriptions lack the preferred exactness of medical terminology. People resort to imagination and simile: "My back feels as if it is caught in a vise," or "My hand feels like it is on fire." Another problem is that patients and physicians use words differently. For example, a patient may use the word *sharp* to mean *severe,* whereas the physician may assume it to mean *knifelike.* Perhaps the most classic example is the patient with acute coronary syndrome who denies chest *pain* but will admit to chest *pressure* upon further questioning. Active listening and clarification yield critical information about pain severity and provide clues to etiology.

One of the most important aspects of the pain experience is the *meaning* it holds for the sufferer. Pain is often greater when its cause is perceived to be life threatening or when it is associated with emotional trauma. Conversely, pain that is perceived to offer some secondary gain can be easier to bear.

Objective Signs of Pain Are Unreliable

The emergency physician cannot rely on objective findings in estimating pain severity: The patient need not *appear* in pain to actually *be* in pain. There are no objective signs that can be used to accurately gauge the magnitude of a patient's pain. Indicators such as heart rate, blood pressure, respiratory pattern, facial expression, and body posture are not reliable. The presentation of pain may be obscured by the effects of medication such as β-blockers that blunt the adrenergic response to pain. Other medications may produce sedation but not analgesia: Drowsiness does not mean absence of pain. Pain may be underdiagnosed because of a patient's cultural bias toward stoicism or complex coping mechanisms, such as joking or maintaining a facade of being calm.

Equally unreliable is an estimate of pain severity based on its etiology. Can a toothache be more painful than salpingitis? Should

an ankle sprain hurt less than pleurisy? These questions cannot be answered, because suffering depends on each individual's pain threshold and sensitivity to a particular condition.

Utilizing the Patient's Self-Report

The subjective nature of pain means that the single most reliable method of assessing pain severity is the patient's self-report. Clinical judgment must always be guided by the patient's own assessment. This situation in which the patient knows more than the doctor is a role reversal with which many physicians feel uncomfortable. Nevertheless, accurate pain assessment must acknowledge the authority of the patient or the insight of a close family member or friend.

Asking the patient whether or not the pain is "tolerable" or "bearable" provides a straightforward assessment of treatment urgency. Patients can be assisted in conveying pain severity with a visual analog scale (VAS) or numeric rating scale (NRS); these have been validated for use in the ED (3,4) and either can be used. The VAS has been typically used for research purposes and requires the patient to physically mark a 100-cm line and the examiner to measure the mark with a ruler. The NRS is administered verbally with the examiner giving clues to the anchor points of 0 and 10. These scales need to be explained (e.g., 0 indicates no pain and 10 indicates the worst pain imaginable). Extreme ratings (e.g., 10 out of 10) should prompt clarification; these may indicate life-threatening pathology such as a subarachnoid hemorrhage or ischemic bowel, or alternatively reveal the severity of a patient's fear and anxiety. Asking a patient to relate their current pain to a past painful condition (e.g., pain of childbirth) can further assist the interpretation of pain scores.

Assessing pain in patients who are nonverbal or who have limited verbal ability is especially challenging. Numerous pain assessment scales are available that rely on behavioral indicators (e.g., grimacing and restlessness).

Distinguishing Pain-Avoiding Versus Drug-Seeking Behavior

The greatest impediment to accepting a patient's self-report of pain is the physician's concern of being manipulated into giving opioids to someone who is feigning illness. Bear in mind that *pain* is the most common reason for drug-seeking behavior. Even a legitimate patient may feel the need to dramatize distress to convince the doctor of his or her need. It may indeed be impossible to know for certain whether the patient's complaint is a sham; the gain of thwarting the possible abuser must always be weighed against the risk of withholding relief from the person who is truly suffering.

Opioid tolerance must not be misunderstood as drug-seeking behavior. Patients with chronic pain syndromes who are maintained on opioid therapy would require supplemental opioid dosing for superimposed acute pain syndromes. Methadone maintenance and combination of buprenorphine/naloxone (Suboxone) treatments for addiction do not provide analgesia and these patients would also require supplemental opioid if indicated. Patients treated with sustained-release naltrexone (Vivitrol) for alcohol or opioid dependence are a special case and require cardiopulmonary monitoring with dedicated personnel during reversal of opioid blockade for analgesia.

The diagnosis of drug abuse is based on a pattern of behavior that is often difficult to be established during a single ED encounter. Nevertheless, a few important steps can be taken: Perform a detailed history and physical examination, being alert to inconsistencies and signs of substance abuse (1); review prior ED and hospital medical records (2); obtain patient permission to confirm the medical history by contacting the personal physician or reviewing outside medical records (3); and develop an ED policy for evaluation and management of patients who raise concerns (4). This may include use of HIPAA compliant habitual patient files, criteria for urine drug testing, and developing a multidisciplinary case management system for selected patients.

Assessing Pain in Vulnerable Populations

As in any adult, pain in a child should be anticipated and aggressively treated. However, children are much less likely than adults to be given adequate analgesia for the same painful condition (5). This observation has been attributed not only to the difficulties inherent to pain assessment but to the persistent myth that young children do not experience or remember pain. Older children are generally able to describe their pain or point to pictures on a pain analogue scale. When assessing pain in younger children and infants, the quality of cry, facial expression, changes in vital signs, and impressions of the caretaker should all be taken into account.

Historically, pain has often been undertreated in older adults. Effective history-taking often requires greater time and patience. Verbal assessment may be limited due to dementia or delirium (6). Unconscious ageist bias may cause the EP to minimize or dismiss the patient's complaints.

Pain assessment depends upon communication and empathy. Medical care across lines of social difference between EP and patient poses challenges to both. Language discordance between physician and patient is an obvious impeding factor. Discordance in race, ethnicity, culture, class, gender, age, and physical ability is also significant. Studies have shown the undertreatment of pain in minoritized populations (1). Physicians must be willing to reflect on negative stereotyping and implicit biases that may interfere with accurate pain assessment, and be particularly self-aware when treating these patients.

ED MANAGEMENT

Expediting Relief

Pain relief should be timely. Unnecessary delays can often be averted. Patients often can and should be treated before a definitive diagnosis is established. Initial interventions can be nonpharmacologic (discussion follows). When the diagnosis depends solely on a laboratory or radiographic finding, there is no need for delaying analgesia while a time-consuming evaluation is proceeding.

The belief that analgesics, particularly opioids, will obscure the underlying diagnosis is generally unfounded. Although it is common to withhold such medication from a patient with abdominal pain who may need surgical evaluation, this practice is not supported by clinical studies (7,8). On the contrary, the judicious use of short-acting agents will serve the needs of both the patient and the consulting surgeon. Providing pain relief may actually enhance the patient's cooperation and improve the accuracy of the examination. Factors to consider in the administration of analgesics include severity of abdominal pain and speed of the surgical consultation (9). The emergency physician should consider administering analgesics with the target of reducing patient suffering but not obliterating the pain to allow a useful physical examination by the surgeon. Ironically, analgesics often continue to be withheld in the ED even after a decision has been made to take a patient to surgery. As the patient's most important advocate, the emergency physician must coordinate a rational and humane approach that takes into account the distress of the patient and the availability of the consultant.

Pain should be treated even if informed consent may subsequently be required. The practice of withholding all opioids from a patient who might later need to sign a consent form for surgery or other procedure is unjustified. Informed consent requires decisional capacity and voluntariness. Concern that *any* dose of opioids compromises decisional capacity is unfounded. Pain itself is distracting and mind altering; its relief can enhance rational decision making. Analgesia can be titrated without clouding consciousness; in rare cases, an opioid antagonist could be administered. The message that pain medication will be administered only after the consent form is signed is itself coercive and violates the requirement of voluntariness.

The physician should anticipate and treat pain before it develops. Good pain management involves anticipating pain prior to its onset or recurrence. Medications should be given before painful procedures (see Chapter 17). Similarly, patients should be discharged with appropriate medication for pain that may continue or recur.

Nonpharmacologic Therapy

A variety of simple and effective interventions can reduce pain.

Provide physical comfort measures. Attending to the overall physical comfort of the patient can alleviate factors that aggravate pain. This includes such actions as helping the patient find a more comfortable position, adjusting the lighting in the room, warming a patient who feels chilled, immobilizing injured extremities, and applying ice and elevation to closed bone and soft tissue injuries.

Provide psychological support. Physical suffering is amplified by fear, anxiety, and helplessness. Fear often relates to the thought that the cause of pain is life threatening or permanently disabling. New pain in a cancer patient raises the specter of disease progression. Patients with chest pain often present with a fear of myocardial infarction. A laborer may associate an acute shoulder injury with the alarming possibility of permanent loss of income. Information and appropriate reassurance may reduce the amount of analgesics needed. Supportive family members or friends should be allowed to sit with the patient. For unaccompanied patients, facilitating phone contact with a friend or family member may provide significant comfort.

It is also important to address the patient's expectations regarding pain medications. The emergency physician should let the patient know from the outset how much time it will take for the medication to work and whether to anticipate partial or complete relief. In addition, the physician can assure the patient that more analgesics can be administered as needed. This can allay a premature concern that the drug "is not working."

Distress also arises in response to the ED experience itself. Patients find themselves in a harsh and unfamiliar milieu, feeling vulnerable, dependent on strangers, and relatively helpless. Building rapport, dignifying interactions, and restoring some sense of control to patients are all essential in emergency pain management.

Pain and distress may also be helped by simple hypnosis or guided imagery techniques that relax the body and calm the mind. Videos, storytelling, and imagining favorite places or activities are distraction techniques used for pediatric patients. The role of

complementary and alternative therapies for adjunctive, acute pain management in the ED is not known. Although the overall analgesic efficacy of acupuncture has been established, limited research has been conducted on its application in the ED.

Pharmacologic Therapy

Dozens of drugs are available to treat pain. To select the best regimen for an individual patient, the emergency physician should consider the following:

1. How intense is the pain?
2. How quickly is pain relief required?
3. Can the patient take oral medications?
4. Are there contraindications to particular agents?

The answers to these questions help direct the choice of drug, dose, and route of administration.

Aspirin and Acetaminophen

Aspirin and acetaminophen are equally effective for the relief of mild-to-moderate pain. eTable 15.1 lists dosing recommendations for these drugs. Aspirin, the prototype nonsteroidal anti-inflammatory drug (NSAID), is believed to work by blocking cyclooxygenase (COX) enzymes, thereby inhibiting the synthesis of prostaglandins, which mediate both pain and inflammation. Unlike aspirin, acetaminophen lacks anti-inflammatory properties, and its central mechanism of action is poorly understood.

eTABLE 15.1
Dosing Information for Nonopioids

Drug	Dosage	Comments	Generic Formula Available
Acetaminophen (Tylenol)	650 mg q4h	No anti-inflammatory activity	Yes
	1,000 mg q6h		
Aspirin	650–975 mg q4h		Yes
Aspirin, nonacetylated (salsalate)	≤1,500 mg BID	No effect on platelet function	Yes
Choline magnesium trisalicylate	1,000–1,500 mg BID	Oral liquid available	Yes
Celecoxib (Celebrex)	400 mg initially	Selective COX-2 action	Yes
	200 mg BID	Contraindicated in sulfonamide allergy; caution in patients with cardiovascular disease	
		May offer less GI toxicity	
		No inhibition of platelet function	
Diflunisal (Dolobid)	1,000-mg load; then 500 mg BID		Yes
Diclofenac (Voltarin)	Diclofenac potassium: 50 mg TID to QID		Yes
	Diclofenac sodium: 75 mg BID		Yes
	Voltarin XR: 100 mg QD to BID		No
	Voltarin Gel: 2 g to upper joint; 4 g to lower extremity joint up to QID	Risk of dermatitis	No
			No
	Flector Patch: 1 BID	Risk of dermatitis	
Etodolac (Lodine)	200–400 mg q6–8h		Yes
Fenoprofen (Nalfon)	200–600 mg q6–8h		Yes
Ibuprofen (Motrin and others)	Oral: 400 mg q4–6h or 600 mg q6–8h or 800 mg q8h	Oral liquid available	Yes
	Parenteral: 400–800 mg IV (IM not approved). Slow infusion over ≥30 minutes.		
Indomethacin (Indocin)	25–50 mg TID	FDA approved only as an anti-inflammatory	Yes
		Frequency of adverse effects higher than other NSAIDs. Available as a suppository	
Ketoprofen	25–75 mg q6–8h		Yes
Ketorolac (Toradol, Sprix)	Oral: 10 mg PO q4–6h; max: 40 mg/day; start: 20 mg PO ×1 if <65 yo and >50 kg	Multiple black box warnings for all formulations (see text); limit to 5 days of therapy	Yes
	Parenteral: Dose: Initial 30 mg IV or 60 mg IM; then 30 mg IV/IM q6h; >65 yo or <50 kg, 15 mg IV/IM q6h, max 60 mg/day		
	Nasal: 1 spray QID		
Naproxen (Naprosyn, Aleve), Naproxen sodium (Anaprox)	500 mg initially, then 250–500 mg BID	Oral liquid available	Yes

Aspirin commonly leads to gastrointestinal (GI) distress. It very rarely causes a hypersensitivity reaction (more common among asthmatics with nasal polyps), characterized by bronchospasm, urticaria, rhinitis, and even shock. Aspirin inhibits platelet function, although salsalate, a nonacetylated aspirin product, does not have this effect. Because acetaminophen is free of these side effects and hypersensitivity risk, it is often the preferable drug. It is available as a rectal suppository for patients who cannot tolerate oral administration.

Nonsteroidal Anti-Inflammatory Drugs

At usual doses, NSAIDs are not as safe as acetaminophen but are generally better tolerated than aspirin. All six major chemical classes of NSAIDs inhibit COX but also act through nonprostaglandin-mediated pathways. Doses in the higher range are generally required to achieve anti-inflammatory effects, which may not be seen for a

few days. Although no oral NSAID has emerged as a consistently superior analgesic, it is widely believed that an individual patient may respond to one agent (or chemical class) and not another.

Nonselective Nonsteroidal Anti-Inflammatory Drugs

Older, nonselective NSAIDs inhibit COX-1 and COX-2 enzymes and may directly modulate neutrophil responses (see Chapter 304). When given as a single, full dose in the acute setting, most NSAIDs are more effective than aspirin or acetaminophen. In some situations, they provide analgesia equal or superior to certain oral opioids.

The onset of analgesia is within 1 hour for the majority of NSAIDs. For drugs with a relatively long half-life, such as diflunisal and naproxen, onset of analgesia is considerably longer but can be hastened by administration of a loading dose. For patients who cannot swallow pills, several agents are available in a liquid form eTable 15.1. For patients who are vomiting or for whom oral medications are contraindicated, rectal suppositories of naproxen and indomethacin are available; another option is parenteral ketorolac, discussed below.

Parenteral NSAIDs

Ketorolac was the first NSAID available in the United States for parenteral administration in the ED, either IM or IV. There is controversy as to whether the analgesic efficacy of parenteral ketorolac is generally comparable to that of parenteral opioids. For example, a single dose of IV ketorolac may be at least as effective as titrated, IV opioid in relieving pain in patients with renal colic (10). However, it is important to note that its efficacy in renal colic appears to be related to ureteral or renal prostaglandin mechanisms and may not be generalizable to other painful conditions. When studied in the ED setting, parenteral ketorolac does not provide superior analgesia to oral ibuprofen (11,12). Given parenterally, ketorolac does not act any faster than many oral NSAIDs: Drug effect is limited by the time to prostaglandin inhibition, not absorption. Thus, in many instances parenteral ketorolac offers no advantage

over far less expensive alternatives. Ketorolac also exists in oral and intranasal formulations.

Ketorolac is associated with the greatest adverse event potential among all NSAIDs and carries black box warnings for GI risk, cardiovascular risk, renal risk, bleeding risk, fetal risk, and risk to nursing infants. Risk increases with duration of use that should be limited to 5 days maximum for all forms of ketorolac. Dosages must be reduced in pediatric and geriatric populations.

Intravenous ibuprofen (Caldolor) carries fewer black box warnings and may be a safer alternative. It is not approved for IM administration.

Topical Diclofenac

Pharmacokinetic data suggest that topically applied NSAIDs can result in enhanced local concentrations without significant toxic systemic effects. Nevertheless, topical Diclofenac still carries black box warnings for cardiovascular and GI risks. Voltaren Gel and Flector Patch are approved for treatment of minor sprains, strains, and contusions. Patches are considered to provide more consistent dosing than gel. Both of these nongeneric preparations are expensive but do provide adequate pain relief and can be prescribed from the ED.

Selective COX-2 Inhibitors (COXIBs)

COXIBs selectively block COX-2, the form of COX that mediates inflammation, without affecting COX-1, the inhibition of which can produce gastric injury (13). They are no more effective than nonselective, less costly NSAIDs. Celecoxib (Celebrex) is currently the only COXIB available for prescription in the United States, with others withdrawn from the market owing to higher risk of cardiovascular thrombotic events. Celecoxib may have an improved gastric safety profile compared with nonselective NSAIDs but still carries a black box warning for GI risk. COXIBs do not interfere with platelet function. They may be considered for a highly select group of patients at risk for peptic ulcers who have a well-established

indication for NSAID treatment, or perhaps for patients at increased risk of bleeding.

Advantages and Disadvantages of Nonsteroidal Anti-Inflammatory Drugs

NSAIDs do not cause respiratory depression and rarely cause mental clouding. Given their anti-inflammatory properties, they treat the cause and the symptom of pain in conditions such as inflammatory arthritis or soft tissue injury. NSAIDs do not have abuse potential. NSAIDs carry black box warnings for cardiovascular and GI risks. Ketorolac carries additional black box warnings as mentioned above. The risk of cardiovascular thrombotic events increases with the presence of concomitant risk factors and duration of use. While other COXIBs may have posed the greatest cardiovascular risk, celecoxib may be associated with a lesser risk than nonselective NSAIDs (14).

Dyspepsia, the most common side effect, can be minimized by administering the drug with food or an antacid. Less commonly, NSAIDs lead to ulcers and upper GI bleeding and perforation, complications that are seen more with chronic rather than short-term use but may occur any time during treatment and without warning, especially in the elderly. NSAIDs are thus strongly contraindicated in patients with active ulcer disease and should be given with great caution to those with a history of upper GI bleeding. The incidence of GI bleeding may be dose dependent; daily doses of ibuprofen exceeding 1,500 mg are associated with increased risk. Other risk factors for GI complications include patient age older than 60 years and concurrent steroid or anticoagulant use (15). In such high-risk patients, the chance of GI bleeding can be reduced by coadministration of a proton pump inhibitor or misoprostol, at least with long-term NSAID use. The benefit these agents offer with short courses of NSAID is less well established. Other agents that were often used for prophylaxis of NSAID-related GI complications are either ineffective (antacids, sucralfate) or marginally effective (H_2 blockers). COXIBs, without gastroprotective drugs, may represent another therapeutic option in patients with risk factors for GI bleeding.

All NSAIDs, *including* COXIBs, may affect the kidneys, causing fluid retention and renal insufficiency, and possibly acute renal failure. Patients at greater risk for renal complications include those with chronic renal insufficiency, those with reduced renal perfusion (congestive heart failure or cirrhosis), and those taking diuretics or angiotensin-converting enzyme inhibitors. NSAIDs should generally be prescribed for no more than a few days in this patient population.

Because they interfere with platelet function, nonselective NSAIDs predispose to bleeding and should not be given to patients with thrombocytopenia or intrinsic clotting abnormalities. They should generally not be used in patients receiving anticoagulants and in those suspected of internal bleeding, as in the case of severe headache with possible subarachnoid hemorrhage.

Very rarely, NSAIDs cause hypersensitivity reactions such as urticaria and bronchospasm; patients who are sensitive to aspirin are at greater risk. NSAIDs are generally contraindicated during pregnancy, particularly in the third trimester, because of known effects on the fetal cardiovascular system (closure of the ductus arteriosus).

Opioid Analgesics

Opioids are usually the first-choice drugs for the prompt relief of severe, acute pain. Unlike the NSAIDs, they have no ceiling on analgesic effect. Given IV, they work within minutes, and their effect can be titrated and reversed. Many patients treated with these agents, however, do not receive adequate pain relief because of physicians' misconceptions about correct dosing, route of administration, and adverse effects.

Dosing by Titration

The effective analgesic dose varies considerably among patients; the *correct* dose of opioid is the dose that works. While some adult patients may respond to a low dose (i.e., morphine 2 mg IV), others may require higher doses for adequate pain relief. The "given" initial doses published in various references can serve only as general guidelines (16). Therefore, in the initial treatment of severe pain, it

makes sense to titrate small frequent doses to effect. In pediatrics, weight-based dosing (i.e., morphine 0.1 mg/kg/dose IV) is traditionally used to guide safe and effective initial treatment (Table 15.1 and eTable 15.2).

TABLE 15.1
Dosing Guidelines for Parenteral Opioids

Drug	Route[a,b]	Dosage	Comments
Morphine	IV	Titrate 2–5-mg increments q5–10 min Peak analgesia in 10–20 min Average = 10 mg q3–4h	Preferred first-line agent in most situations
	IM/XC	Average = 10 mg q3–4h	
Fentanyl	IV	Titrate 25–50-µg increments q2–3 min Peak analgesia in 3–5 min Duration 30–60 min	Ideal for short procedures No histamine release
	IM/SC		Not suitable for the ED
Meperidine (Demerol)	IV	Titrate 12.5–50-mg increments Peak analgesia in 5–10 min Average = 100 mg q2–3h	Risk of unique CNS toxicity with repeated dosing
	IM/SC	Average = 100 mg q3h	IM/SC injection is very irritating to tissue
Hydromorphone (Dilaudid)	IV	Titrate 0.5–1-mg increments Peak analgesia in 5–15 min Average = 1.5 mg q3–4h	High-solubility benefits SC injection
	IM/SC	Average = 1.5 mg q3–4h	
Butorphanol (Stadol)	IV	Titrate 0.5–2-mg increments Peak analgesia in 4–5 min Average = 2 mg q3–4h	Mixed agonist–antagonist May be preferred in biliary colic
	IM/SC	Average = 2 mg q3–4h	

Note: Intervals are approximate. Individual patients may require dosing either more or less frequently.
Caution: Dosing may need to be adjusted in the elderly, patients weighing <50 kg, and those with renal or hepatic insufficiency.
[a]IV route is preferred for faster onset and ability to titrate to effect.
[b]Rapid IV administration increases incidence of respiratory depression, hypotension, nausea, and itching; IV administration should be slow (over 4 to 5 minutes), with the patient recumbent.

eTABLE 15.2
Pediatric Dosing Guidelines for Drugs for Pain Management[a]

Drug	Route	Dosage (mg/kg/dose)
Morphine	IV	0.1–0.2
Fentanyl	IV	0.001–0.003
	Oral/transmucosal	0.005–0.015
Codeine	Oral	0.5–1 q4–6h
Acetaminophen	Oral/rectal	10–15 q4–6h
Ibuprofen	Oral	10 q6–8h

[a]For further pediatric dosing guidelines, see Chapter 220, "Pediatric Procedural Sedation, Anxiolysis and Analgesia."

Once satisfactory analgesia is achieved, another common pitfall is to withhold a subsequent dose until a "standard" dosing interval has elapsed. Statements about "average duration of action" provide only a rough estimate and some patients require more frequent dosing.

A common error is to mistake an inadequate dose with an ineffective agent; this is the tendency to switch opioids when the first dose does not relieve pain, rather than upwardly titrating the initial agent of choice. The upper limit of an opioid dose is determined by its side effects.

Equianalgesic Dosing and Opioid Cross-Tolerance

The potency of opioids varies widely. The emergency physician must understand how to determine the equianalgesic dosages of various agents. See Table 15.2 for dosage equivalencies.

TABLE 15.2
Oral Opioid Dosing Information

Drug	Analgesic Equivalence (mg)[a]	Usual Starting Dose (mg)[b]	Usual Interval (hrs)
Morphine (MSIR, Roxanol, others)	30	15–30[c]	3–4
Morphine: sustained release (MS Contin, Oramorph SR)	30	30[c]	8–12
Meperidine (Demerol)[d]	300	50–100	2–3
Codeine (in Tylenol #3, others)[e]	200	30–60	3–4
Oxycodone (Roxicodone, also in Percocet, Percodan, Tylox, others)	20–30	5–10	3–6
Hydrocodone (in Lorcet, Lortab, Vicodin, others)	30[f]	5–10	3–6
Hydromorphone (Dilaudid)	7.5	4–8[c]	2–3
Tramadol (Ultram)	N/A	25–50	4–6

Note: Addition of a nonopioid may allow lower dosing of an opioid. In using combination products, be careful not to exceed the allowable dose of the nonopioid constituent.
Intervals are approximate. Individual patients may require dosing either more or less frequently.
Caution: Dosing may need to be adjusted in the elderly, patients weighing <50 kg, and those with renal or hepatic insufficiency.
[a]Doses equianalgesic to IV morphine 10 mg and IV meperidine 100 mg.
[b]Doses in this column are not equianalgesic.
[c]Usually reserved for chronic, severe pain.
[d]Meperidine has a unique CNS toxicity with repeated dosing and is not recommended as a first-line agent. See text.
[e]Doses >60 mg are not recommended. See text.
[f]Limited data available.

Opioid cross-tolerance poses the critical exception to calculating equianalgesic dosing. This phenomenon is relevant to pain patients who present to the ED on chronic opioid therapy such as oxycodone. The patient will be somewhat habituated to oxycodone and more sensitive to a different opioid. Should the physician need to treat pain with a different agent—with IV morphine, for example—the calculated equianalgesic dose must be *reduced* initially by 25% to 50%.

Route of Administration

IV administration of opioids is preferable to the IM route for several reasons. Absorption is more reliable, and repeated dosing is painless. It also leads to more rapid onset of analgesia; IV morphine begins to work within 5 minutes (peaks in 10 to 20 minutes), whereas IM morphine requires 10 to 30 minutes to take effect (peaks in 30 to 60 minutes) (16). It is easier to titrate the opioid dose using the IV route. It is also important to keep in mind that the frequency and severity of several side effects, such as respiratory depression,

hypotension, histamine release, and nausea and vomiting, are related to the *speed* of IV injection. Side effects can be minimized if drugs are injected over several minutes, rather than by rapid push. See eTable 15.3 for a summary of safety guidelines for IV administration of opioids.

eTABLE 15.3
How to Administer Intravenous Opioids Safely

1. Initiate infusion of normal saline before administering opioids.
2. Keep the patient in a recumbent position.
3. Have naloxone and airway management equipment available.
4. Adjust dose downward in patients with hypotension, chronic obstructive pulmonary disease, or potential for airway compromise.
5. Give SLOWLY, over 3–5 minutes to minimize side effects.
6. Titrate to pain relief.
7. Supplement careful observation with pulse oximetry or apnea monitoring.

Major Risks

- CNS depression leading to hypoventilation or aspiration
- Hypotension

It is not clear which is the second best parenteral route for opioid administration. Subcutaneous (SC) injection is typically less painful than IM administration; however, this benefit may be offset by an even more delayed onset of action.

Oral opioids are discussed below. When both IV and oral routes are unavailable, alternatives include rectal suppository (morphine, hydromorphone, and oxymorphone), sublingual tablet (buprenorphine), and even a nasal spray (butorphanol). Studies have reported use of nebulized and intranasal administration of fentanyl in a pediatric population. Transdermal fentanyl patches are inappropriate for acute pain management since a therapeutic blood level may not be reached for 24 hours.

Adverse Effects

All opioid analgesics share certain side effects, although some occur more with one drug than another. A patient who has had a problem with one agent may be able to tolerate another opioid without difficulty.

Of all the potential adverse effects, respiratory depression is the most dangerous. Using sophisticated testing, it is possible to show that therapeutic doses of most opiates cause some degree of respiratory depression in nearly all patients. Most of the time, this is not clinically important. However, patients with diminished respiratory reserve, such as those with severe chronic obstructive pulmonary disease or massive obesity, may stop breathing after receiving these drugs. Even in those with normal reserve, removal of a painful stimulus, as occurs with the reduction of a dislocated joint, can precipitate respiratory depression. Except in the case of massive overdose, respiratory arrest does not occur suddenly but is heralded by a decreased respiratory rate and level of arousal.

Hypotension is the second major hazard of opioid use. Through a variety of mechanisms, opioids, particularly those given parenterally, may cause peripheral vasodilation. This seldom affects blood pressure in the supine patient, but the ambulatory patient may experience significant orthostatic hypotension. Volume-depleted individuals are at increased risk for hypotension regardless of body position. Hypotension from opioids generally resolves spontaneously within a few minutes; if necessary, IV fluids and possibly naloxone are effective treatments.

Opioids occasionally trigger the release of histamine from mast cells. Because this occurs through a nonimmunologic mechanism, it is technically not an allergy. Clinical consequences include itching, urticaria, bronchospasm, and hypotension, which are not responsive to naloxone. The agents most frequently implicated in these reactions are morphine, followed by codeine and meperidine. Fentanyl has practically no potential for this complication.

Rapid administration of high-dose fentanyl has been associated with muscle rigidity, including chest wall spasm, which may require treatment with IV naloxone. This is usually seen in the context of

fentanyl anesthesia and may be treated with a neuromuscular blocking agent.

Opioids commonly cause sedation and occasionally produce confusion. Therefore, ED patients should be warned not to drive vehicles or operate power tools when they take them. Opioids present a special set of problems for head-injured patients. They may interfere with the evaluation of central nervous system (CNS) function. The respiratory depressant effect of opioids is exaggerated in this group of patients, and the resultant hypoventilation may actually increase intracranial pressure, mediated by cerebral vasodilation in response to an elevated pCO_2 (16).

Opioids have other effects on the genitourinary and GI systems. They may cause urinary retention, particularly in older men with underlying prostatism. They can sometimes cause abdominal pain or dyspepsia. Nausea and vomiting can be minimized by administering the drug to the patient in the supine position and, if necessary, with an antiemetic (Jaffe 2001). GI side effects, if severe, can be reversed with naloxone. Opioids are constipating even with short-term use; when discharged on a course of opioids, patients should be warned to expect this and advised to use laxatives as necessary. Despite historic concerns over opioids raising biliary pressures, morphine appears to be safe and effective for the relief of biliary colic (17).

Opioids have the potential to mask the diagnosis of serious abdominal disease. Although they can be given safely to patients with abdominal pain who are under close observation, prescribing them for patients who are sent home with undiagnosed abdominal pain is potentially dangerous.

Polypharmacy, multiple comorbidities and an aging brain all make adverse events more likely in older adults (6). Lower initial dosing and frequency, and slower upward titration, are the rule when treating this population.

Choosing an Injectable Agent

A variety of choices of parenteral analgesic agents exist for the emergency physician. Selection is based largely on physician preference as well as the patient's condition.

Morphine is the traditional first-line parenteral narcotic. No other opioid is superior in relieving pain. It is easy to dose and titrate, is relatively inexpensive, and has a relatively long duration of action. **Fentanyl** is another ideal IV agent for performing short, painful procedures because of its very rapid onset and limited duration of action. **Hydromorphone** (Dilaudid) provides effectiveness similar to morphine with a similar side-effect profile, although a lower incidence of pruritus has been noted with its use (18).

Partial agonist and agonist–antagonist opioids were developed to provide analgesia with less sedation, respiratory depression, nausea, and addiction potential (19). Practical benefits, however, have been limited. **Butorphanol** (Stadol) and **buprenorphine** (Buprenex) are available as parenteral agents. **Pentazocine** produces psychotomimetic symptoms, including disorientation, paranoia, and hallucinations, in as many as 7% of treated patients. All drugs in this class can precipitate withdrawal when they are given to patients addicted to pure opioid agonist. These drugs offer no advantages over the strong opioid agonists, except perhaps in the management of biliary pain.

Meperidine (Demerol), another available parenteral opioid, offers few, if any, advantages over morphine. Because of multiple safety concerns, meperidine is not a recommended agent and its use has been eliminated or restricted in many hospitals. With repeated dosing, meperidine has its own peculiar CNS toxicity caused by normeperidine, an active metabolite that is excitatory and may cause mood irritability, agitation, tremors, myoclonus, and seizures. Normeperidine has a longer half-life than its parent compound, accumulating with repeated dose administration of meperidine and thus increasing the risk of CNS toxicity, especially in patients with renal insufficiency. Meperidine should not be given to patients at risk for seizure. It should also be avoided in those receiving monoamine oxidase (MAO) inhibitors because of the potential for a poorly understood interaction, characterized by delirium and hyperthermia, which may be fatal. Patients with renal or hepatic insufficiency require special considerations. See **Table e-15.3**.

Adjuvant Parenteral Agents

Historically, a number of drugs have been administered along with parenteral opioids to minimize adverse effects by reducing the amount of opioid needed to treat pain. Phenothiazines can reduce GI side effects. However, when given along with an opioid, sedative effects are increased, but analgesia is not (16).

The antihistamines hydroxyzine (50 to 100 mg IM or 1 mg/kg IM) and diphenhydramine (25 to 50 mg IM or IV) have been combined with opioids to potentiate analgesia and to provide limited antiemetic effects. Although hydroxyzine does have additive analgesic properties, this practice poses two problems. First, it requires a painful, intramuscular injection. Second, it may not, in fact, decrease adverse effects because hydroxyzine itself is a mild respiratory depressant (20). No study has examined whether the combination of an opioid plus hydroxyzine produces respiratory depression less frequently than an equianalgesic dose of opioid alone.

Choosing an Oral Agent

Table 15.2 lists dosing guidelines for a number of commonly used oral opioids. Because opioids experience a significant first-pass hepatic metabolism, a higher oral than parenteral dose is necessary to achieve the same level of analgesia. See **Table e-15.4** regarding patients with hepatic or renal insufficiency. **Table 15.3** lists DEA Drug Schedules.

TABLE 15.3
DEA Drug Schedules

Schedule	Abuse Potential	Examples
I	High; no accepted medical use	Heroin, marijuana, methaqualone
II	High; less abuse potential than schedule I drugs, with use potentially leading to severe psychological or physical dependence	Cocaine, methadone, hydromorphone, oxycodone, fentanyl, methylphenidate (Ritalin), Adderall
III	Moderate to low; abuse potential less than schedules I and II more than schedule IV	Combination products with less than 15 mg of hydrocodone/dosage unit (Vicodin), products containing less than 90 mg codeine/dosage unit (Tylenol #3 and #4), ketamine
IV	Low	Benzodiazepines (alprazolam, clonazepam, diazepam, lorazepam) and nonbenzodiazepine hypnotics (eszopiclone, zaleplon, zolpidem)
V	Lower than schedule IV	Cough preparations with less than 200 mg of codeine or per 100 mL. (Robitussin AC); diphenoxylate (Lomotil); pregabalin (Lyrica)

Data from http://www.justice.gov/dea/druginfo/ds.shtml. The United States Department of Justice—Drug Enforcement Agency Drug Scheduling.

Codeine is a poor choice of agent for many reasons, despite its widespread use. It is a relatively weak analgesic with a relatively high incidence of GI side effects, especially nausea. NSAIDs are as effective, or more effective, than standard codeine doses of 30 to 60 mg (21). At higher doses, the analgesic effect does not increase significantly, but the rate of side effects is higher. Some patients are poor CYP2D6 metabolizers of codeine and receive no analgesic benefit, whereas a significant number of patients are ultrarapid metabolizers and experience greater-than-expected analgesic effects and side effects. Codeine may have a lower addiction potential than other oral opioid agents. Preparations containing no more than 90

mg per dosage unit are classified by the DEA as schedule III that allows more liberal prescribing.

Hydrocodone is an excellent analgesic. However, similar to codeine, patients may be poor CYP2D6 metabolizers and not receive adequate analgesia, whereas others are ultrarapid metabolizers and may experience faster analgesia but increased toxicity. Preparations containing no more than 15 mg per dosage unit are classified as DEA schedule III.

Oxycodone, another excellent analgesic, is a schedule II medication because of its higher potential for addiction and abuse. It is available as a single agent or in combination with acetaminophen.

The main applications for oral **morphine** and **hydromorphone** (Dilaudid) are in cancer and sickle cell pain. Oral morphine is available in an immediate- and a sustained-release preparation. Oral transmucosal **fentanyl** (Actiq) is a rapid-acting analgesic useful in breakthrough symptoms in patients with severe chronic pain. All three are schedule II medications.

Tramadol (Ultram) is a weak opioid agonist that also inhibits reuptake of serotonin and norepinephrine. It is not a federally scheduled drug but it has abuse potential and some states classify it as a schedule IV controlled substance. It is a centrally acting synthetic analgesic compound with effects comparable to opioid analgesics, approved for the short-term treatment of acute pain in adults. The most common side effects are nausea, vomiting, dizziness, somnolence, and constipation. It does not appear to produce respiratory depression or hypotension, probably because of selective opioid receptor binding. It may or may not be as effective as codeine or hydrocodone in combination with acetaminophen (22). Tramadol is contraindicated in patients taking an MAO inhibitor, as it inhibits monoamine uptake.

Meperidine (Demerol) should not be prescribed routinely. It is a DEA schedule II drug with a short analgesic duration and unique CNS toxicity as discussed earlier in detail. Propoxyphene (Darvon, Darvocet) no longer has FDA approval due to cardiac toxicity and should not be prescribed. Pentazocine is the only oral, mixed agonist–antagonist agent. It is only available in combination with

acetaminophen and is rarely prescribed because of psychotomimetic adverse effects.

COMBINATION THERAPY

Rational pain management often involves combining analgesics of different classes. Adding acetaminophen (or an NSAID) to an opioid may produce better analgesia than a double dose of either agent alone (23). One possible explanation for this is that the drugs work by different mechanisms. Combination therapy may permit a reduction in the opioid dose and a corresponding reduction in opioid-associated side effects.

Many formulations that are commercially available combine aspirin, acetaminophen, or an NSAID with codeine, hydrocodone, or oxycodone. Close attention must be paid to the risk of acetaminophen toxicity with the increasing popularity of acetaminophen containing OTC products, including cough and cold formulations. Patients are often unaware of the acetaminophen content in these products and associated risk of liver injury with amounts exceeding 4 g/day.

Therapy does not need to be restricted to these fixed-ratio products; prescribing the constituents separately may permit greater therapeutic flexibility. For very severe pain, the opioid dose can be increased without risking toxic doses of acetaminophen or NSAIDs. Conversely, as the pain improves, the patient can taper off the opioid but continue the nonnarcotic. For the outpatient treatment of severe pain, one common regimen is ibuprofen 2,400 mg/d in divided doses, along with oxycodone 5 to 10 mg every 4 to 6 hours. An acetaminophen and codeine elixir is available for use in children.

PRESCRIBING OPIOIDS AND ADDICTION RISK

The past decade has seen a precipitous rise in opioid prescribing, opioid abuse, and opioid-related adverse events and deaths. Use of opioids in treating many *chronic* pain conditions may pose far greater risk than benefit. There is ample evidence that opioid dependence and abuse often begins with an opioid prescription. Nevertheless, opioids are an irreplaceable mainstay of acute pain management in

the ED. Patients with acute bone or visceral pain being discharged from the ED may require an opioid prescription. Current guidelines for appropriate prescribing include the following (24).

- Evidence-based use of a nonopioid whenever possible.
- Limiting opioid prescriptions to 3 days as a general rule with appropriate follow-up.
- Screening for addiction and addiction potential. Screening tools are available, such as the CAGE questionnaire adapted to include drug abuse (CAGE-AID). In some cases, prescription of an opioid may still be clinically appropriate but would require special follow-up and case management.

AGENTS FOR TREATING NEUROPATHIC PAIN

Acetaminophen, NSAIDs, and opioids are the key analgesics for treating acute pain in the ED. However, patients discharged from the ED with neuropathic pain (e.g., herpes zoster or radiculopathy) may benefit greatly from the prescription of a second agent specific to treating neuralgia. **eTable 15.4** lists typical agents commonly used for this indication.

eTABLE 15.4
Outpatient Medicines Used for Neuropathic Pain

Agent (Class)	Starting Dose	Comments
Gabapentin (antiepileptic)	300 mg TID	Main side effect is dose-dependent drowsiness that abates over time. Limiting use to bedtime only is better tolerated but less effective is better tolerated but less effective. Can also start at subtherapeutic dose of 100 mg TID and increase as tolerated to minimum effective dose of 300 mg TID
Amitriptyline (tricyclic antidepressant)	10–25 mg qHS	Main side effects are drowsiness and dry mouth. Avoid in patients with AV cardiac conduction abnormalities or prolonged QT
Transdermal lidocaine (topical analgesic/anesthetic)	Apply patch to affected area, 12 hrs on and 12 hrs off	Apply only over intact skint

Common Pitfalls

- Relying too much on “objective” signs of pain severity and not enough on the patient’s self-report.
- Confusing pain avoidance behavior with drug-seeking behavior.
- Misinterpreting sedation as pain relief.
- Delaying analgesia until a definitive diagnosis is made.
- Withholding opioid analgesia because consent for surgery or other procedure may later be necessary.
- Failing to screen for addiction potential.
- Administering opioids IM or SC when the IV route is superior.
- Infusing IV opioids too rapidly and when the patient is not supine.
- Choosing a dosage and dosing interval based on standard guidelines instead of individual patient response.

CHAPTER 16

Chronic Pain Syndromes

Michael A. Turturro and Paul M. Paris

Pain is typically defined as an unpleasant sensory and emotional phenomenon associated with actual or potential tissue damage. Chronic pain is defined as a sustained painful experience that in most cases persists beyond the time in which tissue damage occurs. Although acute pain typically has a rapid onset coinciding with tissue damage, it typically resolves as tissue heals. It serves as a biologic warning of potential illness or injury, prompting the individual to protect the painful area and seek medical attention. Although distressing and anxiety provoking, it usually can be treated effectively with proper selection and use of analgesic drugs.

Chronic pain differs from acute pain in many respects (Table 16.1). In chronic pain, the symptom of pain itself often becomes more of a problem than its underlying cause, altering the patient's well-being and frequently causing both disability and depression. It has been estimated that about 30% of the US population suffers from chronic pain, and the loss of productive time as a result costs more than $60 billion a year (25); additional expenditures are also incurred from health care and litigation related to chronic pain syndromes. The treatment of chronic pain is complex and difficult. Success in treating chronic pain typically requires a multidisciplinary team approach, using various regimens of pharmacotherapy, physical therapy, and behavioral therapy to both reduce pain and restore function.

TABLE 16.1
Differences Between Acute and Chronic Pain

Acute Pain	Chronic Pain
Usually as a result of tissue damage	Often no identifiable pathology
Is related to underlying illness	Is the problem itself
Has a biologic purpose	No biologic purpose
Responds to typical analgesics	May not respond to typical analgesics
Straightforward treatment	Complex treatment
Causes anxiety	Causes depression

CLINICAL PRESENTATION

Patients with chronic pain syndromes are commonly encountered in the emergency department (ED) and often present a management challenge for the emergency physician. Some present with vague signs and symptoms and often are not definitively diagnosed on the first encounter. Treatment is typically complex, requiring several regimens of varying effectiveness. Many patients have other psychological disturbances and a protracted course of exacerbations and remissions, with failures of various therapies. They may be demanding and frustrating for the clinician, because their conditions are not easily managed. Patients may feel uncomfortable with a physician who has not been their regular caretaker. The presentation of patients requesting controlled substances for illicit means may overlap with the presentation of chronic pain exacerbations. As a result, malingering or drug-seeking behavior may inappropriately be suspected in patients with chronic pain syndromes.

In each patient with chronic pain, the development of progressive or new pathology must be considered, and the physician should not simply assume that a patient's chronic pain exacerbation is nothing more than a worsening of an already existing disease process. For example, in a patient with increasing chronic low back pain, one must consider the possibility of new spinal cord pathology. Simply providing analgesics without consideration of acute pathology may result in missing serious disease.

Chronic pain syndromes typically fall into one of the categories listed in Table 16.2.

TABLE 16.2
Categories of Chronic Pain Syndromes

Categories of Chronic Pain Syndromes
1. Pain as a result of prolonged tissue destruction as a result of malignancy or other terminal illness (e.g., AIDS)
2. Pain as a result of dysfunction of the central or peripheral nervous system (e.g., trigeminal neuralgia)
3. Pain as a result of well-known painful syndromes (e.g., fibromyalgia)
4. Pain with no objectively confirmed cause

Although patients with pain as a result of prolonged tissue destruction can be treated successfully with appropriately titrated analgesics in the ED, patients in the remaining categories should also be referred to a chronic pain management center whenever feasible, to facilitate the management of the chronic pain syndrome in a multidisciplinary manner.

Communication between the emergency and pain service physicians fosters a team approach to the management of chronic pain exacerbations. For example, a pain contract and/or specific patient care plan may be developed between the patient, the pain service, the primary care physician, and the ED regarding when the patient will be expected to present to the ED for a pain exacerbation, the analgesic that will be used after appropriate evaluation, and the quantity of analgesics to be prescribed on discharge.

Although chronic pain as a result of any cause may be exacerbated by psychological factors, the pathophysiology of chronic pain without obvious tissue pathology is still being elucidated. Prolonged noxious sensory input from the periphery may result in self-sustaining central neural activity, possibly by reducing inhibitory input into the central nervous system (CNS) and producing changes in neurontransmission at spinal neuron synapses

(27). Activation of *N*-methyl-D-aspartate (NMDA) receptors appears to be central to this process. This phenomenon, known as "windup," essentially produces a memory effect for pain perception in the CNS. These effects persist despite the lack of ongoing tissue injury. As a result, patients become increasingly more sensitive to painful stimuli.

Chronic pain commonly causes the patient to lose a sense of control over his or her environment. Allowing patients to become passively dependent on health care practitioners and medical therapy only feeds this vicious cycle of illness and the helpless victim.

Drug Abuse and Addiction

Drug abuse and addiction are unfortunate yet common problems in our society, and approximately 8% of all adult patients are actively abusing illicit drugs. Unintentional prescription opioid analgesic deaths increased more than 500% between 1999 and 2010, continues to rise, and is now higher than deaths from cocaine and heroin use combined, as well as higher than annual deaths from vehicular trauma (13). Drug abusers (whether or not they suffer from chronic pain) tend to patronize EDs on a frequent basis to obtain opioid analgesics. Because of this, ED staff members may develop a bias against many chronic pain patients. Because it may be difficult to differentiate patients with exacerbations of chronic pain from patients who are seeking drugs for abuse and there are no validated tools to help the clinician distinguish abuse from undertreated pain, many patients with real exacerbations of chronic pain are consequently labeled as drug abusers.

It is important to distinguish between opioid dependence, tolerance, and addiction. *Dependence* refers to the physical phenomenon in which sudden withdrawal of the drug results in a drug-specific withdrawal syndrome. This occurs in patients chronically using opioid analgesics, whether for legitimate or illicit purposes. *Tolerance* refers to the physical phenomenon of a decrease in drug effect at a specific dose over time, requiring increasing doses

to produce the desired effect, whether it is analgesia or euphoria. Tolerance often occurs as a result of downregulation or desensitization of opioid receptors, resulting in a physiologic resistance to opioid therapy (2). Additional physiologic changes may occur at the cellular level with chronic opioid therapy, which may result in abnormally increased sensitivity to painful stimuli.

Dependence and tolerance must be distinguished from *addiction,* which is the psychobiologic state of compulsive use despite signs of toxicity, preoccupation with obtaining and using a substance, and inability to function as a result of compulsive use. With legitimate prolonged use of opioid analgesics for chronic pain, dependence and tolerance do occur; however, addiction is uncommon. Conversely, when pain medication is withheld from patients with chronic pain, such patients may learn pain avoidance or maladaptive behaviors to obtain opioids. These drug-seeking behaviors do not imply addiction but inappropriate techniques used by patients to satisfy a physiologic need state. This phenomenon is often referred to as *pseudoaddiction.* Underdosing and giving pain medication on an as-needed basis for sustained pain (rather than around-the-clock dosing) contribute to this phenomenon, as the patient learns to express both exaggeration of symptoms and maladaptive behavior to obtain the reward of receiving pain medication.

Drug abusers may have a history of medical noncompliance, discharge from pain services, polysubstance abuse, multiple visits for treatment of various nonspecific painful conditions, an unusual reluctance to try new therapies, or a report that their primary physician is unreachable. They may have a history of selling prescription drugs (diversion), forging prescriptions, using aliases, or injecting oral preparations. The use of a state prescription monitoring program may help identify patients who exhibit these behaviors (4). Because it is not appropriate and is unethical to withhold analgesics from patients experiencing pain unless the emergency physician has clear objective evidence that the patient is a drug abuser, the patient's pain should be treated. Guidelines limiting the prescribing of opioid analgesics from the ED, while well intentioned and designed to reduce the harm of inappropriate

opioid use, have the unintended consequence of potential undertreatment of patients with exacerbations of painful conditions, some of whom have limited access to care outside of the ED. Sometimes, a known substance abuser may present with an acutely painful condition. In these cases, pain should be adequately relieved in the ED, and judicious amounts of analgesics to be taken at regular intervals should be given on discharge. The use of opioid agonist–antagonists may be useful in these patients, as they are less likely to cause euphoria. However, they should not be given to a patient physically dependent on opioids, as they may precipitate withdrawal.

ED MANAGEMENT

Although many of the concepts that apply to acute pain management (see Chapter 15) also apply to patients with chronic pain, the endpoint of marked relief may not be attainable. Exacerbations of chronic pain (breakthrough pain) are often a result of a combination of both physical and psychological factors, and the primary goal in the ED is to reduce pain to the point where the patient becomes functional, with pain service referral when appropriate. In additon, certain pain syndromes (e.g., neuropathic pain) may not be effectively treated by the usual doses of typical analgesic agents. Therefore, an understanding of both the physical and psychological pathophysiologies associated with these disorders will ensure optimal treatment.

The treatment of chronic pain includes the use of many modalities (**Tables 16.3–16.5**). Nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are often employed early in the patient's course; however, many patients are unable to be adequately controlled with these agents alone.

TABLE 16.3
Therapies for Chronic Pain

Therapy	Indications
Opioid analgesics	Most causes of chronic pain; limited effectiveness in neuropathic pain
Tricyclic antidepressants, selected SSRIs, SNRIs	Most causes of chronic pain
Skeletal muscle relaxants	Chronic low back pain, fibromyalgia
Anticonvulsants	Neuropathic pain
Topical anesthetics	Neuropathic pain
Capsaicin	Neuropathic pain, arthritic pain
NMDA receptor antagonists	Neuropathic pain
Salmon calcitonin	Complex regional pain syndrome, phantom limb pain
Behavioral therapy	Most causes of chronic pain
Physical therapy	Complex regional pain syndrome, temporomandibular disorders, tension myalgia
Surgery	Refractory trigeminal neuralgia, complex regional pain syndrome, phantom limb pain

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin–norepinephrine reuptake inhibitors; NMDA, *N*-methyl-D-aspartate.

TABLE 16.4
Opioid Pharmacotherapy for Chronic Pain

Drug	Starting Dose[a]
Morphine, extended release	15–30 mg PO q8–24 h
Oxymorphone, extended release	5–10 mg PO q12 h
Oxycodone, extended release	10–20 mg PO q12 h
Levorphanol	2 mg PO q6–8 h
Hydromorphone	2–8 mg PO q3–4 h
Fentanyl	25–100 µg/h patch q 72 h
Methadone	2.5–10 mg PO q 8–12 h

[a]Higher starting doses often required in opioid-dependent patients.

TABLE 16.5
Nonopioid Pharmacotherapy for Chronic Pain

Drug Class/Agent	Dosing
Antidepressants	
Amitriptyline, desipramine, nortriptyline	50 mg PO QHS up to 150 mg/d
Duloxetine	30 mg PO daily, increase to 60 mg daily after 1 wk
Venlafaxine	37.5 mg PO daily, increase by 75 mg each week to 225 mg daily
Doxepin	25–50 mg PO QHS
Bupropion	150 mg PO BID
Anticonvulsants	
Gabapentin	300 mg PO TID increase as necessary to maximum of 3,600 mg/d
Pregabalin	50 mg PO TID increase to 100 mg PO TID over 7 days
Carbamazepine	100 mg PO QHS[a] increase to 100 mg PO BID
Oxcarbazepine	maximum 1,200 mg/d 300 mg PO BID increase to 600 mg PO BID in 7 days
Skeletal Muscle Relaxants	
Cyclobenzaprine	10 mg PO TID
Orphenadrine	100 mg PO BID
Carisoprodol	200–400 mg qid
Chlorzoxazone	250–750 mg PO TID or qid
Methocarbamol	1.5 g qid
Baclofen	5 mg PO TID increase to 20 mg PO TID
Topical Anesthetics	
Lidocaine patch	1–3 patches for 12 HQD
Prilocaine/lidocaine	2.5 g cream or 1 g disc
Substance P inhibitor	
Capsaicin	Apply to affected area qid
NMDA Receptor Antagonists	
Ketamine	0.4–0.5 mg/kg PO or IV
Dextromethorphan	60–240 mg PO BID titrated to effect
Other Agents	
Salmon calcitonin	200 IU intranasal daily

NMDA, *N*-methyl-D-aspartate.
[a]Obtain baseline complete blood count.

Opioid analgesics are the most useful drugs in treating exacerbations of chronic pain. The agents used are discussed in the chapter on acute pain (see Chapter 15), but longer-acting preparations such as those listed in Table 16.4 may be more appropriate for the treatment of chronic pain. These agents also avoid the risk of aspirin or acetaminophen toxicity from the nonnarcotic component of combination products, which may occur when doses sufficient to provide adequate amounts of the opioid component are taken. The use of extended release preparations of oxycodone and oxymorphone has gained considerable attention as a result of its potential for abuse. In the ED, they should typically be reserved for patients with pain as a result of an advanced terminal illness such as malignancy, as alternatives can be successfully used in other patients.

Pain as a result of malignancy, although chronic in nature, may be considered sustained acute pain because it is typically associated with progressive tissue damage. Although nonnarcotic analgesics and physical therapy are often used to treat malignant pain, progressively increasing doses of opioid analgesics remain the mainstay of therapy. Despite the risk of opioid dependence, opioid analgesics should never be withheld from patients with terminal malignant pain, as pain control is the most important factor contributing to overall quality of life (16). Acute exacerbations of malignant pain must be treated as an emergency, with aggressive opioid analgesia. Higher doses of opioids titrated more rapidly than in opioid-naive patients are typically needed, and this approach is both safe and effective.

Tramadol is a centrally acting oral analgesic that activates opioid receptors in the CNS and also inhibits monoamine neurotransmitter reuptake (similar to tricyclic antidepressants [TCAs]). Tolerance and withdrawal symptoms appear to be absent with tramadol. However, it has been demonstrated to be less effective in the management of acute pain than other opioids when used alone (26) and is associated with a high incidence of side effects, including seizures. It appears to be most appropriate for adjunctive treatment in mild to moderate chronic pain.

TCAs are useful in treating chronic pain, both by controlling depression, increasing inhibitory fiber stimulation, and by altering nociceptive responses to painful stimuli, thereby altering the cerebral process in pain perception. They are effective in pain control even if no evidence of depression exists. TCAs are effective in various chronic pain syndromes, particularly neuropathic pain, facial pain syndromes, fibromyalgia, and arthritis. TCAs act synergistically with opioids in controlling chronic pain. It is likely that all TCAs are effective in treating chronic pain, but amitriptyline has been the most extensively studied. The recommended starting dose for all TCAs in managing chronic pain is half the antidepressant dose, which may be titrated up if necessary. Analgesic effects may not be evident for several days. Referral for follow-up is essential in patients started on TCAs in the ED. Available evidence suggests that other agents used for depression may be used but are less effective than TCAs in the management of most types of chronic pain (22). However, the serotonin–norepinephrine reuptake inhibitors (SNRIs), duloxetine and milnacipran, have been effectively used to treat neuropathic pain. The association between depression and chronic pain is clear, but in some patients the painful process produces depression, and in others chronic pain is a manifestation of a depressive disorder. In patients with chronic pain in whom no etiologic basis can be established, management is also focused on treating the underlying depression. In addition, depression is also known to increase opioid analgesic requirements.

Transcutaneous electrical nerve stimulation (TENS) may be effective in certain acute and chronic pain syndromes. It is used most often in chronic low back pain and complex regional pain syndrome, although the evidence for its benefit is limited by the lack of well-designed clinical trials. In addition, most patients note a decrease in the analgesic effect over time. The “gate control” theory of pain postulates that in the periphery, small unmyelinated C fibers transmit nociceptive information, and large myelinated A fibers transmit light touch and pressure sensations. Both of these fibers synapse at the substantia gelatinosa in the dorsal horn of the spinal

cord. Stimulation of the A fibers inhibits the transmission of nociceptive C fiber stimuli into the CNS, thereby “closing the gate.” By using electricity to stimulate the A fibers preferentially, the pain stimulus entering the CNS can be controlled.

In neuropathic pain syndromes, pain originates from peripheral nerve dysfunction. Therefore, anticonvulsants play a primary role in treating most of these disorders, with carbamazepine, gabapentin, and preganalin commonly used. In addition, because substance P may be the principal mediator of neuropathic pain, an effort to inhibit substance P may be beneficial. When applied topically, capsaicin, a substance derived from red chili peppers, releases substance P from primary afferent nerve fibers. With repeated application, capsaicin depletes substance P from these nerve fibers. Consequently, capsaicin may have some benefit in treating the neuropathic pain of postherpetic neuralgia, complex regional pain syndrome, metabolic neuropathy, and other chronic pain syndromes such as psoriatic and rheumatoid arthritis. Capsaicin causes skin redness and burning. This may also contribute to its analgesic effect, as peripheral counterirritation causes pain relief by a “gate-closing” effect, as described for TENS. However, this skin irritation also limits the concentration that may be used, thus reducing its potential efficacy (18). It has been postulated that in chronic pain, NMDA may play a central role in the windup phenomenon of sensitizing the CNS to a prolonged painful stimulus, possibly by recruitment of C fibers. Consequently, substances that antagonize the NMDA receptor are gaining attention as possible agents in the management of chronic pain. Ketamine, dextromethorphan, methadone, memantine, and amantadine all antagonize the NMDA receptor and have been studied as agents for chronic pain management (particularly in neuropathic pain). However, the doses needed to produce analgesia exceed the doses that cause untoward adverse effects (12).

Behavioral and physical therapy help patients cope with chronic pain and regain a sense of self-control, thus improving overall day-to-day function. The focus with these therapies is rehabilitation, not

total pain relief. However, patients must be motivated to be successful.

The most effective ways to treat these chronic pain syndromes are the multidisciplinary approaches used by pain clinics, in which combinations of the various therapies are coordinated. Thus, the emergency physician should confer with the patient's primary care or referring physician and make arrangements for follow-up before initiating or changing therapy.

SPECIFIC CHRONIC PAIN SYNDROMES

Chronic Low Back Pain

Chronic low back pain is the most common chronic pain syndrome seen in the ED. Approximately 8% of US adult patients develop nonspecific low back pain annually, and of these about 5% will continue to experience persistence after 3 months (7).

Opioid and nonopioid analgesics, including acetaminophen, remain the mainstay of therapy for chronic back pain. As with other chronic pain syndromes, tolerance and dependence can occur with prolonged opioid use, and gastrointestinal and renal damage can occur with prolonged NSAID use. Antidepressant therapy may be added to patients poorly controlled on analgesics alone. Skeletal muscle relaxants may improve range of motion, but their use is limited in chronic back pain owing to a high incidence of CNS side effects (drowsiness and dizziness).

In patients with sciatica, treatments specific for neuropathic pain may be beneficial, and trials using gabapentin or topiramate have shown modest improvement in pain relief as compared with placebo (6). Although sometimes prescribed, systemic corticosteroids have not been associated with any clinically significant benefit when compared with placebo.

Nonpharmacologic therapies have been used with varying degrees of success. Regular exercise with an emphasis on core stability appears to be important to improve function, and behavioral therapy, massage hydrotherapy, and acupuncture seem to have modest beneficial effects (5). A review of 26 randomized controlled

trials on spinal manipulative therapy concluded that this intervention results in a clinically insignificant benefit on short-term pain relief (19). The evidence of effectiveness of other therapies such as traction and TENS is lacking, with studies either showing no benefit or conflicting results (14).

Myofascial Pain and Fibromyalgia

Myofascial pain syndrome and fibromyalgia are conditions in which acute or chronic muscle pain, stiffness, and tenderness occur at specific anatomic sites ("trigger points"). A trigger point is an area within a taut band of skeletal muscle that, when palpated, produces referred pain in the area in which the patient complains of pain (a "reference zone"). It may be activated by physical trauma, other trigger points, or psychological stress.

Fibromyalgia and myofascial pain syndrome may be considered opposites in the spectrum of a single disorder (Table 16.6). Myofascial pain tends to be localized, and the involved muscle group may twitch involuntarily. Fibromyalgia pain tends to be diffuse and is associated with systemic symptoms such as chronic fatigue, sleep disturbance, headaches, vertigo, visual disturbances, and irritable bowel syndrome. Symptoms may begin after an acute viral illness, trauma, or psychological stress. Physical findings may be nonspecific, and the patient may be told that the symptoms are unexplained or psychogenic.

TABLE 16.6
Myofascial Pain Syndrome Versus Fibromyalgia

Location	Myofascial Pain Regional	Fibromyalgia Generalized
Muscular twitch	Yes	No
Systemic symptoms	No	Possible
Sleep disturbances	No	Yes
Trigger-point injection useful	Yes	Sometimes
Physical therapy useful	Yes	No
Skeletal muscle relaxants useful	No	Yes

Although it has been postulated that psychological causes may underlie the pathophysiology of fibromyalgia (e.g., patients may not respond in a normal fashion to physical or psychological stress or may have a heightened perception of bodily discomfort), elevated CSF, and levels of plasma substance P and decreased plasma levels of serotonin have been demonstrated (20). Windup due to noxious stimuli appears to be enhanced in these patients (24). Consequently, fibromyalgia patients may experience pain from stimuli that are below the painful threshold in normal patients as a result of neurochemical alteration of pain pathways. Complicating matters are that depression is a frequent result of fibromyalgia, and somatization disorders are more frequent in fibromyalgia patients than the general population. Many patients seen in the ED for exacerbations of fibromyalgia pain may have failed traditional therapies and may be using alternative treatments such as guaifenesin, magnetic therapy, diet therapy, acupuncture, herbal therapy, and zone therapy.

Other painful systemic illnesses such as systemic lupus erythematosus, polymyalgia rheumatica, polymyositis, metabolic myopathy, hypothyroidism, chronic fatigue syndrome, and irritable bowel syndrome should be considered. Because symptoms often overlap, the diagnosis is frequently one of exclusion.

The treatments of myofascial pain and fibromyalgia have certain similarities. Trigger-point injection of local anesthetics is a technique easily performed for both fibromyalgia and myofascial pain, often with rewarding results. Relief of local and referred pain and a decrease in muscle tension may be seen after injection. Topical vapor coolant sprays using fluoromethane or ethyl alcohol followed by stretch of the affected muscle may provide relief, but this mode of therapy is difficult to provide in the ED setting.

Although aerobic exercise and strength training may have some benefit in fibromyalgia, other physical techniques, such as muscle stretching, biofeedback, and exercise, are useful in myofascial pain syndrome but are of limited value in fibromyalgia (23). In fibromyalgia patients, analgesics usually provide only partial relief, and additional therapy with antidepressants or anticonvulsants is

often needed. The SNRIs, duloxetine and milnacipran, are now FDA approved for the treatment of fibromyalgia (10). TCAs are useful to improve pain, depressive symptoms, and sleep disturbances; cyclobenzaprine, a skeletal muscle relaxant chemically similar to the TCAs, may also be useful. The anticonvulsants, pregabalin and gabapentin, have shown effectiveness in the treatment of fibromyalgia and NMDA receptor antagonists may be useful (1,8,9). If these therapies are initiated in the ED, follow-up care should be ensured.

Temporomandibular Disorders

Temporomandibular disorders affect the temporomandibular joint (TMJ) and surrounding facial structures, resulting in orofacial pain and dysfunction. Patients typically report facial pain, chewing difficulties and nonspecific headache, in addition to joint noise and difficulty in joint motion. Muscular and joint tenderness and limited TMJ range of motion may be found. The disorder is similar in many respects to both myofascial pain syndrome and fibromyalgia and is often referred to as a form of myofascial pain. Many patients with TMJ dysfunction also are diagnosed with fibromyalgia or other myofascial pain syndromes.

The etiology of TMJ disorders is unclear. Some patients may exhibit signs of TMJ dysfunction but may not have troubling symptoms. Many patients have coexistent psychiatric diagnoses, and behavioral therapy is often employed to supplement medical care. Many patients show a greater sensitivity to certain noxious stimuli than do pain-free controls (21). Patients who clench or grind their teeth secondary to stress may develop masticatory muscle hyperactivity and fatigue, which can lead to pain and altered joint mechanics. Patients may present before definitive diagnosis with a complaint of nonspecific facial pain or may present during a symptom exacerbation. Facial neuralgias, myofascial pain syndrome, tension headache, and somatization disorder should be considered in the differential diagnosis.

As in other chronic pain syndromes, treatment frequently requires analgesics, antidepressants, and nonpharmacologic therapy. Physical therapy, biofeedback, and intraoral splinting help relax the afflicted muscles and reduce discomfort. Some patients improve with trigger point or TMJ joint injections; however, pain control with analgesics is usually necessary. Patients should be discharged on TCAs if the diagnosis is certain and should be referred to a maxillofacial specialist so that an intraoral splint can be fitted and physical therapy started.

Neuropathic Pain Syndromes

Patients with neuropathic pain syndromes (Table 16.7) commonly present when symptoms first develop. The pain in these syndromes develops from nerve malfunction, sometimes as a result of physical damage to the involved nerve. The pain may be described as burning, tingling, stabbing, or electric shock like. In certain neuropathic pain syndromes, the pain is exacerbated by other stimuli that also stimulate the same nerve, such as light touch, temperature changes, or emotional stress. This phenomenon is known as *allodynia.* The pain is typically described as burning in nature, and treatment is often frustrating, because the usual doses of opioid and nonopioid analgesics are typically ineffective in relieving it.

- Postherpetic neuralgia
- Complex regional pain syndrome, types I and II
- Phantom limb pain

Generally, selected antidepressants, anticonvulsants, and topical anesthetics are considered first-line therapies for neuropathic pain syndromes, with opioids considered to be second line and useful as adjunct therapy (8). Antidepressants are of modest benefit and include the tricyclics amitriptiline, nortriptyline, and desipramine and the SSRIs, duloxetine and venlafaxine; anticonvulsants that are commonly used include gabapentin, pregabalin, and carbamazepine. However, there are certain considerations unique to the management of various neuropathic pain syndromes that should be understood by clinicians in the ED.

Facial Neuralgias

Trigeminal neuralgia is a relatively common, often debilitating disorder. Typically older patients (beyond age 50) are affected, and the development of this disorder in patients younger than age 40 suggests a secondary cause, typically multiple sclerosis (11). Women develop this disorder more often than men do. The right side is more frequently involved, and bilaterality is rare. The second division of the fifth cranial nerve (V2) is most frequently affected. Attacks at the third division (V3) and first division (V1) are uncommon. The initial attacks are brief but severe and lancinating, often described as an “electric shock” sensation. Allodynia is prominent, and attacks may be triggered by touching the face, cold

air blowing against the face, eating, shaving, or talking. Unlike other neuralgias, an objective sensory deficit is atypical and if found should alert the clinician to the possibility of nerve compression as a result of malignancy. As the condition progresses, the attacks become more frequent and a background ache may develop.

Glossopharyngeal neuralgia is less common and usually less severe than trigeminal neuralgia. It affects equal numbers of men and women. About 25% of cases are bilateral. Typically, a single episode of lancinating pain along the ninth cranial nerve sensory distribution (neck, throat, and ear) occurs. Atypical facial pain may occur, which is poorly localized but frequently involves the mandible. Unlike other facial pain syndromes, it is not clearly neuropathic and consequently does not respond as well as trigeminal neuralgia to anticonvulsants.

Cluster headache, maxillary sinusitis, postherpetic neuralgia (especially with V1 distribution), dental pain, and temporomandibular disorders should also be considered. Swallowing and chewing may trigger the pain from both facial neuralgias and TMJ dysfunction. Allodynia and the absence of TMJ tenderness suggest the former diagnosis.

The mainstay of treatment for the facial neuralgias is the administration of anticonvulsants, particularly carbamazepine, oxcarbazepine, and gabapentin. Unfortunately, patients typically present in extreme pain, and anticonvulsants usually require several days before a demonstrable effect is noticed. The recommended doses for gabapentin oxcarbazepine and carbamazepine are listed in Table 16.5. Other drugs, such as baclofen and clonazepam, may also need to be added. Because carbamazepine may cause neutropenia, a baseline complete blood count should be obtained if this drug is used. Carbamazepine may also cause nausea, dizziness, or somnolence, which may limit patient compliance. Follow-up with the patient's primary care physician or a neurologist should be arranged. Patients who fail medical therapy for trigeminal neuralgia often need surgical destruction of the sensory distribution of the trigeminal nerve, either by percutaneous thermocoagulation, cryosurgery, microvascular decompression, or glycerol injection.

Postherpetic Neuralgia

Postherpetic neuralgia is the most common type of neuropathic pain as well as the most common complication from herpes zoster. It occurs in 10% of cases of herpes zoster, and it is more common in the elderly. It may begin during or after an attack of zoster; it typically persists for several weeks after the rash resolves, and it has no relation to the severity of the zoster attack. Burning pain occurs in the involved dermatome, which is most commonly thoracic (about 50%), ophthalmic (about 20%), and cervical (about 20%). Diabetic neuropathy, demyelinating polyneuropathy, radiculopathy, and alcoholic neuropathy should all be considered in the differential diagnosis.

Many treatments used in other neuropathic pain syndromes (e.g., painful diabetic peripheral neuropathy) have been recommended for the treatment of postherpetic neuralgia. However, it is difficult to determine what is truly effective because few well-designed, controlled clinical trials exist, and some cases may resolve with no treatment. The longer the condition is allowed to persist, the less likely that any one treatment will be effective.

Opioid analgesics may provide modest temporary improvement in pain, but they are typically not useful alone in the treatment of postherpetic neuralgia. TCAs are often used early in the course of therapy, and there is some evidence to suggest that preemptive treatment with antidepressants during an attack of herpes zoster may reduce the prevalence of postherpetic neuralgia (3).

Anticonvulsants reported to be useful in treating postherpetic neuralgia are primarily gabapentin, pregabalin, and carbamazepine, however, there is no clear superiority of any of these agents; phenytoin, valproic acid, and the antispastic drug baclofen are occasionally used as well. Local anesthetics have been used in IV forms, in topical preparations such as lidocaine patch (Lidoderm) and EMLA (prilocaine/lidocaine) cream, and in nerve blocks. All of these methods appear to provide additional short-term relief of pain as a result of this condition. Capsaicin appears to provide temporary but effective relief if used four times a day for 3 to 4 weeks,

however discontinuation due to skin irritation is common. Botulinum toxin, the NMDA antagonists dextromethorphan, memantine, and ketamine have also been reported to treat postherpetic neuralgia, but the data on their effectiveness is limited.

Acyclovir, valacyclovir, and famciclovir may be useful in the treatment of an acute attack of herpes zoster to decrease viral shedding and the duration of lesions. However, there is insufficient evidence to suggest that antiviral therapy decreases the incidence of postherpetic neuralgia (15). Likewise, steroids are occasionally prescribed to enhance the resolution of zoster lesions, although they are not effective in preventing or treating postherpetic neuralgia.

Complex Regional Pain Syndrome

Complex regional pain syndrome (formerly referred to as *reflex sympathetic dystrophy* and *causalgia*), is a neuropathic pain syndrome characterized by a vicious cycle of pain, disuse atrophy, and peripheral autonomic dysfunction. Patients are usually 40 to 60 years old, although children are occasionally affected. It typically occurs after major extremity trauma, but it has also been related to minor trauma, cerebrovascular accident, myocardial infarction, arthritis, infection, and local tumor infiltration. Drugs such as isoniazid, ethanol, and phenobarbital have also been implicated as causative factors. It often occurs after prolonged extremity immobilization, presumably as a result of irritation of the sympathetic ganglia.

The term *causalgia* is reserved for complex regional pain syndrome related to a major peripheral nerve injury. After nerve damage as a result of an extremity injury, a positive feedback loop develops in which sympathetic efferent neurons stimulate afferent pain fibers and vice versa. Stimuli that cause sympathetic efferent outflow, such as temperature changes, often trigger this vicious cycle. Peripheral nociceptors are sensitized, and when stimulated, they then stimulate sympathetic fibers. Thus, the cycle of pain and sympathetic overflow occurs.

The median, ulnar, and femoral nerves are most commonly affected. In patients with minor trauma, the degree of initial pain is often much greater than suggested by objective findings. The first (acute) stage occurs during the first several weeks of the disease process. Symptoms include pain, swelling, sympathetic underactivity, joint stiffness, warm skin, hypertrichosis, and edema. As the disease progresses, joint stiffness, hair loss, allodynia, sympathetic overreactivity, and muscular dystrophy occur, along with paroxysms of pain. After several months, decreased joint motion and muscle and skin atrophy occur. At this stage, the extremity appears cool, pale, shiny, and hairless. Radiographs are usually normal early in the disease and later show patchy osteopenia and erosions. The differential diagnosis for complex regional pain syndrome includes collagen vascular disease, phlebitis, degenerative arthritis, and conversion hysteria.

Treatment is difficult, and most therapies provide only temporary relief. Medications that may be helpful include salmon calcitonin, TCAs, anticonvulsants, botulinum toxin, corticosteroids, β-blockers, α-blockers, calcium channel blockers, serotonin antagonists, capsaicin, NMDA receptor antagonists, and type Ib antiarrhythmics. However, the benefit of any individual therapy is limited (28). As with other forms of neuropathic pain, opioids and NSAIDs are often ineffective. Regional blocks using guanethidine may be effective but can exacerbate the pain before it improves. Physical therapy is essential, and other nonpharmacologic therapies, such as TENS or implantable neurostimulators, may be used. Sympathetic blocks may provide only temporary analgesia but may allow aggressive physical therapy.

This disorder can be prevented by avoiding prolonged immobilization in patients with extremity trauma. Recognizing the early stages and intervening before the disease progresses is important. Patients should be referred for early physical therapy.

Phantom Limb Pain

Phantom limb pain is a poorly understood syndrome that occurs after extremity amputation. It can be debilitating and is difficult to treat. After amputation, phantom sensation is nearly universal and usually resolves in less than a year. Persistent pain is thought to be related to neural damage in the postamputation period, and mechanisms in the peripheral nerve, spinal cord, and brain all contribute to the development of phantom limb pain. It has been postulated that the last impulses received by the limb before amputation may be stored in "memory," and if these impulses are painful, the sensation may persist (17). Consequently, the incidence of phantom limb pain is decreased in patients given preoperative regional anesthesia. As with other chronic pain syndromes, psychological stress exacerbates the degree of pain experienced. The differential diagnosis includes complex regional pain syndrome, metabolic neuropathy, and neurosarcoma.

There are few well-designed studies that evaluate the various treatment regimens for phantom limb pain. Antidepressants, anticonvulsants, analgesics, anesthetics, ketamine, capsaicin, and β-blocking agents all seem to provide temporary relief. Surgical techniques such as cordotomy, stump revision, and neuroma removal have been reported, with variable degrees of success. A combination of long-term behavioral therapy and antidepressants appears to be the most useful mode of therapy.

CRITICAL INTERVENTIONS

- Use nonanalgesic interventions that are specific for particular chronic pain syndromes.
- In the ED, prescribe opioids to the endpoint of improved function.
- Facilitate referral to pain service or primary care for long-term symptom management.

DISPOSITION

Most chronic pain patients can be discharged from the ED. The primary care physician or pain clinic should be consulted before

initiating or changing long-term therapy in patients with chronic pain syndromes. Follow-up should be arranged for patients with neuropathic pain syndromes.

Common Pitfalls

- Missing acute disease by assuming that an exacerbation of chronic pain is due to pre-existing disease.
- Routinely labeling chronic pain patients who have true pain as drug seekers.
- Overrelying on analgesic drugs to treat neuropathic pain.
- Failure to appreciate the risk of aspirin or acetaminophen toxicity when using escalating doses of combination opioid products to treat chronic pain.
- Assuming that pain from fibromyalgia or temporomandibular disorders is of purely psychogenic origin.

CHAPTER 17

Procedural Sedation and Analgesia

Robert J. Vissers and James R. Miner

The care of patients with painful conditions and the performance of painful diagnostic and therapeutic procedures are routine aspects of emergency care. Approximately half of emergency department (ED) visits are for pain-related chief complaints. Many of these conditions are also associated with anxiety. Accordingly, procedural sedation and analgesia (PSA) has become a fundamental skill of emergency physicians and an important part of emergency medicine residency training (1).

Despite the emphasis on PSA, oligoanalgesia has been well described in emergency care. Inadequate pain control has been ascribed to underestimation of patient pain, concern for patient safety, fear of delays associated with oversedation, and the alteration of physical findings (1,2). PSA can improve quality of care and patient satisfaction through the relief of pain and anxiety and the facilitation of therapeutic or diagnostic procedures such as cardioversion, incision and drainage of abscesses, tube thoracostomy, lumbar punctures, fracture reduction, complex suturing, and imaging studies (1,3–5). Many drugs used for sedation and analgesia have the potential to cause respiratory, cardiovascular, and central nervous system (CNS) depression. The introduction of protocols using shorter-acting, more effective drugs, the development of noninvasive monitoring devices, and published clinical policies for PSA have made it an extremely safe, practical procedure. The airway and

critical care expertise of emergency physicians make them ideal providers of safe PSA (1).

The wide variety of procedures and patient types requires the ability to individualize PSA. This can be achieved only through a comprehensive understanding of the drugs used and by proper patient assessment. Protocols delineating staffing responsibilities, monitoring guidelines, medications, observation periods, and discharge criteria and instructions are recommended before implementing PSA in the ED.

DEFINITIONS

The term *conscious sedation* has previously been used to describe the process of providing analgesia, sedation, and amnesia for patients undergoing painful procedures. However, this term may be misleading. A more precise and preferred term is PSA. In a recent clinical policy published by the American College of Emergency Physicians, PSA was defined as a technique of administering sedatives or dissociative agents with or without analgesics to induce a state that allows the patient to tolerate unpleasant procedures without undue pain or anxiety while maintaining cardiorespiratory function. PSA is intended to result in a depressed level of consciousness that allows the patient to maintain oxygenation and airway control independently and continuously (1).

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO), in its 2003 Comprehensive Accreditation Manual for Hospitals, states that “the standards for sedation and anesthesia care apply when patients receive, in any setting, for any purpose, by any route, moderate or deep sedation and general, spinal, or other major regional anesthesia” (6). JCAHO has adopted the American Society of Anesthesiologists (ASA) definitions of sedation and analgesia created in 1999 to better describe the continuum of sedation and analgesia. *Moderate sedation* most closely approximates the replaced term *conscious sedation.*

Minimal sedation is primarily anxiolysis for a procedure, during which patients respond normally to verbal commands. Ventilatory and cardiovascular function remains unaffected.

Moderate sedation/analgesia is a drug-induced depression of consciousness during which the patient responds purposefully to verbal commands, alone or accompanied by tactile stimulation. Typically, no interventions are required to maintain a patent airway. Spontaneous ventilation is adequate, and cardiovascular function is maintained; therefore, this is associated with less respiratory depression than deep sedation. At this level of sedation, patients generally are amnestic, even to painful procedures, but moderate sedation should be used only when the procedure is likely to be successful on a more responsive patient rather than a deeply sedated patient (7–9).

Deep sedation/analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully following repeated or painful stimulation. Assistance may be needed to maintain a patent airway, and independent ventilation may be inadequate. Cardiovascular function is usually maintained. This level of sedation is associated with a greater degree of respiratory depression than moderate sedation but is often necessary for the successful completion of procedures for which patient relaxation and amnesia is required (9–11).

General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. Independent ventilatory function is often impaired, and ventilatory and airway support is often required. Cardiovascular function may be impaired.

The response to medications can vary greatly between individuals and may be unpredictable. Therefore, it is recommended that clinicians be competent in the skills required to manage patients at least one level greater than the intended sedation (12). The management of impaired ventilatory function is a usual part of the practice of emergency medicine and represents a critical skill for the management of procedural sedation in the ED.

ED EVALUATION

Careful patient selection is necessary to provide safe and effective PSA. The comorbid illness or injury, any underlying medical

problems, patient age, the procedure, and the ability to manage the airway are important considerations in determining the indication for and the method of PSA. Not all patients or procedures are appropriate candidates for PSA and may be best served in the operating room.

The agents used in procedural sedation, to some degree, all cause hypoventilation and diminished airway reflexes. The principle complication of procedural sedation associated with significant morbidity is aspiration pneumonia from the loss of airway reflexes (3,13–15). Luckily, this is a rare complication, but a principle goal of sedation must be to avoid situations where a patient is at risk of its occurrence. Other complications include hypoxia, hypotension, and paradoxical agitation reactions from the sedative agents.

A patient's physical status can be conveniently described using the ASA's classification (Table 17.1) (16). This is frequently incorporated into the documentation of the preprocedure assessment. Patients with ASA physical status scores of 3 and 4 are more likely to have complications from hypoventilation and hypotension than patients with scores of 1 and 2, and the risk/benefit ratio of performing PSA in these patients must be considered (17).

TABLE 17.1
American Society of Anesthesiologists Physical Status Classification

I.	Normal, healthy patient
II.	Mild systemic disease
III.	Severe systemic disease
IV.	Severe systemic disease that is a constant threat to life
V.	Moribund patient, not expected to survive the procedure

A history of prior problems with anesthesia or PSA should be elicited. Particular attention should be paid to underlying hypovolemia, cardiorespiratory diseases, neurologic diseases, medications, and intoxicants. Physical examination should focus on the cardiovascular, respiratory, and neurologic systems and performing an assessment of airway difficulty. There is no evidence

to support the need for specific diagnostic testing before PSA. A discussion including the risks, benefits, and potential side effects of PSA should take place before the procedure. Written consent is recommended when possible; however, patient condition may preclude this (12).

There is insufficient literature to recommend a necessary period of fasting prior to PSA. The combination of vomiting and loss of protective reflexes during PSA causing aspiration is considered to be a rare event (13). There is no evidence that gastric emptying or antacids reduces the incidence of PSA-associated complications. It is likely, however, that increasing depth and duration of PSA is associated with an increased risk of aspiration, and it may be beneficial in patients who have recently taken more than clear liquids and require nonurgent procedures to delay until 3 hours after the last oral intake. For patients needing a procedure urgently (fracture reductions, intractable pain, etc.) recent intake should be considered in the choice of the target sedation level and duration of the planned PSA. The complimentary use of local anesthesia when appropriate, such as a regional block, can reduce the amount of sedation required. Patients at high risk for aspiration may benefit from the lightest level of sedation for the shortest amount of time that will allow successful completion of the procedure. Recent food ingestion is not a contraindication but rather a consideration when choosing the targeted level of sedation (13,17,18).

KEY TESTING

- Interactive monitoring
  - Airway assessment
  - Physical status score
  - Procedural plan
  - Sedation plan
- Mechanical monitoring
  - Capnography
  - Pulse oximetry
  - Cardiac monitor
  - Blood pressure

ED MANAGEMENT

Preparation

The necessary equipment and supplies should be gathered in an appropriate setting prior to the initiation of PSA. There does not have to be a specific dedicated area for PSA. However, the capability to provide cardiovascular and respiratory support and availability of personnel may dictate the location. Monitoring equipment, oxygen, suction, advanced life support equipment and medications, a bag-valve-mask, and intubation equipment must be readily available. IV access should be established and maintained before PSA with IV agents. The antagonists naloxone and flumazenil should be available when opioids and benzodiazepines are being used (19).

The Joint Commission and compliant institutions insist that the PSA provider demonstrate adequate training to administer the agents effectively and safely and have the skills to manage all potential complications (6). These are all within the scope of the emergency physician's expertise, especially in the unpredictable setting of the ED, which is unique to the practice of emergency medicine. There is no clear guideline in the literature or organizational policies regarding the required number of support personnel. It is essential that an individual is present who is capable of recognizing the respiratory and hemodynamic responses to the medications and is able to perform interactive monitoring without interruption throughout the procedure. The performance of a procedure often precludes the continual clinical assessment of the patient. Therefore, one individual provider not performing the procedure is usually recommended to monitor and document patient status when providing deep sedation (15). Moderate sedation using a single provider has been described (20).

The use of supplemental oxygen during PSA is somewhat controversial. Although its routine use may prevent hypoxemia in some patients, there is concern that it will delay the recognition of respiratory compromise and hypercarbia, due to its effect on the sensitivity of pulse oximetry to changes in ventilation (21,22).

Evidence supports the use of supplemental oxygen in patients undergoing PSA to reduce episodes of hypoxia; but care must be taken to use monitoring modalities other than pulse oximetry, such as close interactive monitoring, when supplemental oxygen is used (11,23).

Monitoring

The most important aspects of monitoring during PSA are the interactive observation and assessment of physiologic changes and the level of consciousness. The patient's ability to follow commands and the response to varied levels of stimulation are useful in quantifying the level of consciousness. Direct observation of the patient's airway and breathing (interactive monitoring) are likely to be the most accurate monitors of a patient's ability to maintain adequate ventilations and airway protection and to assess the safety of giving further medication to patients who have not yet achieved the desired level of sedation, and are therefore critical to the safe titration of sedatives and the avoidance of oversedation and its associated adverse effects (15,24,25). Interactive monitoring can be augmented by blood pressure, oxygen saturation, capnometry, and cardiac rhythm monitors.

The use of pulse oximetry is widely recommended in national and institutional PSA guidelines. Many studies have demonstrated its utility in monitoring oxygenation; however, there is no clear demonstration that its use during PSA affects patient outcome other than decreasing episodes of transient hypoxia (1,26). This may be as a result of the extremely low risk of morbidity and mortality during PSA when the patient's respiratory efforts and level of consciousness are clinically monitored. Furthermore, the clinical significance of transient decreases in oxygen saturation is not known (26), but we at least assume it is a marker of ventilatory depression and therefore a marker of risk for aspiration. Pulse oximetry measures oxygenation, not ventilation. A patient breathing supplemental oxygen may not exhibit changes in the oxygen saturation until several minutes after the onset of hypoventilation. In a patient breathing room air with a normal oxygenation prior to PSA, however, decreases in oxygenation

correlate with decreases in ventilatory effort. In either case, it represents useful information and should be utilized during PSA. However, it should not be a substitute for continuous clinical assessment.

Capnometry can be used to monitor ventilation. Capnographs measure expired CO_2 and display a waveform that represents the patient's ventilation. The peak of each wave represents the end-tidal CO_2, or the maximum concentration of CO_2 in the expired air. Large changes in the end-tidal CO_2 values and in the shape of the waveform have been associated with respiratory depression in sedated patients and may allow earlier identification of hypoventilation than oximetry (21,22,26,27). An increasing end-tidal CO_2 value can represent CO_2 retention from hypoventilation. A decreasing end-tidal CO_2 value can represent hyperventilation and decreasing arterial CO_2 levels, or increased mixing of room air and expired air in the upper airway owing to airway obstruction. An absent waveform on the capnograph can represent apnea or possibly upper airway obstruction if respiratory effort is present. The earlier detection of hypoventilation associated with the use of capnographic monitoring has been shown to decrease episodes of hypoxia during procedural sedation in the ED (26). Capnographic monitoring of end-tidal CO_2 improves the detection of hypoventilation, even in patients receiving supplemental oxygen, and decreases episodes of hypoxia. It should be considered in patients undergoing deep sedation who are receiving supplemental oxygen.

Blood pressure, heart rate, and respiratory rate should be assessed at regular intervals throughout PSA. Patients are at the highest risk for complications when they are at their deepest level of sedation, primarily within 90 seconds to 3 minutes of receiving IV sedatives, and when noxious stimuli are removed (immediately after the procedure). Continuous electrocardiographic monitoring is not routinely recommended. However, it should be used in older patients or those with a history of cardiovascular or pulmonary disease. Documentation of the level of sedation can be quantified using a

predefined sedation score, such as the Aldrete score or a simplified version suggested in Table 17.2.

TABLE 17.2

Fully awake
Arouses easily
Arouses with tactile stimuli
Arouses to vigorous stimuli
Responsive to painful stimuli
Unresponsive

Drug Selection and Administration

The ideal agent for PSA would provide analgesia, anxiolysis, amnesia, and somnolence rapidly and predictably with no adverse effects. Unfortunately this drug does not exist. As a result, multiple sedative hypnotics, opioids, and various anesthetic agents have been employed, singly and in combination, in an attempt to achieve the desired level of PSA (Table 17.3) (2). The agent selected, and its dose and route of administration, should be guided by the type of procedure and by the specific patient. Drug availability and physician experience are also important determinants.

TABLE 17.3
Agents Commonly Used in Procedural Sedation and Analgesia

Drug	Class	Effect	Side Effects	Dose	Peak	Clinical Duration
Morphine	Opioid	Analgesia Sedation	↓ Respirations N&V ↓ BP, HR ↑ Histamine	Children: IV: 0.05–0.1 mg/kg Adults: IV: 3–5 mg	IV: 20 min Oral: 60 min IM: 30–60 min	1–3 h
Fentanyl	Opioid	Analgesia Sedation	↓ Respirations N&V Chest wall rigidity	Children: IV: 1–2 µg/kg Adults: IV: 1 µg/kg	IV: 0.5–2 min	30–60 min
Midazolam	Benzodiazepine	Sedation Amnesia	↓ Respirations ↓ BP ↓ Pulse	Children: IV: 0.05 mg/kg PO: 0.5 mg/kg Adults: IV: 0.5–5 mg	IV: 1–5 min PO: 30 min	30–60 min
Diazepam	Benzodiazepine	Sedation Amnesia	↓ Respirations ↓ BP ↓ Pulse	Children: IV: 0.05 mg/kg PO: 0.2 mg/kg Adults: IV: 2.5–5 mg PO: 10 mg	IV: 5–15 min PO: 45–60 min	2–6 h

N&V, nausea and vomiting.

Prior to PSA, patients with pain should receive pain medications titrated to pain relief. Morphine 0.1 mg/kg, followed by 0.05 mg/kg every 2 to 3 minutes until pain is relieved, is a common approach. For situations in which the patient is likely to have much less pain after PSA owing to the nature of the procedure (the reduction of a severely comminuted fracture, e.g.,), fentanyl 1.5 µg/kg followed by 0.75 µg/kg may be preferable. Fentanyl is short-acting, with a duration of action of 30 to 45 minutes (25,28). It does not cause histamine release and has minimal cardiovascular effects. Like all opioids, fentanyl is reversed by naloxone. Respiratory depression is

more likely at higher doses, when given rapidly IV push, or when combined with other CNS depressants, such as benzodiazepines or alcohol. Lower doses should be used in elderly patients and when other CNS depressants may have been previously ingested. Side effects of fentanyl include hypoxemia, apnea, vomiting, and pruritus. Hypotension is rare. Bradycardia may occur with high doses. Truncal rigidity and glottic spasm, which make ventilation difficult, are unique complications seen with doses above 10 μg/kg, or at lower doses if the drug is given rapidly.

The duration of action of these agents is often much longer than the sedatives typically used in ED PSA; therefore, their titration should be performed prior to the PSA encounter rather than as part of it. Many of the sedative agents used in PSA have amnestic but not analgesic properties, and patients may have a brief transient increase in pain during their procedure. Combining sedatives with opioids for procedural sedation, however, has been associated with an increased risk of hypoventilation (25,29–31). Furthermore, patients receiving moderate or deep sedation, are unlikely to recall the event. The physiologic significance of brief pain that is not recalled is unlikely to outweigh the risk of prolonged or deeper sedation than was intended and the associated hypoventilation (31).

Regardless of the agent used, an important principle in PSA is the titration of drugs to the desired level of sedation with the least possible respiratory depression. Drugs given IV have a rapid onset with a more predictable response than agents given orally, transmucosally, or IM (2). Drugs should be titrated slowly, because rapid administration is more likely to cause hypotension or respiratory depression (32). To avoid oversedation, it is important to allow adequate time to achieve and assess peak effect before a second dose is given. A possible exception to the preferred IV route may exist in children, in whom IV access is often difficult and the IM response to ketamine is very predictable (33,34).

Sedatives

Methohexital is an ultrashort-acting barbiturate with sedative and hypnotic effects. It produces deep sedation but provides no analgesia

(35). Methohexital produces a state of deep sedation, which may be preferred for such procedures as cardioversion, chest tube insertion, or complicated orthopedic reductions. It has a rapid onset of action of 30 to 60 seconds, a duration of action of 3 to 5 minutes, and a short recovery phase. Deep sedation is achieved with bolus doses of 1 to 2 mg/kg (35).

Intramuscular doses of 10 mg/kg produce effects that begin in 2 to 3 minutes and last almost 1 hour. Rectal methohexital has been used in children when a motionless state is needed. A dose of 20 to 30 mg/kg induces sleep within 10 minutes and lasts for about 45 to 80 minutes. Cardiorespiratory complications rarely occur with rectal administration. Adverse reactions associated with the use of methohexital include dose-dependent respiratory depression and apnea. Oxygen desaturation is especially common when concomitant respiratory depressants are used. Hypotension is uncommon but can occur, especially in patients with hypovolemia and sepsis. It is easily corrected by giving IV fluids (2). Hiccups can occur, and protective reflexes may be impaired. Methohexital induces epileptiform activity by electroencephalogram in seizure patients and should be avoided in patients with epilepsy.

Midazolam is a benzodiazepine with amnesic and anxiolytic properties. Midazolam has a more rapid onset and shorter duration of action than diazepam and rarely causes phlebitis. Its amnestic properties also appear to be superior to those of diazepam (2). It is eliminated by hepatic metabolism. The IV dose is 0.03 to 0.1 mg/kg, with a starting dose of 1 mg. Onset of sedation is within 3 to 5 minutes, and the duration of action is about 30 to 60 minutes. With IM administration, the same dose is typically used, but the onset of sedation is delayed. Its duration of action is similar to fentanyl; therefore, the two drugs are frequently used together to induce extended PSA. It is often used to provide minimal procedural sedation.

In children, oral, rectal, and intranasal routes are effective alternatives to IV sedation. Oral doses are 0.2 to 0.75 mg/kg, and sedation is achieved within 1 hour. Rectal administration is effective at doses of 0.3 to 0.5 mg/kg, but the response is variable as a result

of the unpredictable effect of first-pass hepatic metabolism and it is not well tolerated or accepted by older children. Intranasal administration can be used when an intravenous line is not needed or when sedation is necessary to establish one. Doses of 0.2 to 0.4 mg/kg result in sedation in about 10 to 15 minutes.

Lower doses should be used when analgesic agents are given concomitantly and in elderly patients. Prolonged effects may occur in elderly patients as a result of decreased metabolic clearance and decreased first-pass metabolism.

Side effects include dose-dependent hypoventilation and hypoxemia. At high doses, midazolam blunts the central respiratory center's sensitivity to hypercapnia (2). Apnea is rare, except when other CNS depressants, such as opioids, are used. Hypotension can also occur with high doses.

Etomidate is an ultrashort-acting, nonbarbiturate sedative hypnotic with no analgesic properties. Like methohexital, it causes deep sedation, has a very rapid onset of less than 1 minute, and has a duration of action of 3 to 5 minutes. Etomidate has minimal cardiac effects. Although respiratory depression can occur, it is usually transient and associated with the use of other respiratory depressants (24,36,37). In critically ill patients (ASA physical status 3 and 4), it is associated with less hypotension than propofol (17).

Etomidate is given IV (0.1 to 0.15 mg/kg) and is currently not approved for children younger than age 10. Side effects are uncommon. Transient respiratory depression can occur. Myoclonic jerking occurs in up to 25% of patients and has been mistaken for seizures (17). Adrenal suppression can occur after long-term use but is not an issue in ED PSA (1,30). Published experience with the use and safety of etomidate in the ED suggests a rate of respiratory depression similar to other agents used for moderate and deep PSA (24).

Ketamine is an anesthetic that causes a dissociation between the thalamic and limbic systems. This, in turn, hinders the perception of visual, auditory, and painful stimuli, leaving the patient in a trancelike state (13). After absorption, ketamine is rapidly distributed and taken up by cerebral tissue. Effects are maintained

until the drug redistributes into the peripheral tissues and is metabolized by the liver (34).

Ketamine can be given by multiple routes. An IV dose of 1 to 2 mg/kg, an IM dose of 2 to 6 mg/kg, a rectal dose of 5 to 15 mg/kg, or an oral dose of 6 to 10 mg/kg induces a dissociative state (34). Sedation is achieved within 1 minute when the drug is given IV, 5 minutes when given IM, and 5 to 20 minutes by other routes. The duration of action is 15 to 30 minutes for IV dosing and 30 to 40 minutes for IM dosing.

Ketamine's most common side effect is the emergence phenomenon, in which the patient wakes up hallucinating. This is more common in patients older than age 10, in females, and in those with an underlying psychiatric disorder. It is less common with IM injection and can be attenuated by the concomitant use of benzodiazepines.

Laryngospasm and emesis are infrequent complications. Patients given ketamine may develop nystagmus and muscular hypertonicity. The pharyngeal–laryngeal reflexes remain intact, although laryngospasm sometimes occurs (13). Ketamine has minimal effects on oxygen delivery. Respiratory depression may occur with high doses or rapid IM infusion. The drug stimulates tracheobronchial and salivary secretions, but this effect can be minimized by the concomitant use of an anticholinergic such as atropine. Mild-to-moderate elevations in pulse rate and blood pressure may result from ketamine's ability to block the reuptake of catecholamines, especially with IV infusion. Twitching, hypertonus, and myoclonic jerking can occur and have been mistaken for seizures. Electroencephalographic studies, however, have shown that ketamine does not cause convulsions.

Ketamine is contraindicated in patients with cardiovascular disease, chronic obstructive pulmonary disease, intracranial and intraocular injuries, and increased intracranial or intraocular pressure. It is not recommended for use in patients with a history of psychiatric illness or children younger than 3 months of age.

Propofol is a very short-acting sedative hypnotic agent, with a rapid onset of action. Propofol is given intravenously as an initial

bolus of 1 mg/kg, followed by 0.5 mg/kg bolus injections every 3 minutes until adequate sedation is achieved. It has a duration of action of 5 to 7 minutes following this dosing regimen. The duration of action of propofol increases with the quantity of propofol used, and can extend to 10 to 20 minutes after a prolonged infusion. It is metabolized by the liver and excreted by the kidneys. It is thought to have a secondary form of metabolism, because it can be used safely in patients with liver cirrhosis and renal failure. Propofol is often used in combination with analgesics such as fentanyl.

ED PSA using propofol has been evaluated in multiple studies of adults and children. Hypoxia has been reported in 5% to 30% of patients (10,15,17,28,32). The use of bag-valve-mask assisted ventilations has been reported to be necessary in 3% to 9% of adults, with a much lower rate of oral airway use (0.3% to 0.5%). Hypotension has been reported to occur in 2% to 7% of adult patients, with emesis occurring in 0% to 0.5% (17,32). These rates are not unique to propofol but are typical of moderate and deep PSA. In comparisons with etomidate and methohexital, propofol was found to have similar rates of respiratory depression (15,17,24,32,35). If hypotension occurs, it is easily reversed with fluids or by terminating the infusion. However, propofol should be avoided in patients with pre-existing hypotension or hypovolemia.

Propofol and ketamine have been combined in an attempt to make a new sedation protocol that maximizes the benefits of both drugs while minimizing their adverse events (38,39). Theoretically, by combining the medications, the dose-related respiratory depression of propofol can be avoided with smaller doses due to the effect of ketamine, whereas the dose-related vomiting and emergence phenomena of ketamine could be avoided through the effects of propofol. Combinations ranging from 1:1 to 4:1 mixtures of propofol and ketamine have been described, with research showing a trend toward less respiratory complications than propofol alone. The duration of sedation appears to be longer than propofol alone, resulting in longer patient stays in the ED. More research will be required to determine the role of this combination of medications in

the ED, but the practice appears to be a safe alternative to either agent alone.

Nitrous oxide is a colorless gas that, when used in combination with oxygen, provides analgesia and sedation. The gas diffuses rapidly across membranes, providing a rapid onset and elimination (2). The level of sedation is often disproportional to the analgesia provided. The use of analgesics in combination with nitrous oxide appears to synergistically enhance the level of sedation and pain control; however, potential side effects, such as hypoventilation, also are compounded.

Nitrous oxide is given as a 30% to 70% mixture with oxygen by a demand valve-mask or a mouthpiece, held by the patient. A variety of delivery systems are available that allow titration of the concentration of nitrous and ensure adequate scavenging of the gas. Nitrous oxide is a teratogen, and it is important to avoid exposing pregnant patients or staff to the agent. Scavenger devices and adequate room ventilation are important to minimize the escape of the gas into the air, preventing potential acute and chronic adverse effects on providers.

Because the gas rapidly diffuses into gas-filled pockets, it potentially can worsen conditions such as pneumothoraces, small bowel obstructions, decompression sickness, chronic obstructive pulmonary disease, and ear effusions (6). Nitrous oxide has the potential for abuse, and every effort should be made to safeguard against this. Many systems available currently have lock systems that allow for controlled access to the medication.

Reversal Agents

Naloxone is a competitive antagonist of opioids at the μ receptors and is used primarily for the reversal of opioid-induced respiratory depression. The initial dose is 1 to 2 mg IV. However, if the patient is opioid-dependent, a titrated dosing of 0.1 to 0.2 mg IV every 1 to 2 minutes may prevent unpleasant withdrawal symptoms. Naloxone may have a shorter duration of action than the opioid used; therefore, continued observation for delayed respiratory depression

is required. It may not reverse the chest wall rigidity occasionally associated with high-dose fentanyl.

Flumazenil is a competitive antagonist of benzodiazepines and is given in titrated doses of 0.1 to 0.2 mg IV, every 1 to 2 minutes to desired effect. It has a half-life of 45 to 100 minutes; therefore, a similar caution must be exercised when used with benzodiazepines having a longer duration of effect. Flumazenil may not be effective at reversing respiratory depression. It should be used with caution in patients with benzodiazepine dependence or a history of seizures.

Elective reversal of PSA remains controversial. It has been proposed that reversal may reduce the time required for postprocedure observation. Several factors caution against this practice. Naloxone has a clinical effect of 30 minutes, which may be shorter than the continued duration of effect for the opioid (2). Flumazenil has not been shown to be effective at reversing the respiratory depression associated with benzodiazepines (9). No effect on discharge time has been demonstrated with reversal in the ED setting. Therefore, elective reversal is not recommended.

CRITICAL INTERVENTIONS

- Assess the patient's underlying medical conditions and potential airway difficulty prior to the initiation of PSA.
- Continue to monitor the patient after the completion of the procedure until recovery to baseline. Patients may become more sedated after the removal of a painful stimulus.

DISPOSITION

Patients must be observed after PSA, and monitoring and documentation should continue until they have regained their baseline mental and physical status. Complications after this time are very rare. Discharge criteria should include regaining baseline mental and physical status when complications of PSA are no longer expected. Patients may require treatment for pain and nausea after sedation. Discharge instructions should otherwise focus on the care necessary for the disease process that necessitated the PSA.

Common Pitfalls

- Forgetting that the most important aspect of patient monitoring is interactive clinical assessment of the level of sedation and respiratory effort
- Using the "one-drug-fits-all" strategy. The selection and dosing of agents should be individualized to the patient and the procedure.
- Failure to treat pain adequately

SECTION IV
Trauma

Section Editor: CARLO L. ROSEN

Medical Foramen

PART 1 • GENERAL CONSIDERATIONS

CHAPTER 18

General Principles of Trauma

Eric Legome and Ashika Jain

Accidental trauma is the leading cause of death in the United States in the 1- to 44-year-old age group and the fifth leading cause overall. In the United States, injuries cost an estimated $117 billion in medical expenditures each year. This represents approximately 10% of total medical spending, similar in magnitude to the medical costs associated with other leading public health concerns. These estimates do not include the lost productivity, nonmedical expenditures, insurance costs, property damage, litigation, decreased quality of life, and long-term noninjury health consequences (e.g., mental health care costs). In addition, the personal and social costs owing to premature loss of life or livelihood is immeasurable (1,2).

Optimal care of the trauma patient begins in the prehospital setting, continues throughout the emergency department (ED) course, and extends into the intensive care and rehabilitation phases. All of these parts must work in concert to provide for the best outcome. Although not always feasible, the outcome for the severely injured trauma patient is optimized when they are initially treated at, or expeditiously transferred to, a regional trauma center with expertise in and dedication to all facets of trauma care (3–5).

In addition to treatment of the individual patient, resources must be allocated to the prevention of trauma, an often underappreciated aspect of trauma care. Even minor changes in traffic safety, alcohol

and drug use, and gun safety have a tremendous potential to decrease trauma morbidity (4,6).

CLINICAL PRESENTATION

Prehospital

After extrication and immobilization, rapid transport to a trauma center is the most efficacious prehospital trauma intervention. Many prehospital interventions such as military antishock trousers for hypotensive patients have not been found to be helpful, and even interventions such as rapid-sequence intubation (RSI) in the head-injured patient, once thought invaluable, have become controversial. The use of intravenous fluids has likewise become controversial, with timing, amount, and end point a current focus of contention. Current and future studies may offer a clearer understanding of which prehospital interventions have the most utility (5,7).

There are several reasons for rapid transport to a trauma center. While community hospitals have physicians with excellent skills and training in managing trauma patients, major trauma centers evaluate a significantly higher number of major trauma patients with appropriate resource allocation. Furthermore, their personnel are more likely to have advanced skills, appropriate ancillary staffing, up-to-date technology, readily available consultants, rapid operating room (OR) capability, intensive care unit (ICU) capability, and rehabilitative care to restore a patient to full health. In addition, when compared to nontrauma centers, they have been shown to decrease death rates in the most seriously injured patients (3,5). Some areas do not have an available trauma center; for example, there are no major level 1 trauma centers in rural states such as Idaho or Montana (8). In these areas, it may be prudent to take a high-risk patient to a center with available surgical and interventional capability, even if it means bypassing a closer hospital. Often a local hospital will have to stabilize a patient prior to transfer to a convenient trauma center. Therefore, transfer agreements, routes and the mechanics of evacuation should be

worked out well in advance of the individual patient's need. These decisions are often community-specific and based on an understanding of local resources, demographics, and transport times. Regardless of the setting, most emergency physicians (EPs) will encounter both major and minor trauma throughout their career, and competence and confidence in caring for these patients is essential to the skill set of the EP.

Due to funding constraints, a number of hospitals have closed their trauma service because of an inability to support the expensive personnel and equipment needs of a 24-hour service. Moreover, lack of reimbursement, along with the risk of malpractice suits that often accompany major trauma, has discouraged many specialists from participating in trauma care. Subsequently, this has led to a crisis in the ability to deliver timely and appropriate subspecialty care (9).

Emergency Department

On arrival to the ED, trauma patients with abnormal physiologic parameters, a major mechanism of injury or a potentially serious injury should be triaged to a suitable treatment area capable of major resuscitation. It is safer to initially overestimate the degree of injury and then downgrade the patient after initial evaluation, rather than upgrade a patient to more aggressive care. Appropriate personnel should accompany the patient to the resuscitation room to ensure that adequate life-support measures are being accomplished en route. Details regarding the mechanism of injury may offer important clues in predicting potential injuries.

Mechanism of injury must always be taken seriously and is essential for injury evaluation. While a significant mechanism may not lead to major injury, and a trivial mechanism may cause severe morbidity, knowing the mechanism should heighten the suspicion for significant trauma. The most sensitive way to prognosticate major injury is to take both physiologic parameters and mechanism into consideration (Table 18.1).

TABLE 18.1
Mechanism of injury

Blunt Trauma

Motor vehicle collision

1. Estimated speed of both vehicles on impact
2. Orientation of the vehicles (e.g., head-on, broadside)
3. Location of the patient in the vehicle
4. Trajectory and extent of damage to patient's vehicle
5. Amount of intrusion into the vehicle
6. Was there an explosion or fire?
7. Was the patient restrained?
8. Were airbags deployed?
9. Was the windshield intact?
10. Was the steering wheel intact?
11. Was there an initial loss of consciousness at the scene?
12. Was any alcohol or drugs recovered from the patient or car?
13. How long did it take to extricate the patient?
14. What is the ambient temperature (potential for hypothermia)?
15. Was any person killed in the crash?

Fall

1. Estimated height
2. Possible reason for fall (e.g., electrocution; explosion; medical cause of syncope such as a dysrhythmia)
3. Was there an initial loss of consciousness at the scene?
4. Was any alcohol or drugs recovered from the patient or scene?
5. How long was the patient down?
6. What is the ambient temperature (potential for hypothermia)?

Penetrating Trauma

Stab wound

1. Description of the weapon (e.g., length, width)

Gunshot wound

1. Description of the weapon (including caliber)
2. Number of gunshots heard

Triage must take into account the immediate threat to life and limb and patient discomfort and anxiety. A variety of options exist for triage including emergency nurses, a dedicated trauma nurse and even a triage physician.

Major trauma is best evaluated by a dedicated trauma team. The team must have a captain, and the training and experience of this person may vary and should be appropriate to the specific hospital. Usually, the captain is initially an EP; given the increasing economic pressures and the decrease in number of trained trauma surgeons, there is increasing movement to involve trauma surgeons only after full ED evaluation or if urgent operation is required. EPs have also undergone advanced training in trauma care and may have joint appointments with surgical departments. This has led to ongoing controversy, and there is no widespread agreement on when or whether the trauma surgeon is needed routinely in the initial resuscitation (10–12). In some settings, an EP may be the only physician physically present in the ED (and, for that matter, in the hospital). Ideally, surgical support personnel are available within 10 to 30 minutes.

In trauma centers, surgical support is generally rapidly available within the hospital. In this system, the EP may assume the role of trauma captain for the initial assessment and resuscitation. When the attending trauma surgeon arrives, a defined transition of leadership may occur. The team concept must be maintained at all times.

If the responsibility for the major orchestration is formally handed over to the attending trauma surgeon, it does not relieve the EP of responsibility for the patient. The EP should assist until the patient physically leaves the ED for the OR, ICU, or special diagnostic study. Exceptions of course are made if there are other critical patients who demand the attention of the EP. When the EP has to leave the patient, the departure should be coordinated with the team and the team leader. The team may summon subspecialty consultations, but there must be a single person, generally the EP or trauma surgeon, in charge of the orchestration of total patient needs.

Nurses who care for trauma patients should have the requisite special knowledge and skills. In large urban centers, there is usually an abundance of physicians to perform resuscitative procedures, but in the rural ED, the trauma nurse may require technical skills ordinarily performed by physicians. Other institutions may use a

combination of midlevel providers including specially trained nurse practitioners or physician assistants. Prehospital personnel who do not need to immediately return to the field may be requested to remain in the ED so that their technical skills can be utilized.

The area of the radiology department designated for emergency patients should optimally be adjacent to the ED. As radiology has become essential to trauma management, the radiologist must be considered a member of the trauma team and should be readily available for consultation. The ability to perform portable radiographs in the trauma resuscitation room is necessary since these patients should not be moved from the area during the initial stages of evaluation. Likewise point of care ultrasound (US) has become common in trauma centers to provide immediate information at the bedside. Protocols and guidelines should be available regarding expectations of all ancillary staff. A coordinated, knowledgeable response from the blood bank, laboratory, respiratory therapy, and radiology department is vital to an effective trauma system. Social workers, clergy, and lay support should be included in the team framework.

The OR must be rapidly accessible to the ED for operative resuscitation of critically injured patients. Some centers have emphasized this by having an OR as part of the ED or by reserving a single OR for trauma use, but others have utilized a special OR in the surgical suite in which to perform the initial resuscitation.

ED EVALUATION AND MANAGEMENT

Prior to Arrival

When notice is given by EMS that a critical patient is en route, the ED should consider potential needs, for example, having blood for an exsanguinating patient. The entire trauma team should ensure standard precautions, with gloves, gowns, masks, and protective eyewear. All patients should be presumed to be potentially infectious from blood-borne or body fluid–borne diseases and should be treated accordingly until risk can be fully assessed. These precautions apply to blood and to other body fluids containing

visible blood, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. Prior to arrival, the team captain should assemble the team and assign roles; this may include setting up for necessary procedures (i.e., airway management and tube thoracostomy).

Primary Survey

The approach to the trauma patient begins with a rapid initial examination. While the initial assessment proceeds in a stepwise approach, when performed with multiple providers, several steps may occur simultaneously. This is appropriate as long as one clinician is clearly overseeing the entire process. On arrival, the patient must be immediately undressed. Care should be taken to avoid hypothermia by placing warm blankets on the patient after the evaluation is done. The cervical spine should be immobilized until it is cleared of injury by radiographic or clinical criteria, but early relief from the back board is critical to patient comfort.

The initial trauma assessment, or the ABCs, begins with evaluation of the airway. The need for airway management is the most critical initial question in the patient with multiple trauma. Table 18.2 lists common criteria that serve as guidelines for this decision.

TABLE 18.2
Indications for Intubation

Mandatory

Inability to protect airway, oxygenate, or ventilate

Head injury with Glasgow Coma Scale <8

Penetrating injury to the cranial vault or high energy to the neck

Massive facial injuries

Blunt injury to the neck, with expanding hematoma, painful phonation, or alteration of the voice

Bilateral missile penetrating injuries of the thorax

Multisystem trauma with persistent shock

Relative Indications

Need for significant ongoing sedation/pain control

Expectation of significant worsening

Any patient with injuries impairing ventilation, e.g., flair chest, severe pulmonary contusions, deteriorating respiratory status

Need to transport long distances with potential or actual instability

Bilateral pneumothorax

Expanding hemothorax that recurs or does not respond to thoracostomy

Any patient developing severe hypovolemic shock or with extensive burns, or patients with pulmonary, facial or neck burns

The airway assessment should include patency, ability to speak clearly, and ability to control secretions. If this is not the case, the EP should search for possible obstruction in the form of foreign body or relaxed tongue that might obstruct the airway. Oxygenation of the tissues is critical, and clearing the airway is the initial step in oxygen delivery. A suction apparatus may be used to clear the upper airway. The patient with facial injuries, but no neck injuries, may be turned onto the side or sat up leaning forward to allow rapid clearing of the airway. A patient may also be turned on the backboard or while maintaining spinal immobilization (log rolling) if the condition of the cervical spine is unknown.

An oral airway may be placed in the unconscious trauma victim to allow for oxygenation but this is generally followed rapidly by intubation. In some cases of severe maxillofacial trauma or direct tracheal injury, cricothyrotomy is indicated. The need for intubation and active airway management is a clinical decision and should never be withheld pending a blood gas. Once the airway is patent, breath sounds should be rechecked.

If the patient is not breathing spontaneously or adequately, ventilation must be controlled. Initial control may be by bag-valve-mask ventilation with high-flow supplemental oxygen. Once the patient is oxygenated and hypercapnia has been corrected, intubation is less hazardous, but undertaking bag-valve-mask ventilation must be weighed against the risk of distending an already full stomach.

Major trauma victims often need early airway management, even if they are breathing spontaneously. Patients may have injuries distorting their airways (e.g., a gunshot wound to the neck). It is prudent to intubate these patients early in their course before intubation is impossible to perform such as if the neck is distorted by a large hematoma. In addition to airway protection and maintenance of anatomic function, other reasons to intubate the major trauma patient exist. Intubation will allow for multiple tests and transport in patients with serious injuries or altered mental status who may require ongoing sedation or narcotic pain control. In some cases, airway management is indicated owing to the expectation that the injuries are so severe that the patient will eventually need intubation. Patients with severe or suspected head injury with a Glasgow Coma Score (GCS) of <8 or a declining mental status should be intubated to protect the airway, prevent hypoxia, and allow for controlled breathing. Finally, because few trauma patients have an empty stomach at the time of injury, intubation can help lower the risk of vomiting and aspiration.

Oral intubation using RSI is the optimal approach in the ED. It has been very successful and has virtually eliminated the need for cricothyrotomy. The preferred approach to intubation in the patient with a possible cervical spine injury is to keep the neck immobilized by inline stabilization and perform RSI. A second pair of hands other than those of the intubator provides in-line stabilization of the head and neck, which also allows for opening the anterior collar.

Nasal intubation, which is still occasionally performed in some prehospital systems, is rarely used in the ED. Many EDs are commonly using specialized approaches to the airway, especially video-assisted laryngoscopy, often as the initial procedure (13). A

surgical airway may be necessary if there is extensive damage to the patient's larynx, complete tracheal separation, or significant midfacial or orofacial trauma or neck distortion.

Laryngeal mask airway may be used as a rescue technique in the ED but generally does not provide a long-term secure and safe airway and should be replaced as soon as possible by a secure endotracheal tube.

After evaluation and management of the airway, breathing and circulation must be assessed.

In assessing breathing, the physician should observe the chest for sucking wounds or paradoxical motion, palpate for bony crepitus or subcutaneous air, and auscultate for breath sounds. Severe dyspnea, hypoxia, subcutaneous air, or tachypnea in the presence of penetrating chest trauma should lead to the presumption of an underlying hemo- or pneumothorax.

The major causes of pulmonary dysfunction in the trauma patient are hemo- and pneumothorax. The patient may also hypoventilate owing to multiple rib fractures or underlying pulmonary contusions.

Tension pneumothorax causes shock by increasing intrathoracic pressure, shifting the mediastinum, and compressing the great veins, thereby preventing venous return. The diagnosis is probable in a trauma patient in shock who has distended neck veins and an increased resistance to bagging. An ipsilateral decrease in breath sounds may be noted and a contralateral tracheal shift. Unfortunately, these physical findings are often not present acutely and the only clues to the presence of this may be a sudden rise in pulse, a drop in blood pressure, and an increased resistance to ventilation. If tension pneumothorax is suspected in the field, it should be immediately decompressed with a large-bore over-the-needle catheter in the fifth intercostal space or the second intercostal space in the midclavicular line. Treatment of a suspected tension pneumothorax should not be delayed to obtain radiographic confirmation. The physician should needle decompress the chest or perform thoracostomy by inserting a large-bore chest tube in the fifth intercostal space, midaxillary line, to evacuate any blood or air.

After pulmonary evaluation, circulation must be rapidly assessed. Any obviously bleeding source should be controlled by pressure, and vascular access should be obtained. There is no single answer to which method of intravenous access is the best. Each patient must be evaluated individually, and the risk–benefit ratio of the chosen routes weighed. In the patient in shock or with concerning findings, it is best to insert a minimum of two large-bore (14 to 16 gauge) peripheral lines, adding more as necessary. Patients with minimal or no injuries may not require such aggressive intervention. Sometimes it may be necessary to proceed immediately to a central line or peripheral cut down to gain access. A central venous catheter may be helpful in monitoring central volume, in addition to delivering fluid and blood. Central line placement utilizing an US probe has become a much safer procedure and will not only give access with a large-bore catheter but allow successful central venous pressure monitoring. Intraosseous techniques, more common in children, may be used in adults also. This has become more common, especially in the prehospital arena when standard access is unobtainable (14).

Most traumatized adults can tolerate generous fluid infusions because they are usually young and previously in good health. Whether this is best however, is still unclear. Classic teaching has been that an initial dose of 20 mL/kg is safe and an appropriate starting point. If the patient still shows signs of significant volume deficit after administration of 50 mL/kg or 2 L of crystalloid, type-specific or O-negative blood should be started. In the patient who has an injury that obviously will produce a major volume deficit (e.g., shotgun blast with marked tissue destruction and loss), blood should be given very early. Massive transfusion protocols have become much more common, based largely on experiences in the military. While there is little prospective research showing their benefit, retrospective case control studies suggest that when performed with appropriate ratios of blood to platelets and factors, they may be effective in decreasing mortality. When massive transfusions are used, they generally should be part of a hospital wide strategy and protocol (15–17).

Both the end point and the aggressive use of fluid resuscitation are controversial. Owing to concerns, based mostly on animal studies, that aggressive fluid resuscitation to normotension in the actively bleeding patient may lead to increased mortality, a less assertive response to hypovolemia has been advocated. This mortality is due to factors such as increased bleeding from increased arterial and venous pressure, dilution of clotting factors, clot disruption, and decrease in blood viscosity. Multiple animal studies have upheld this idea of “hypotensive resuscitation.”

In clinical practice, however, it has yet to be fully proven beneficial. Few significant studies have been performed in human beings, one with penetrating and one with a combination of penetrating and blunt trauma patients. Although one study found a benefit to not actively resuscitating patients with penetrating torso trauma, there have been concerns about the methodology and validity of the study. In addition, patients with severe head injury have a worsened outcome with hypotension, making this approach unlikely to be helpful in this group of patients. However, many clinicians and academic centers believe strongly in the concept of less aggressive resuscitation. This approach should be considered as an appropriate alternative while awaiting more definitive research in this area (18–20).

The amount of fluids administered depends on continued losses, which should be minimized as much as possible. Though intra-abdominal bleeding may require definitive surgical or angiographic intervention, interventions in the ED such as proper splinting, bandaging, and avoidance of probing large soft tissue wounds will maximize hemorrhage control. The degree to which long-bone and pelvic fractures bleed is not generally appreciated; it is far more effective to administer blood when these injuries are recognized than to wait until the patient is in shock. Direct pressure should be applied to control external hemorrhage. Blind probing and clamping deep within a wound may cause further injury to vessels and nerves. A soft tissue injury, especially to the scalp, may result in large amounts of bleeding. The best treatment for hypovolemia is to locate the source of bleeding and stop the blood loss. Hemostasis

can be rapidly obtained in a scalp laceration either by the use of Raney clips (neurosurgical skin clips that can be quickly applied to the scalp laceration edges) or by placement of a 2-0 nylon running locked stitch.

While most trauma patients in shock are hypovolemic and this should be actively pursued, other options should still be considered. Cardiac causes of shock must also be in the differential diagnosis. Pericardial tamponade is rare with survivable closed-chest injuries; another source of the shock should probably be sought. It must always be considered with penetrating injuries, even if the entrance wound appears anatomically remote. The physiologic response to tamponade is to compensate for the fall in cardiac output by raising the pulse rate. The classic physical findings may be absent in the acute situation. Thus, one may not see distended neck veins if the patient is profoundly hypovolemic. Furthermore, heart sounds may be difficult to appreciate in the ED. The use of focused assessment with sonography for trauma (FAST) in the trauma bay is highly useful in evaluating for pericardial fluid. If not available in the trauma bay a pericardiocentesis can be performed. If, on the other hand, the patient has just lost vital signs an immediate thoracotomy should be performed.

Blunt cardiac injury may cause dysrhythmias. An electrocardiogram should be obtained in patients with significant anterior blunt chest trauma. Continuous cardiac monitoring is indicated. A normal EKG and period of monitoring in the ED generally rules out a significant blunt cardiac injury. Myocardial infarction may occur as a result of the stress associated with blood loss and catecholamine release, or it may have preceded the traumatic injury.

The presence of spinal cord trauma with loss of sympathetic vascular tone can be assessed by rectal examination and examination of peripheral reflexes. The extremities should be palpated; if they are cool, moist, or pale, hemorrhagic shock must be presumed.

If the patient has a cardiac arrest from hypovolemia or pericardial tamponade, immediate emergency thoracotomy may be indicated.

In general, thoracotomy in the presence of penetrating injury and a patient who arrests in the ED or just prior to arrival offers the best prognosis. Maximal benefits are obtained in the presence of low-velocity penetrating injury to the chest, particularly the heart. Blunt trauma arrests in general have an extremely poor prognosis, especially with a prehospital arrest or multiple concomitant injuries (9).

Operative intervention is part of the resuscitation of the unstable trauma victim. In the patient unable to be resuscitated from shock without an obvious source of blood loss, immediate exploration may be indicated. A chest radiograph helps determine whether the chest or the abdomen is the site of initial exploration.

Patients with penetrating trauma, in the absence of contraindications, should be rolled onto the side to ensure that there are no wounds on the back, buttocks, or in the axillae. Blood pressure determination from the field should be repeated. Although not clearly correlated with a specific blood pressure, locating a palpable pulse provides information about the perfusion pressure.

When intravenous lines are placed, blood is drawn for typing and other tests. If possible, the prehospital providers may draw blood. Though it may be more efficient to use a large, 50-mL syringe and simultaneously draw all needed blood samples and measure arterial blood gas from the femoral artery, this may also increase the possibility of needle sticks when the blood is transferred. It is the trauma captain's responsibility to ensure that blood is obtained in a timely manner.

The priorities of definitive management are still vigorously debated, and it is often necessary to perform invasive procedures without the luxury of confirmatory diagnostic studies. In general, one should attempt to approach the pathology that poses the most immediate threat to the patient's life—usually in the abdomen.

Secondary Survey

In the patient who stabilizes during resuscitation, the next priority is a complete head-to-toe examination, including repeat maxillofacial,

cardiopulmonary, abdominal, neurologic, and orthopedic examinations. In addition to the examination, further history about the timing and mechanism of the injury should be obtained with the past medical history, medications, and allergies.

If the patient is unconscious, determining the level of brainstem function and the presence of a herniation syndrome is paramount. Most trauma victims die of central nervous system–related injuries. While in the stable patient with little clinical concern the rectal examination is rarely helpful and may be misleading, in the multiple trauma patient, a rectal examination may reveal displacement of the prostate, or gross blood, and provide for neurologic assessment of the anal sphincter tone and sensation (21). The absence of tone or sensation may indicate a spinal cord injury in a patient previously assessed to have only a head injury.

It is necessary to immobilize the spinal column until its status can be ascertained, but it is not necessary to spend long periods of time trying to clear the cervical or other spinal column before dealing with more life-threatening injuries. The patient can be maintained supine with a hard collar while more immediate life threats are determined.

Open fractures should be gently irrigated (realizing that this procedure will not substitute for more effective and complete irrigation and debridement under anesthesia) and splinted to prevent further injury and reduce pain and bleeding. Open fractures should be covered with clean dressings and intravenous antibiotics administered, to provide antistaphylococcal coverage. Definitive care may have to be delayed while surgical treatment of more serious, life-threatening injuries occurs.

Laboratory and Diagnostic Studies

Laboratory analysis of the trauma patient is generally more extensive than necessary. Routine laboratory studies on preoperative patients are not useful or cost effective unless indicated by the history and physical. However, owing to the limitations in obtaining this information in the multiple trauma patient, an extensive array of tests is often completed. Though testing based on clinical

parameters has been shown to be cost effective without compromising care, most trauma centers use some type of protocol to standardize and speed the laboratory evaluation of patients (22). The patient who is fully awake and alert, who has sustained minimal trauma, and who has no distracting injuries may require no testing. Rational laboratory analysis of most patients with moderate trauma can probably be limited to a complete blood count, a basic metabolic panel, blood type and screen, and urinalysis.

Clinical screening for basic risk factors for renal insufficiency (i.e., history of renal disease or diabetes) in ED patients has been repeatedly shown to be an excellent screening tool for patients who need a serum creatinine prior to receiving intravenous contrast for CT. If risk factors are absent, an urgent CT scan should not be withheld while awaiting serum creatinine. The multiple trauma patient or one about to undergo urgent operative management may require more thorough testing. Women of childbearing age should have a pregnancy test performed.

The sequencing of radiologic studies should be prioritized in the same manner as the other components of the resuscitation. Though cervical spine imaging is essential in the patient who cannot be clinically cleared, the imaging may be delayed and the patient kept in a collar and immobilized while addressing more pressing issues. In victims of blunt trauma, chest and pelvic films should be obtained next and, if necessary, extremity films obtained thereafter. The chest radiograph should be taken as soon as possible in the patient with penetrating injury, although with proper training, the test characteristics of bedside US for lung pathology are excellent and arguably better than radiographs (23). Empiric treatment of a presumed pneumo- or hemothorax should take priority if the patient is unstable. Clinical evaluation of the pelvis without radiographic study is accurate to exclude a clinically important fracture. It is still wise to routinely obtain a study on the patient with altered mental status, hypotension or significant distracting injury and appropriate mechanism (24).

One of the most important decisions in the management of the multiple trauma patient is when and how to obtain an objective

evaluation of the abdomen. Generally a combination of mechanism, physical findings and age are the most important factors. With a major mechanism of injury even in the well-appearing patient, it is reasonable to consider further evaluation of the abdomen for occult hemorrhage. Clinical judgment, however, should be used (25). The physical examination of the abdomen is less reliable when there are multiple injuries, competing pain from skeletal trauma, or altered mental status from head injury, shock, or substance abuse. In the presence of these factors, objective evaluation should generally be obtained. Finally, in any patient who demonstrates hemodynamic instability without obvious source, it is critical to evaluate the abdomen for hemorrhage.

Objective evaluation of the abdomen is generally performed by one of two common methods: CT or US. While previously a common option, diagnostic peritoneal lavage (DPL) has largely been replaced by US (26).

DPL is highly accurate (92% to 98%); it has reliable significance when negative. However, as noted, it has largely been supplanted by CT and US, both noninvasive tests. DPL is still recommended in the unstable patient with an unclear US result or in the stable patient with a significant concern for a hollow viscous or mesenteric injury, either by examination or after an equivocal CT. The only absolute contraindication for DPL is the need for emergency laparotomy.

Ultrasonography can also be performed at the bedside. The FAST examination, a four-view, directed US examination, is able to reliably find fluid within the abdomen and within the pericardial sac. It is accurate with significant intra-abdominal hemorrhage, and as it is noninvasive, it has mostly replaced the DPL. FAST is performed on the supine patient with the examiner positioned on the right side. Four locations are scanned: (a) the right upper quadrant, (b) the left upper quadrant, (c) the suprapubic region, and (d) the pericardium. The examiner looks for unclotted blood, a black or anechoic finding on the US's screen. It is reasonably reliable, especially with enough bleeding to cause hemodynamic instability, but may need to be performed more than once if the patient is seen very soon after the trauma prior to large amounts of bleeding. The

level of accuracy is comparable regardless of whether an EP, surgeon or radiologist performs the study. The major limitation of US is that it shows fluid in the abdomen but not its source or the magnitude of injury. Therefore, a positive US in a stable patient is generally followed by a CT scan. An advantage of US is that the heart can be assessed for pericardial effusion. The bedside US has good diagnostic accuracy for long-bone fractures and hemothorax and is more accurate than supine chest radiograph for detection of a pneumothorax (23).

Though the main use for US is in blunt abdominal trauma, a positive FAST in a penetrating trauma patient has an extremely high positive predictive value for an operative lesion. A negative test cannot rule one out (27).

CT offers both quantitative and qualitative information. It is the gold standard for evaluation of the abdomen in the hemodynamically stable blunt trauma patient. It may also be used to evaluate penetrating trauma, although with greater limitations. With the advent of the multidetector CT, the test is performed rapidly with excellent accuracy. These scanners also allow for reformations of areas of concern for pathology, including the spine and aorta. The major limitation of abdominal CT is the decreased sensitivity for bowel, mesenteric, diaphragmatic, and pancreatic injury, although there is usually some direct or indirect sign of injury such as unexplained free fluid (28,29). A normal CT in trauma has an extremely high negative predictive value for operative intra-abdominal pathology and should provide clinicians with a very high probability that they are not missing an operative lesion (30). Of course, technology and those who interpret its data are not infallible. If the clinical examination still suggests the possibility of injuries not revealed on CT, the patient should undergo further testing or observation.

Additional evaluation depends on specific concerns. Gross hematuria should prompt evaluation of the genitourinary (GU) tract. Microscopic hematuria is poorly sensitive and specific for significant GU injury and, in the absence of a pelvic fracture, gunshot wound of the abdomen, or unexplained hypotension after blunt trauma, does

not mandate workup. Penetrating trauma with any hematuria should be followed by a formal evaluation of the GU tract. Gross penile bleeding should be evaluated by retrograde urethrography before passage of a Foley catheter.

Many modern EDs have a scanner either in or immediately adjacent to the ED. The speed of the newest scanners along with their proximity to the ED has allowed for safer use in patients who previously would not have been scanned owing to borderline blood pressure or concern over absolute stability. This must be done with extreme caution, however, as resuscitation is best not performed in CT. One approach that some trauma centers are now using is to perform a CT from head to pelvis, that is, the pan-scan. This may be cost effective as the extra time is measured in minutes, there is no increased use of film if the images are stored on a picture archival retrieval system, and scans of the bones can be included, obviating the need for plain films. Reformations allow for the ability to image the aorta and have essentially replaced aortography in the diagnosis of aortic injury. Radiation exposure, though not acutely dangerous, is essential to consider when making decisions about performing CT scans, especially in young patients. Although the lifetime risk of developing cancer from CT scanning remains low it is still a real concern. Therefore, a CT should not be performed as a replacement for physical examination when the patient is fully evaluable (31–33).

Interventional angiography is increasingly important in the management of trauma patients. Angiography is the definitive modality in controlling hemorrhage from major pelvic fractures. In patients with ongoing hemorrhage from major pelvic trauma, angiography with embolization has been shown to be more effective and definitive than external fixation devices or operative packing. For stable patients with intraperitoneal injuries, if an actively bleeding spleen, liver, or kidney is visualized, a dedicated angiography team may be able to embolize the lesion and avoid laparotomy. Though effective, angiography still remains resource-intensive and is not readily available at all centers (34,35).

Angiography may also be used to diagnose arterial injuries in the neck or extremities. Doppler US may reveal flow impairment in the carotid or vertebral vessels after a whiplash trauma to the neck. Arteriography is then used to define the injury. Currently, many centers have switched to CT angiography as the definitive test for vascular injury and are using catheter-based angiography only for treatment or in equivocal cases. Other centers utilize magnetic resonance angiography in the stable patient. Another place for angiography is in the patient with a penetrating wound near a large vascular structure with massive tissue damage or evidence of distal pulse deficits. If the patient is unstable, however, it is more prudent to take the patient to the OR, obtain vascular control, and perform the angiography intraoperatively. In some cases, for example, possible aortic rupture, transesophageal echocardiography is an excellent option to perform in the OR in the patient unable to tolerate CT angiography.

Though the management priorities in patients with head, chest, and abdominal injuries still present a challenge, the critical ordering should be to diagnose and treat injuries to the abdomen, head, and then chest (aorta), in that order. However, the specific patient and clinical judgment may alter this approach. In addition, the rapid speed of the multidetector CT allows for the full body scan with little additional time once the patient is on the CT gurney. The initial priority is to assess for intraperitoneal bleeding. An US study or DPL that shows blood in the abdomen does not reveal the specific organ injured or the amount of damage, and the patient may also have evidence of intracranial injury. A head CT requires transfer to the radiology suite, but the rapidity of the procedure may enable a quick assessment of the head en route to the OR for laparotomy. It also adds little time to the assessment to take cuts of the chest and abdomen. If intraperitoneal bleeding is present in the unstable patient, then management of pelvic fractures or aortic injury must be delayed until after laparotomy.

Finally, it is imperative to recognize that the trauma patient needs prompt definitive care. Time wasted in the field, the ED, or the radiology suite may increase mortality. Sometimes, the trauma

surgeon must proceed to the OR with a paucity of diagnostic information rather than have the patient continue to hemorrhage.

KEY TESTING

Laboratory *Depends on presentation and underlying concern.* *If major trauma*	Minor trauma—low suspicion Generally urinalysis and HCG for all females of childbearing age	Moderate trauma—moderate suspicion Generally urinalysis and HCG for all females of childbearing age Consider CBC, chemistries, type and screen	Severe trauma—high suspicion Urinalysis and HCG for all females of childbearing age CBC, chemistries, type and screen/cross
Radiology *Depends on presentation and underlying concern.* *If major trauma*	Minor trauma—low suspicion Consider chest radiograph FAST	Moderate trauma—moderate suspicion Chest radiograph Pelvic radiograph (unless CT planned and stable) FAST Consider CT (head/chest/abdomen pelvis depending on suspicion)	Severe trauma—high suspicion Chest radiograph Pelvic radiograph (unless CT planned and stable) FAST CT (head/chest/abdomen pelvis)

DISPOSITION

The stable trauma patient may spend a number of hours between the ED and the radiology department during the completion of diagnostic tests. During this time, the patient must be monitored to ensure that deterioration does not occur or that a quick transfer to the OR has not become necessary. This may be visual or with cardiac monitoring, depending on the clinical situation.

The patient remains the responsibility of the ED until admitted. Once admitted, overall ED care of the patient may depend on institutional policies and resources. However, the EP should assist in care of any patient who remains in the ED. Even if the trauma team monitors the patient in the radiology department, when the patient returns to the ED, it again becomes the EP's responsibility to remain involved in the care of the patient, unless pre-existing protocols are in place and the trauma service has the proper manpower to observe the patient. After careful evaluation and a period of observation, many patients can be discharged from the ED.

Transfer of the patient to another institution depends on multiple factors. If the patient is unstable, the only rationale for transfer is to achieve a level of care higher than what is available at the original treating facility. It may be necessary to care for life-threatening injury (e.g., removal or salvage of a ruptured spleen) and then transfer the patient for more sophisticated neurosurgical, orthopedic, or thoracic management.

TRAUMA SCORING SYSTEMS

Trauma scores are an imperfect but commonly used tool in trauma systems. Prehospital providers, EPs, and inpatient trauma services use these scores for planning purposes and as a quality assurance screen to monitor system performance. Regional trauma planners use these scoring systems to compare institutions and assess resource needs and as a tool for performing research on the effects of different interventions.

Economic and geographic constraints have dictated that many trauma patients cannot be cared for in a trauma center. Unfortunately, it is extremely difficult to devise a system based on inpatient data that is accurate in the prehospital setting for triaging patients. Prehospital triage protocols are complicated by factors such as drugs, alcohol, and competing injuries, and many serious injuries are often hidden until there is a catastrophic decompensation. For example, most of the trauma scores utilize the GCS as part of their scoring estimation. Although the GCS is often

applied in the field, it was not intended to be used until after all alcohol has been metabolized. As at least half of all major traumas involve patients who are intoxicated, the GCS is not likely to solely represent brain injury. It is also difficult to calculate the GCS in the intubated and paralyzed patient. Even mechanism of injury, which provides useful clues to the seriousness of the forces involved, is inaccurate because the recipients of those forces sustain such variable degrees of injury. Data suggest that physiologic criteria and altered mental status are the best predictors of the need for major interventions; however, these criteria are bound to miss serious occult injuries that may not present until later in the ED or hospital course. Even at the trauma center, the initial recognition of injury severity is often difficult, and the variations of response to what appears to be minor trauma can lead to increased morbidity or mortality.

The optimal scoring system should be easy to apply to patients and have validity and good interrater reliability. It must have easily measured and understandable criteria and should not be so complex that it is difficult to calculate or understand the outcome measurements. Most scoring systems are based on anatomic scoring systems, physiologic scoring systems or a combination of both (36).

In the prehospital system, scores may be used to monitor quality assurance and to assist in deciding whether a patient requires a major trauma center. They may also aid trauma centers in formulating their needs and levels of response prior to patient arrival. In the ED, scores may be chosen to assess the need for a trauma team response, the need for prophylactic intubation, the likelihood of occult injury, or the need for ICU admission.

Physiologic Scores

Physiologic scores are employed in prehospital decision making, to evaluate the appropriateness and efficacy of injury treatment and to prognosticate outcome.

Revised Trauma Score

The original trauma score evaluated respiratory rate, respiratory expansion, systolic blood pressure, capillary refill, and GCS. Owing to variability in assessing several of the components, a revised score was developed in 1989, using data from the Washington Hospital Trauma Center and the Major Trauma Outcome Study. The Revised Trauma Score (RTS) was broken into three components: GCS, systolic blood pressure, and respiratory rate. Numbers were assigned to each parameter, with a higher number representing improved function. As this score is based entirely on physiologic variables, there is a risk of inappropriate decision making when patients are scored early after injury. Though the RTS is a commonly used score, several factors contribute to decreasing its specificity. This score is partially driven by the GCS score. As mentioned earlier, the GCS is skewed by alcohol and drugs, but it is also skewed by how quickly the patient is evaluated after the head trauma. For example, many patients who are ultimately deemed minor head injuries would actually have a low GCS if examined immediately after being struck on the head.

Anatomic Scores

Injury Severity Score

The Injury Severity Score (ISS) was developed as an extension of the Abbreviated Injury Scale (AIS) (4), one of the original scoring systems. The AIS grade was developed by dividing the body into six regions (the thorax, abdomen, and visceral pelvis; head and neck; face; bony pelvis and extremities; and external structures) and utilizing the site with the worst injury from each region when calculating the overall score. The original ISS was devised by summing the squares of the highest AIS grade in each of the three most severely injured areas. This modified scale was shown to correlate with fatality from trauma. Death from trauma begins to rise significantly when the ISS is above 15. Unfortunately, both the AIS and the ISS can be calculated accurately only after the full extent of the patient's injuries is known. The ISS is now commonly

used as a quality assurance tool, but it has no role in decision making either in the ED or in the prehospital setting.

Other Scoring Systems

Trauma and Injury Severity Score

Though the ISS accounts for patients' injuries, prediction of mortality should take into account factors that affect likelihood of survival. The trauma and injury severity score (TRISS) methodology incorporates the patient's age and ISS into a score that predicts the chance of survival. Patients with outcomes different from those predicted by the formula may be candidates for quality assurance review. TRISSs are heavily weighted toward head injury. The W statistics, derived by comparison of a hospital's results to those from the Major Outcome Trauma Study, portray the number of excess survivors per 100 patients (8).

A Severity Characterization of Trauma System

A severity characterization of trauma system (ASCOT) was developed based on analysis of the shortcomings of TRISS seen in the Major Trauma Outcome Study. In addition to the RTS variables, ASCOT adds scoring assignments for injury to three body regions (brain–spinal cord, thorax–neck, and abdomen-major vessel). In comparison, ASCOT seems to perform better than TRISS for adults with blunt trauma. Both TRISS and ASCOT appear adequate for pediatric patients.

Clinical Judgment

After reviewing the available scores and methodologies for triaging trauma patients, the practicing physician may wish to consider the role of clinical judgment. In a large study evaluating the ability of urban EMTs to assess trauma, none of the scores were found to perform better than EMT judgment. The physician considering the use of these scores will need to consider the setting in which the scores will be used. Most urban EMTs have the ability to recognize major trauma patients (37). Depending on the purpose for which

they are being used, EDs have a number of scoring systems available for their use. The RTS may be used to monitor changes in a patient's condition during the course of the patient's initial resuscitation. Clearly, the use of mechanism of injury to activate the trauma team will lead to an overuse of that resource, but a degree of overtriage is accepted in the effort to include all potentially injured trauma patients. EMS systems commonly use the Prehospital Index or the RTS.

Common Pitfalls

- Failure to appreciate the severity of the mechanism of injury.
- Ascribing positive physical findings to a benign cause.
- Failure to anticipate patient needs prior to arrival.
- Failure to have a visible trauma captain throughout the resuscitation.
- Failure to use a well-thought-out, systematic approach to the patient.
- Chaotic and inefficient resuscitation because of poor use of team members or because too many physicians are trying to give orders.
- Focusing on subspecialty needs at the expense of real or potential life threats.
- Overemphasizing diagnostic tests in an unstable patient.

ACKNOWLEDGMENT

Authors Gratefully acknowledges the contribution of Peter Rosen to the content of this chapter.

CHAPTER 19

Trauma Airway Management

Timothy J. Fortuna and John H. Burton

Expertise in airway management is an essential skill for the emergency physician (EP), and this is especially true of airway management in patients with multisystem trauma. Many trauma patients benefit from early control of the airway to ensure adequate oxygenation and ventilation and to protect against aspiration.

There are many special considerations to take into account when faced with controlling and maintaining an adequate airway in the trauma patient; some are listed in Table 19.1. The EP should assume the presence of cervical spine injury in most victims of blunt trauma. Owing to the common occurrence of altered mental status and hemodynamic instability, as well as the difficulty of rapidly obtaining adequate cervical spine imaging, cervical spine injury cannot typically be excluded in many trauma patients who require emergent intubation.

TABLE 19.1
Factors Complicating Trauma Airway Management

1. Inability to optimally position the airway for intubation owing to the possibility of spine injury
2. Presence of hypovolemic shock or occult hypovolemia
3. Presence of full stomach and risk of aspiration
4. Possibility of concomitant head injury
5. Known or unknown pre-existing disease states
6. Obstruction of the airway and normal anatomy owing to blood, emesis, or injury

There are many methods for predicting the difficulty of intubation in a patient (see Chapter 1). Though these are helpful as a structured approach to airway management, their application in the trauma patient is frequently limited. Coexisting facial and penetrating neck trauma may exacerbate the challenge of both the assessment and visualization of the airway. The inability to optimally position the airway in the trauma patient can be problematic for adequate laryngeal visualization during intubation.

All trauma patients should be assumed to have hypovolemia or compensated shock. Therefore, caution must be used when choosing medications to facilitate airway management to avoid hemodynamic compromise. Trauma patients should also be presumed to have a full stomach. This places the trauma patient at an elevated risk for aspiration during the initial assessment and airway interventions. Patients immobilized by cervical collar and long spine board are not always able to fully protect their airways.

Concomitant head injury alters the approach to airway management in the trauma patient. Adequate cerebral perfusion pressure should be maintained in these patients and the consequence of potentially increased intracranial pressure (ICP) should be considered for all interventions. Drugs or alcohol, which may cause altered mental status and combative behavior, complicate the determination of the presence of closed head injury and the need for emergent airway management.

INDICATIONS FOR AIRWAY MANAGEMENT IN THE TRAUMA PATIENT

The most common reasons for deciding to perform endotracheal intubation (ETI) in the acutely injured patient are for oxygenation, ventilation, and airway protection. Severe chest and pulmonary injuries, hemorrhage, traumatic brain injury, and airway obstruction may lead to the inability of trauma patients to adequately oxygenate or ventilate. Protective airway reflexes may be impaired due to depressed mental status from traumatic brain injury, severe alcohol intoxication, and upper airway trauma. Trauma patients are often combative and resistant to calming techniques as well as physical and chemical restraints. These patients may benefit from intubation in these circumstances to expedite their evaluation. The increasing frequency of elderly trauma patients, who commonly have comorbidities, may provoke the clinician to consider early airway interventions to facilitate both the assessment and treatment of their traumatic injuries.

TECHNIQUES OF AIRWAY MANAGEMENT

Orotracheal intubation (OTI), video-assisted intubation (VAI), blind nasotracheal intubation (NTI), and surgical cricothyrotomy are choices for definitive airway management in the trauma patient. Proper preparation is essential in the anticipation and execution of all airway interventions. The use of the mnemonic SOAPME may be helpful to ensure readiness (eTable 19.1).

eTABLE 19.1
Preparation for Airway Management: Mnemonic

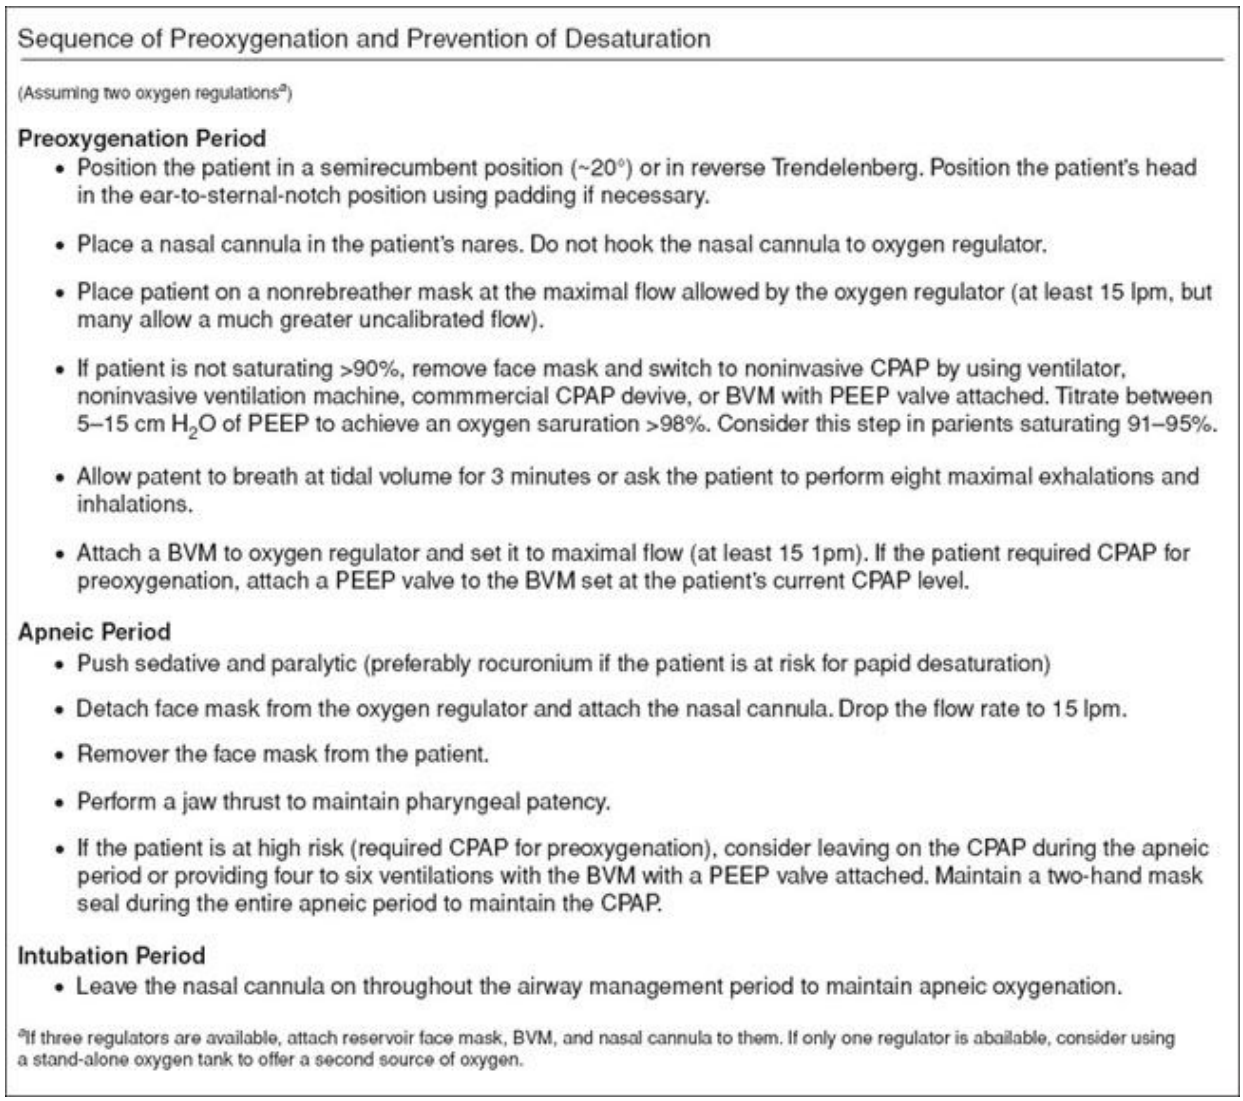
S	*S*uction should be readily available with Yankauer or tonsil tip apparatus.
O	High-flow *O*xygen with appropriate methods of delivery such as bag-valve-mask device and nonrebreathing masks should be available.
A	*A*irway supplies should be present in various sizes. These include naso- and oropharyngeal airways, endotracheal tubes with stylets, 10-mL syringes, and functioning straight- and curved-blade laryngoscopes. Airway adjuncts should be available for difficult airways including gum elastic bougie, fiberoptic intubating scope, and/or laryngeal mask airways.
P	*P*harmacology in the form of induction, sedative, analgesic, and neuromuscular blocking agents, as well as local anesthetics, should be available for immediate administration.
ME	*M*onitoring *E*quipment such as ECG, pulse oximetry, end-tidal CO_2 monitoring, and stethoscopes should be applied and in working condition.

ECG, electrocardiography.

Orotracheal Intubation and Rapid Sequence Induction

OTI may be performed in several ways, ranging from having the patient totally awake to performing OTI in conjunction with rapid sequence induction (RSI). OTI with RSI is the preferred approach to the airway management of the majority of patients with traumatic injuries. Although different pharmacologic agents may be chosen for neuromuscular blockade and induction, the major components of this intervention include preoxygenation, administration of agents that cause loss of consciousness (induction), administration of paralytics (neuromuscular blockade), and administration of postintubation analgesia and sedation.

Preoxygenation is performed to maintain hemoglobin saturation during airway management. Desaturations below 70% put patients at risk for dysrhythmia, hemodynamic decompensation, hypoxic brain injury, and death. Preoxygenation is achieved either actively or passively. A logistic flow of preoxygenation to prevent desaturation is shown in eFigure 19.1 (7).



Sequence of Preoxygenation and Prevention of Desaturation

(Assuming two oxygen regulations[a])

Preoxygenation Period

- Position the patient in a semirecumbent position (~20°) or in reverse Trendelenberg. Position the patient's head in the ear-to-sternal-notch position using padding if necessary.
- Place a nasal cannula in the patient's nares. Do not hook the nasal cannula to oxygen regulator.
- Place patient on a nonrebreather mask at the maximal flow allowed by the oxygen regulator (at least 15 lpm, but many allow a much greater uncalibrated flow).
- If patient is not saturating >90%, remove face mask and switch to noninvasive CPAP by using ventilator, noninvasive ventilation machine, commmercial CPAP devive, or BVM with PEEP valve attached. Titrate between 5–15 cm H_2O of PEEP to achieve an oxygen saruration >98%. Consider this step in parients saturating 91–95%.
- Allow patent to breath at tidal volume for 3 minutes or ask the patient to perform eight maximal exhalations and inhalations.
- Attach a BVM to oxygen regulator and set it to maximal flow (at least 15 1pm). If the patient required CPAP for preoxygenation, attach a PEEP valve to the BVM set at the patient's current CPAP level.

Apneic Period

- Push sedative and paralytic (preferably rocuronium if the patient is at risk for papid desaturation)
- Detach face mask from the oxygen regulator and attach the nasal cannula. Drop the flow rate to 15 lpm.
- Remover the face mask from the patient.
- Perform a jaw thrust to maintain pharyngeal patency.
- If the patient is at high risk (required CPAP for preoxygenation), consider leaving on the CPAP during the apneic period or providing four to six ventilations with the BVM with a PEEP valve attached. Maintain a two-hand mask seal during the entire apneic period to maintain the CPAP.

Intubation Period

- Leave the nasal cannula on throughout the airway management period to maintain apneic oxygenation.

[a]If three regulators are available, attach reservoir face mask, BVM, and nasal cannula to them. If only one regulator is abailable, consider using a stand-alone oxygen tank to offer a second source of oxygen.

eFIGURE 19.1 Logistic flow of preoxygenation and prevention of desaturation. (From Weingart SD, Levitan MD. Preoxygenation and prevention of desaturation during emergency airway management. Ann Emerg Med. 2012;59:165–175, with permission.)

A standard reservoir facemask with the oxygen flow rate set as high as possible is the recommended source of high FiO_2 in the emergency department (ED). A passive approach will allow for spontaneous respirations through this nonrebreather facemask.

Active preoxygenation techniques should be considered for patients who cannot achieve greater than 95% oxygen saturation even with high FiO_2 delivered passively. The risk categorization of

patients during preoxygenation and the means by which oxygen should be applied is shown in eTable 19.2 (7). Active techniques for oxygenation include the use of continuous positive airway pressure (CPAP) masks, noninvasive positive-pressure ventilation, or positive end-expiratory pressure (PEEP) valves on a bag-valve mask (BVM). Optimal application of a BVM for the purposes of oxygenation and ventilation in the trauma patient typically requires two medical providers: one to ensure a proper mask-to-patient seal and one to manage bag compression.

TABLE 19.2
Selected Pharmacologic Agents for Use During Trauma Airway Management

Opiates	Dose	Comments
Fentanyl	2–4 μg/kg	Onset, 1–2 min; duration, 1–2 hrs Increasing dose increases incidence of respiratory depression Chest wall rigidity rare complication associated with high doses
Sedatives	**Dose**	**Comments**
Midazolam	0.1 mg/kg	Onset, 1–2 min; duration, 1–2 hrs Respiratory depression, especially in combination with opiates or high doses May cause hypotension in patients with hypovolemia or cardiovascular instability
Thiopental	3–5 mg/kg	Onset, 1–2 min; duration, 5–10 min Respiratory depression is significant with induction dose Associated with profound hypotension, specifically with hypovolemia or patients with cardiovascular instability
Propofol	1–2 mg/kg	Onset, 1 min; duration, 4–8 min Respiratory depression is significant with induction dose Associated with profound hypotension, specifically with hypovolemia or patients with cardiovascular instability
Etomidate	0.3 mg/kg	Onset, 1 min; duration, 4–6 min Excellent choice for trauma patient induction owing to minimal effects on cardiovascular stability and head-injured patient Adrenal suppression of no known significance in trauma patient
Ketamine	1–2 mg/kg	Onset, 1–2 min; duration, 20–30 min Offers sedation, analgesia, and amnesia through interactions with cortical, limbic, and spinal opiate sites Minimal suppression of respiratory drive Use in head-injured patient is controversial Elevates mean arterial pressure and venous return via norepinephrine release

eTABLE 19.2
Risk Categorization of Patients During Preoxygenation

Risk category, based on pulse oximetry while receiving high-flow oxygen	Preoxygenation period (3 min)	Onset of muscle relaxation (≈60 sec)	Apneic period during tracheal intubation (variable duration, depending on airway difficulty; ideally <30 sec)
Low risk, SpO_2 96–100%	Nonrebreather mask with maximal oxygen flow rate	Nonrebreather mask and nasal oxygen at 15 L/min	Nasal oxygen at 15 L/min
High risk, SpO_2 91–95%	Nonrebreather mask or CPAP or bag-valve-mask device with PEEP	Nonrebreather mask, CPAP, or bag-valve-mask device with PEEP and nasal oxygen at 15 L/min	Nasal oxygen at 15 L/min
Hypoxemic, SpO_2 90% or less	CPAP or bag-valve-mask device with PEEP	CPAP or bag-valve-mask device with PEEP and nasal oxygen at 15 L/min	Nasal oxygen at 15 L/min

Risk categories are based on patient's initial response to high-flow oxygen through a tightly fitting nonrebreather mask. Patients who are already hypoxemic exhibit shunt physiology and are prone to rapid desaturation during the peri-intubation. Patients with saturations of 91% to 95% have values close to the precipice of the steep portion of the oxyhemoglobin dissociation curve and should be considered high risk. Patients with saturations greater than or equal to 96% are at low risk for peri-intubation desaturation. Patients in all risk categories should receive preoxygenation in a head-elevated position (or reverse Trendelenburg if there is a risk of spine injury).

From Weingart SD, Levitan MD. Preoxygenation and prevention of desaturation during emergency airway management. *Ann Emerg Med.* 2012;59:165–175, with permission.

Apneic oxygenation is also a key component of adequate preoxygenation. When high flow oxygen (15 L/min) is delivered through a nasal cannula after induction and during the apneic period patients can maintain oxygen saturations of more than 98% for 18 to 55 minutes (5).

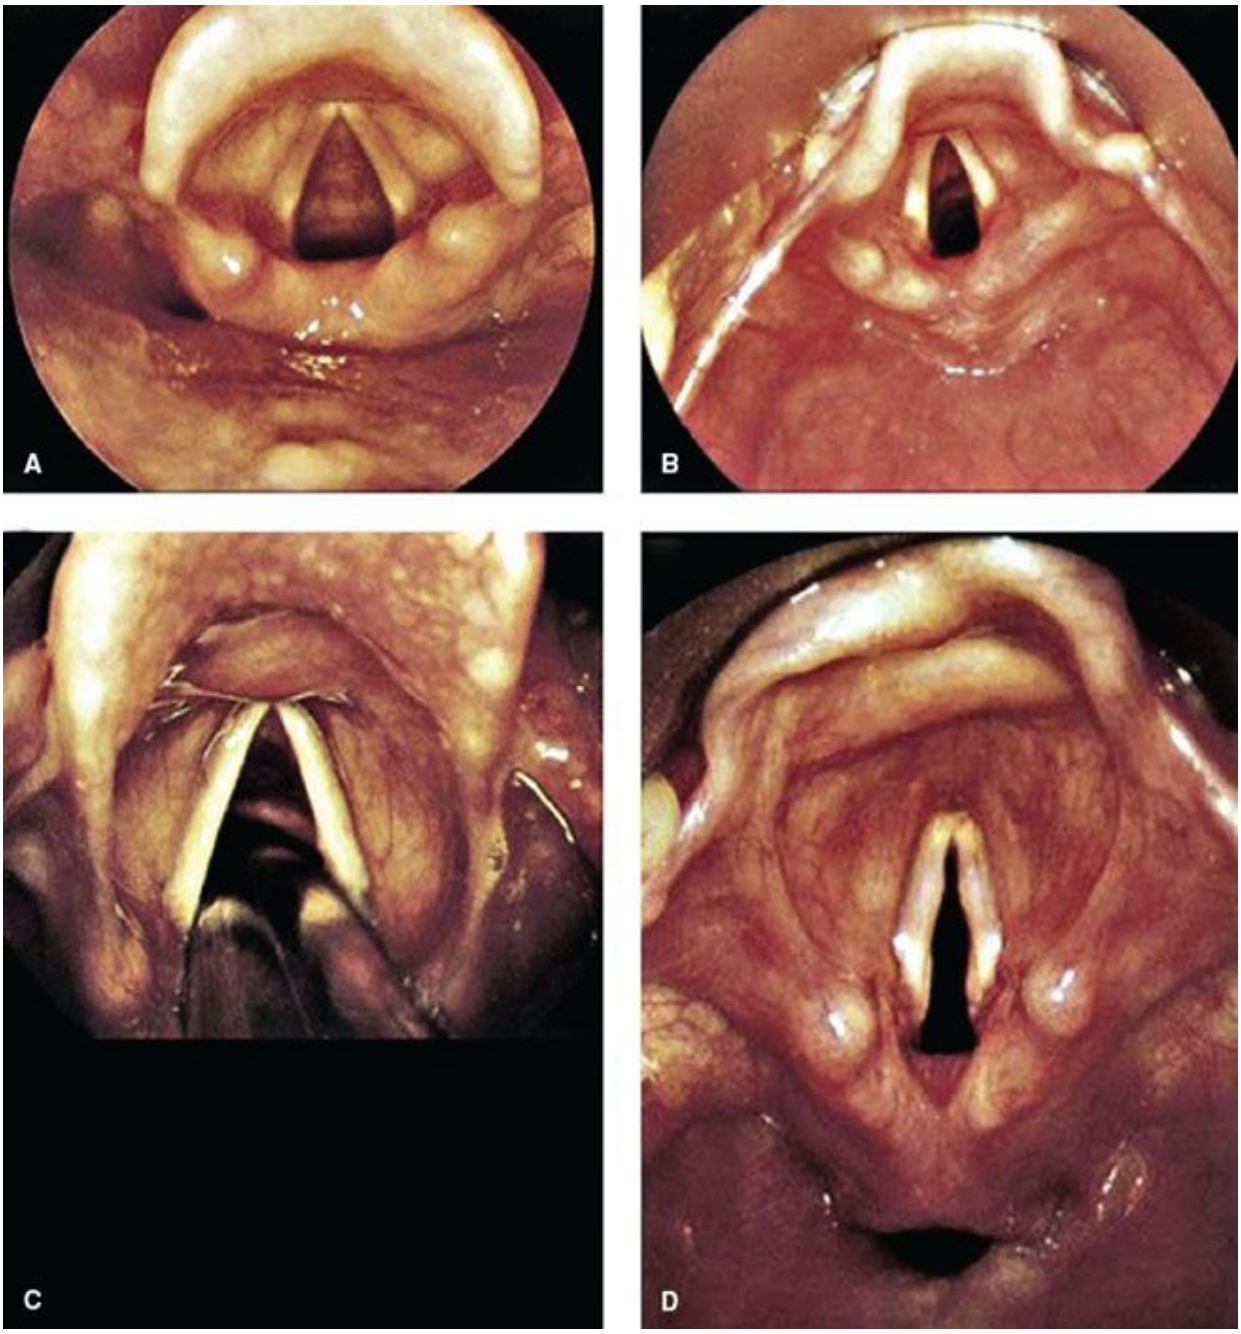
Difficulty in providing maximal preoxygenation may occur in patients with chest trauma or those with bronchospasm from pre-existing reactive airway disease or from smoke inhalation. In cases where pneumothorax is strongly suspected, consideration should be given to delaying intubation and mechanical ventilation until after performance of tube or needle thoracostomy. Artificial ventilation can result in rapid progression of a simple pneumothorax to a tension pneumothorax, even with a brief period of mechanical ventilation.

Neuromuscular blockade is performed during RSI for a number of reasons. Muscular paralysis reduces the aspiration risk by eliminating the gag and cough response to laryngoscopy. Paralysis also effectively relaxes the upper airway musculature to allow for an optimal view of the larynx. It prevents patient movements that might complicate efforts to visualize the airway during intubation. Caution should be exercised in the use of paralytic agents if difficulty ventilating the patient via BVM is anticipated.

Rescue airway adjuncts, as well as cricothyrotomy equipment, must be immediately available at all times during RSI of trauma patients. In cases where a difficult airway is anticipated, a modified approach may be used to provide adequate sedation or anesthesia to allow for airway intervention without the use of neuromuscular blocking agents.

Video-Assisted Intubation

Video-assisted devices are becoming more commonplace in EDs, particularly in the training environment. There have been many studies to date that have shown users obtain better laryngeal visualization and have a higher first-pass success rate in the difficult airway patient (6). There are many commercially available video laryngoscopes and all require some added training. Even in the hands of novice video laryngoscopy improves visualization and visual confirmation of proper tube placement (eFig. 19.2). Intubation can be performed by passing a tube over a flexible fiberoptic scope while visualizing the vocal cords or using a rigid video laryngoscope, such as the Glidescope or Storz video system. The same principles of RSI apply when using a video device.



eFIGURE 19.2 Larynx appearance with videolaryngoscope. A: Preintubation view of an adult airway. B: Preintubation view of a pediatric airway. C: ETT passing between the vocal cords. D: The larynx and hypopharynx (note the horizontally oriented space below the laryngeal inlet, which is the esophagus). (From Nagdev A. Airway, breathing, circulation: Normal airway. In: Greenberg MI, Hendrickson RG, Silverberg M, et al., eds. Greenberg's Text-atlas of

Emergency Medicine. Philadelphia, PA: Lippincott Williams & Wilkins; 2004, with permission.)

The utility of the video-assisted device is limited in certain trauma situations particularly when visualization is impaired by blood, vomit, secretions, or direct trauma to the airway. As with any intubation attempt proper preparation should include having backup plans for failed attempts, this includes the ability to perform direct laryngoscopy and the tools for a surgical airway.

Blind Nasotracheal Intubation

NTI has several drawbacks and few advantages when compared to other techniques that are readily available for emergency airway management. Nasotracheal intubation requires a clinician who is experienced in the technique, a cooperative patient who is spontaneously breathing, and proper preparation of the nasal mucosa. This technique has largely fallen out of favor because it is more time consuming, has a larger failure rate, a higher complication rate, and requires a smaller tube size than other techniques. Despite these drawbacks NTI is still an important skill because it may be useful in certain situations such as limited mouth opening or severe oral trauma. The safety of NTI in patients with significant midface trauma has been suggested in clinical experience and the literature (13).

If NTI is attempted, oxygen should be administered by high-flow delivery throughout the procedure to improve oxygenation. The larger nostril should be chosen for placement of the endotracheal tube. The nasal mucosa should be prepared using a topical anesthetic and vasoconstrictive agent such as 4% lidocaine and 1% phenylephrine. Mild or moderate sedation may improve patient cooperation and decrease patient movement. Endotracheal tubes specifically designed for NTI are helpful as well, including tubes in which the tip can be manipulated anteriorly by a proximal trigger, thus enhancing the success of tracheal placement.

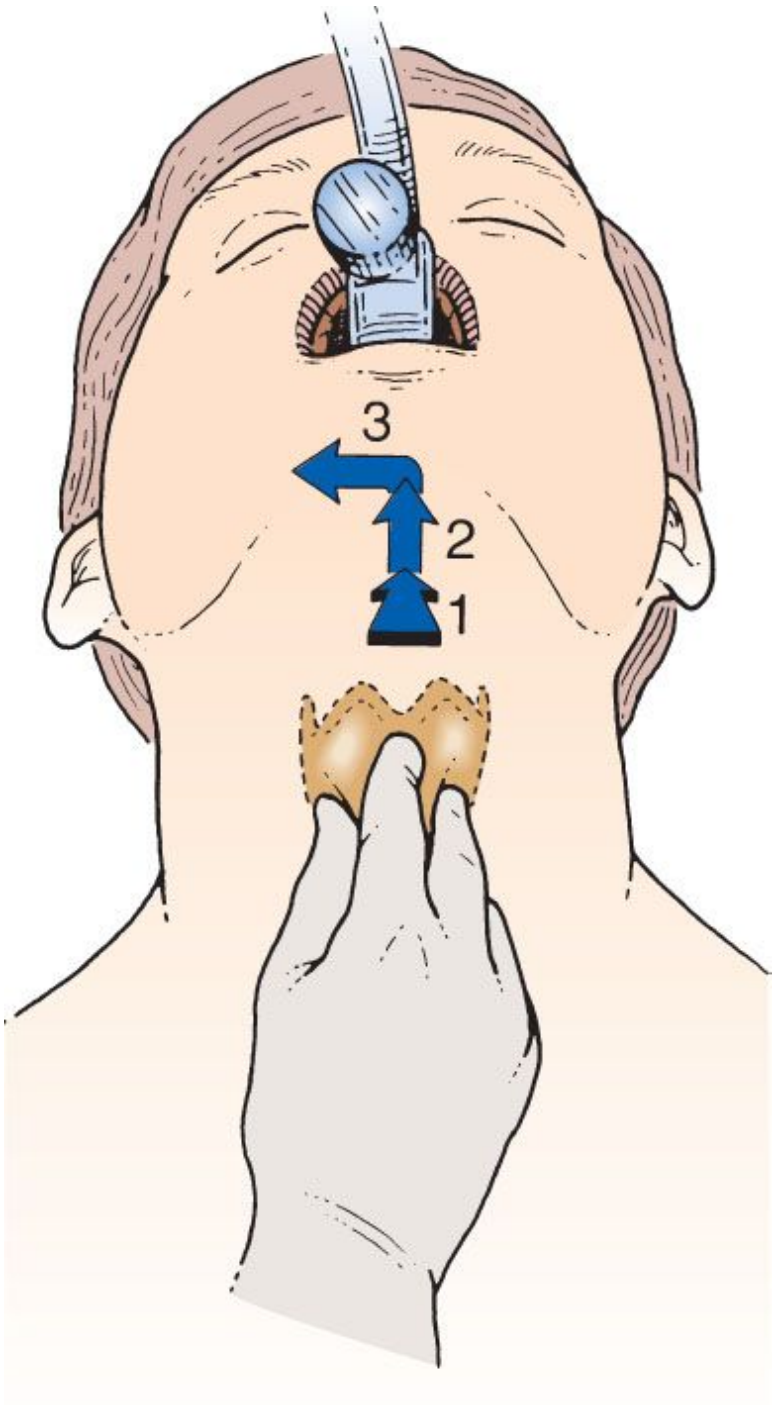
Surgical Airway Management

Cricothyrotomy equipment should be immediately available for any trauma patient undergoing emergent airway interventions, including RSI. The major indication for cricothyrotomy is failure of other methods of intubation with the simultaneous inability to ventilate and oxygenate the patient via BVM. Many cricothyrotomies involve patients with significant facial trauma or upper airway hemorrhage.

Patients with anterior neck trauma (penetrating and blunt) deserve particular consideration since they have a relative contraindication to cricothyrotomy. In addition, there will always be a small percentage of patients whose oral anatomy or body habitus renders intubation by any means very difficult and limits the feasibility of using airway adjuncts for more than a very limited amount of time. Perhaps the greatest mistake regarding the use of cricothyrotomy is its timing, as it is frequently used too late in the course of management when the patient is already severely hypoxemic.

Special Maneuvers and Intubation Adjuncts

Displacement of the thyroid cartilage *B*ackward against the cervical vertebrae, *U*pward or as superiorly as possible, and laterally to the *R*ight (the BURP maneuver) has been described and demonstrated to improve the view of the glottis during laryngoscopy (eFig. 19.3) (22). The mechanism by which BURP improves visibility may lie in the ability to move the glottis into the line of vision given that laryngoscopy tends to push the tongue and possibly the larynx toward the left. Application of the BURP maneuver may require a third provider in addition to the laryngoscopist and individual holding inline stabilization of the neck.



eFIGURE 19.3 Diagram of application of the BURP maneuver to improve the glottic view during laryngoscopy. The thyroid cartilage is moved Backward against the cervical vertebrae, Upward or as superiorly as possible, and laterally to the Right.

Several airway adjuncts can aid in the intubation process or are designed to temporarily substitute for intubation if it cannot be performed (3,14). These devices should be included as part of the difficulty airway algorithm for trauma airway management. The lighted stylet and gum elastic bougie, allow blind placement (placement without visualization of the vocal cords) of an endotracheal tube (12). Ventilation and oxygenation adjuncts for temporary airway support in the sedated or unconscious patient include the laryngeal mask airway (LMA), the combitube, and the King airway. LMAs are increasingly utilized as rescue airway devices for the failed intubation patient and often provide excellent airway management until intubation can be achieved. LMAs that allow for intubation through the lumen of the device have been developed and should be considered for their potential to achieve airway management as a blind intubation technique.

Pharmacologic Agents

Pharmacologic agents are chosen to accomplish several goals including topical anesthesia, sedation, analgesia, amnesia, and paralysis. Judicious use of these agents may facilitate intubation while avoiding such complications as increases in ICP and emesis. Selection of the proper agent in the trauma setting is essential to avoid complications such as prolonged paralysis with inability to ventilate, rises in ICP, or cardiovascular deterioration. There is very little published data from the acute care setting upon which to base and evidence-based practice for trauma airway management. As a result, preference for specific agents is based largely on theoretical principles as well as extrapolation of data from other settings. There is no pharmacologic agent that has been proven to offer a comprehensive advantage without limitations when compared to other selections.

Local Anesthetics

Lidocaine is an amide that can be used topically, locally, or intravenously to aid in airway management. Maximum doses are 3 to 4 mg/kg. When applied topically in a 4% solution, lidocaine may be

used with topical vasoconstrictors to aid in NTI. Nebulization of a 4% solution to a spontaneously breathing patient can produce complete topical anesthesia of the oro- and nasopharynx and the vocal cords in 5 to 7 minutes (4). When given intravenously, in a dose of 1.5 to 2 mg/kg 2 to 3 minutes prior to intubation, lidocaine may attenuate the hemodynamic and cough reflex–mediated rise in ICP (20). This application remains controversial with debatable advantages and few drawbacks other than complicating the RSI approach by addition of another agent.

Induction Agents

Sedatives, hypnotics, and potent opioid analgesics may be used as pharmacologic adjuncts to achieve states ranging from light sedation to complete loss of consciousness (Table 19.2). There is a balance between the risks and potential benefits for each of these agents in the trauma setting. The hemodynamic effects of each agent should be a primary consideration. Additional considerations include the following factors: (a) the agent's reliability of induction at a given dose, (b) the need to maintain spontaneous respiration, (c) the likelihood of a traumatic brain injury, and (d) the patient's pre-existing physiologic state including comorbidities.

Although adverse effects on respiration can be countered in most instances with artificial ventilation, there is no simple maneuver to counteract the cardiac dysfunction that may be produced by these agents in the trauma victim.

Barbiturates

Thiopental and methohexital are very short-acting sedative, hypnotic agents with no analgesic properties. Their onset of action is within 1 minute with duration of clinical effects between 5 and 10 minutes (21). The benefits of these agents are their induction reliability and rapidity of onset.

The major disadvantage of barbiturates is their effect on cardiovascular stability in the hemodynamically compromised patient, primarily due to significant reductions in venous return and contractility (21). While these effects are typically not a major

consideration in the nontrauma patient, their use in the hypovolemic or unstable trauma patient may result in sudden, profound hypotension as well as reduction in cerebral perfusion pressure. Given the principle that all acutely injured trauma patients should be assumed to have injuries rendering them unstable from a cardiovascular standpoint, the use of barbiturates in this population should be approached with caution. If barbiturates are to be utilized, meaningful reductions in induction dosages should be employed with thiopental doses ranging from 0.5 to 1 mg/kg are generally recommended (21).

Propofol

Propofol is a substituted isoprophylphenol that is highly lipophilic and capable of producing profound sedation, hypnosis, and amnesia, with no analgesic properties (21).

A unique characteristic of propofol is its rapid metabolic clearance and redistribution, which is approximately 10 times faster than thiopental. Clinical recovery is rapid, occurring within 4 to 8 minutes, with little residual sedation.

Caution must be exercised if propofol is used in the undifferentiated trauma patient, particularly owing to the hemodynamic effects on venous return that often result in clinically observed decreases in blood pressure. Propofol should be avoided in patients at high risk for hemodynamic compromise and instability due to hemorrhage or hypovolemia.

The primary use of propofol in the trauma setting is as a postintubation sedative with continuous infusion. The brief duration of clinical effects associated with propofol allows for rapid recovery of neurologic status and levels of consciousness. This advantage is often cited as a benefit in the trauma patient who may undergo recurrent neurologic assessments over an extended time period.

Etomidate

Etomidate is a carboxylated imidazole induction agent with no analgesic properties (21). In doses of 0.3 mg/kg, induction is reliably produced in <1 minute, and the duration of action is between 6 and

8 minutes. Etomidate has several properties that make it attractive for use in the multisystem trauma patient. When given in single induction boluses, etomidate causes minimal changes in heart rate and cardiac output compared with equipotent doses of thiopental (21). This is particularly advantageous in patients with hypotension or compensated shock, as well as in those with pre-existing myocardial dysfunction.

Etomidate also causes significantly less respiratory depression than barbiturate agents, although transient apnea may occur when it is given rapidly. Etomidate may in fact stimulate ventilation. For this reason it may be advantageous when maintenance of respiration is desirable, such as during sedation with NTI or modified RSI.

Although etomidate occasionally causes side effects, there are no contraindications to its use as a single injection in the trauma patient. Side effects include transient burning on injection, transient myoclonus after administration in up to 40% of patients, and transient suppression of endogenous cortisol production for up to 12 hours after single bolus administration. The temporary suppression of cortisol production has not been demonstrated to affect outcome in the trauma patient and should not limit the use of etomidate in this population (15,21).

Ketamine

Ketamine is a phencyclidine derivative that produces dissociative anesthesia. It is the only agent commonly used for induction in the ED that possesses sedative, hypnotic, analgesic, and amnestic properties (21). Ketamine provides the most cardiovascular and respiratory support of any agent. Although it is a direct myocardial depressant, heart rate and blood pressure are usually maintained or increased owing to centrally mediated sympathetic stimulation via increases in norepinephrine. Central sympathetic stimulation also results in transient bronchodilation.

The major advantage of ketamine, in comparison to other agents, lies in the setting of the hypovolemic patient (21). Its onset of action is within 1 minute when given intravenously (1 to 2 mg/kg), with a duration of action ranging from 5 to 15 minutes. Ketamine may also

be given intramuscularly (4 mg/kg), with the onset of action delayed by several minutes.

Because it is a phencyclidine derivative, ketamine can cause an emergence delirium. Though this is a concern during procedural sedation, it should not prohibit its use as an intubation adjunct in a critically ill trauma patient. Intubated trauma patients are typically kept sedated and paralyzed for many hours after their initial presentation, and emergence delirium at that time is rare (21). Continued sedation with benzodiazepines virtually eliminates this issue as a concern.

The primary concern with the use of ketamine in the trauma population is its potential to affect ICP owing to its ability to increase cerebral blood flow by 30% to 60% (21). Even though the cerebral metabolic rate is increased with ketamine, cerebral blood flow is probably sufficient to meet demand. There is evidence that this increase in cerebral blood flow does not increase ICP (11). In fact, there is evidence that ketamine is neuroprotective in the setting of head trauma because it is an *N*-methyl-D-aspartate receptor antagonist (19). The use of ketamine may be warranted in the setting of head injury when induction is required in a hypotensive patient. Any reduction in MAP has greater potential to worsen cerebral ischemia than to affect clinical outcome from a transient rise in ICP.

The routine use of ketamine in the trauma patient remains an area of controversy. Its use in the hypotensive patient appears to be a reasonable decision given the relative concerns for other agents in this setting.

Benzodiazepines

Benzodiazepines (diazepam and midazolam) have been used alone, and in combination with opioids, as induction agents. They provide good anxiolysis and amnesia, but no analgesia is provided. Large doses are usually needed to produce predictable states of induction equivalent to those of the agents discussed above (21). Midazolam is currently the most commonly used benzodiazepine for airway management. An induction dose of midazolam (0.1 mg/kg) takes effect within 1 to 2 minutes and has a duration of action between 30

and 60 minutes. Even at doses of 0.1 mg/kg, induction is not always predictable.

Benzodiazepines can be accompanied by side effects such as severe respiratory depression. Significant decreases in venous return, MAP, and cardiac contractility can also occur, especially in patients with hypovolemia or heart disease (1). All of these effects are more pronounced when opioids are given simultaneously.

Subinduction doses (0.03 to 0.05 mg/kg) of midazolam are not commonly associated with these complications and can serve as valuable adjuncts in providing continued sedation for patients after intubation.

Opiates

Synthetic opioid agonists including fentanyl, sufentanil, and alfentanil are 100, 500 to 1,000, and 20 times more potent than morphine, respectively (21). These agents are fast acting, having an onset of action of <1 minute, with a duration of action between 15 and 60 minutes.

Fentanyl results in little or no histamine release, and its cardiovascular effects in the normal host are minimal. At higher doses, however, small but potentially significant decreases in blood pressure may occur (21). Depending on the existing state of consciousness and the presence of drugs such as alcohol, the dose necessary to produce unconsciousness can range from 2 to 20 μg/kg or more. The effect of fentanyl on ventilation varies, but doses >2 μg/kg result in a high incidence of respiratory depression in "normal" subjects (2). This incidence is even higher when used together with other agents such as midazolam.

Fentanyl is often used as a preinduction adjunct for intubation of the head-injured patient owing to its ability to attenuate the hemodynamic response to intubation. However, when given in doses sufficient to achieve this effect, 2 to 3 μg/kg given 2 to 3 minutes before laryngoscopy, increases in ICP may occur that may negate any advantage to its use in the setting of traumatic brain injury. Decreases in MAP were also noted to occur after administration of fentanyl at these doses. Coupled with the potential for producing

premature hypoventilation and apnea, this makes the routine use of these agents as induction or preinduction agents in the setting of multisystem trauma controversial. An additional role for these opiates is to provide postintubation sedation and analgesia to attenuate the hyperdynamic responses from pain and intubation and for patient comfort.

In summary, despite the most careful use of pharmacologic agents, any induction agent may result in sudden and profound hypotension unresponsive to simple fluid boluses. In cases of head injury, hypotension, even if transient, can result in prolonged cerebral hypoperfusion (16).

Neuromuscular Blocking Agents

The use of neuromuscular blocking agents to facilitate intubation has become widespread in emergency airway management. These agents are classified as depolarizing and nondepolarizing agents.

Depolarizing Agents

Succinylcholine (1.5 to 2.0 mg/kg) is the agent of choice during emergent RSI. No neuromuscular blocking agent has a faster onset (<1 minute) or is of shorter duration (4 to 6 minutes). Succinylcholine can also be given intramuscularly (4 mg/kg), but its onset is delayed by 2 to 4 minutes.

The disadvantages of succinylcholine in the trauma patient population are relatively few and should not preclude its use in the acutely injured patient. Fasciculations, hyperkalemia, and transient rises in intragastric, intraocular, and ICP may occur (9). Succinylcholine-induced hyperkalemia in burns and crush injuries does not occur in the acute setting. If fasciculations and elevated intraocular, intragastric, and ICP are major concerns, administration of a defasciculating dose of a nondepolarizing agent (i.e., vecuronium 0.01 mg/kg) 2 to 3 minutes before succinylcholine administration has been demonstrated to prevent these occurrences (21). If a defasciculating dose of a nondepolarizing agent is used, the dose of succinylcholine should be increased to 1.5 to 2 mg/kg to maintain its rapidity of onset.

Nondepolarizing Agents

There are several nondepolarizing neuromuscular blocking agents in current use. Vecuronium and rocuronium are the major nondepolarizing agents used in trauma airway management. The advantages of these agents are that they are longer acting, cause no fasciculations, and cause no reported increase in intraocular, intragastric, or ICP. These agents also have little effect on the cardiovascular system (9,21).

The standard dose of vecuronium for paralysis is 0.15 mg/kg. This results in complete paralysis within 2 to 3 minutes, with a duration of action of 30 to 40 minutes. The onset of action of rocuronium (0.9 mg/kg) approaches that of succinylcholine, although its duration of action is similar to that of vecuronium (25 to 40 minutes) (21).

A major disadvantage of vecuronium and rocuronium in the trauma patient is the relatively slower onset of clinical effects, taking up to 2 to 3 minutes for a full clinical effect. Large doses of vecuronium (0.25 mg/kg) and rocuronium (1.2 mg/kg) may be used as an initial bolus to achieve more rapid paralysis within 60 to 90 seconds. However, this strategy lends an extended period of duration of paralysis, lasting as long as 90 minutes. The duration of action of nondepolarizing agents is longer relative to succinylcholine, creating significant problems if intubation attempts are unsuccessful.

Nondepolarizing agents can be reversed to some extent by drugs that block cholinesterases, such as neostigmine, edrophonium, and pyridostigmine. The routine use of these reversal agents in the acutely injured patient is not advised owing to the potential for cardiovascular complications.

SPECIAL CONSIDERATIONS

Cervical Spine Injury

OTI utilizing RSI is now the preferred procedure to achieve definitive airway control in patients with suspected cervical injury (17). As positioning the airway in this setting is limited, use of a straight laryngoscope blade may be preferable to a curved blade because it will lift the epiglottis directly. The use of VAI has also been shown to

be of particular benefit in these patients with an improved first-pass success rate (6).

Removal of the front of the cervical collar while maintaining in-line immobilization (not traction) significantly improves the view of the larynx during intubation and should be a routine component in airway management of the trauma patient (8). When manual immobilization is being performed, an applied cervical collar offers no significant advantage.

Regardless of approach, airway management in the setting of potential cervical spine injury is optimally performed with at least three people: one as the laryngoscopist, one to provide in-line immobilization of the cervical spine, and one to perform cricoid pressure. Rational use of airway adjuncts such as special laryngoscopes, the gum elastic bougie, and the LMA may be indicated based on the experience of the operator.

Penetrating Neck Trauma

In cases of penetrating neck trauma with possible altered upper airway anatomy or signs of airway obstruction, OTI with RSI is the procedure of choice when injuries do not impair OTI visualization (18). Administration of paralytics may be strategically deleted if proper sedation and upper airway anesthesia are provided.

Use of induction agents with less effect on ventilation (etomidate and ketamine), along with intravenous or nebulized lidocaine, will aid in reduction of gagging and further hemorrhage and anatomic distortion of the neck. Ketamine without paralysis is an alternative as it preserves respiratory drive. This may be essential for intubating patients who have anatomic distortion owing to an expanding hematoma. The presence of anterior neck trauma is a relative contraindication to cricothyrotomy.

Head Injury

The pathophysiology of traumatic brain injury is complex and involves a combination of mechanical and biochemical events initiated by the trauma itself, followed by secondary injury in the

form of ischemia. The most preventable forms of secondary brain injury are systemic hypoxemia and hypotension. Because most head injuries occur in association with multisystem trauma, a reasonable approach would be to administer agents that cause a predictable loss of consciousness, cause no increase in ICP, and maximize the chance to maintain MAP.

Traditional approaches to the head trauma victim requiring intubation assumed that the brain had lost some degree of its ability to autoregulate its blood flow. The MAP minus the ICP determines cerebral perfusion pressure and hence cerebral blood flow in this setting. Emphasis has been placed on blocking the rise in ICP during intubation with the use of agents such as barbiturates. However, maintaining the mean arterial pressure in these circumstances is critical given that cerebral blood flow is directly related to perfusion.

Although an attempt to block the rise in ICP during intubation of the head-injured patient is of theoretical benefit, this concern has not been demonstrated to affect outcome in controlled studies. Attempts to manage ICP during intubation must be carefully balanced with the pharmacologic agent's effect on blood pressure, as lowering mean arterial blood pressure may lower cerebral blood flow and cause secondary ischemic brain injury (16).

Facial Trauma

Patients with facial injuries represent an airway management challenge, especially when there is severe upper airway hemorrhage. The airway management technique of choice depends on several factors, including the patient's level of consciousness, level of oxygenation, amount of upper airway hemorrhage, and risk of other injuries such as cervical spine injury. The availability of one or more large-volume suctioning devices is critical if upper airway hemorrhaging is present. OTI with RSI remains the best approach in the majority of facial trauma cases.

Airway adjuncts should be readily available in all trauma patient encounters, particularly in those patients with facial injuries. If OTI is unsuccessful, placement of the esophageal tracheal combitube or LMA can reverse hypoxemia and temporarily protect the airway

while cricothyrotomy is performed. Fiberoptic laryngoscopy may be of limited use in these patients as blood and other secretions render visualization of the glottis a challenge.

SUGGESTED APPROACHES

In most emergent trauma airway management scenarios, OTI with RSI using in-line cervical stabilization is the preferred approach. This approach should be followed with continued sedation and analgesia. The immediate concerns in this population are the prevention of hypoxemia and hypotension.

- The physician should assume that every trauma patient is hypovolemic, even if there are no signs of shock during the initial evaluation.
- The clinician should assume that all victims of blunt trauma have suffered an intracranial injury, with loss of cerebral blood flow autoregulation.
- All patients should be treated as if a cervical spine injury is present.
- The patient should not experience further decreases in MAP secondary to administration of medications or airway maneuvers.
- The patient should not develop premature apnea or hypoventilation.
- The patient should not develop large increases in ICP.

Figure 19.1 outlines intubation algorithms that will meet the needs of the majority of severely injured trauma patients.

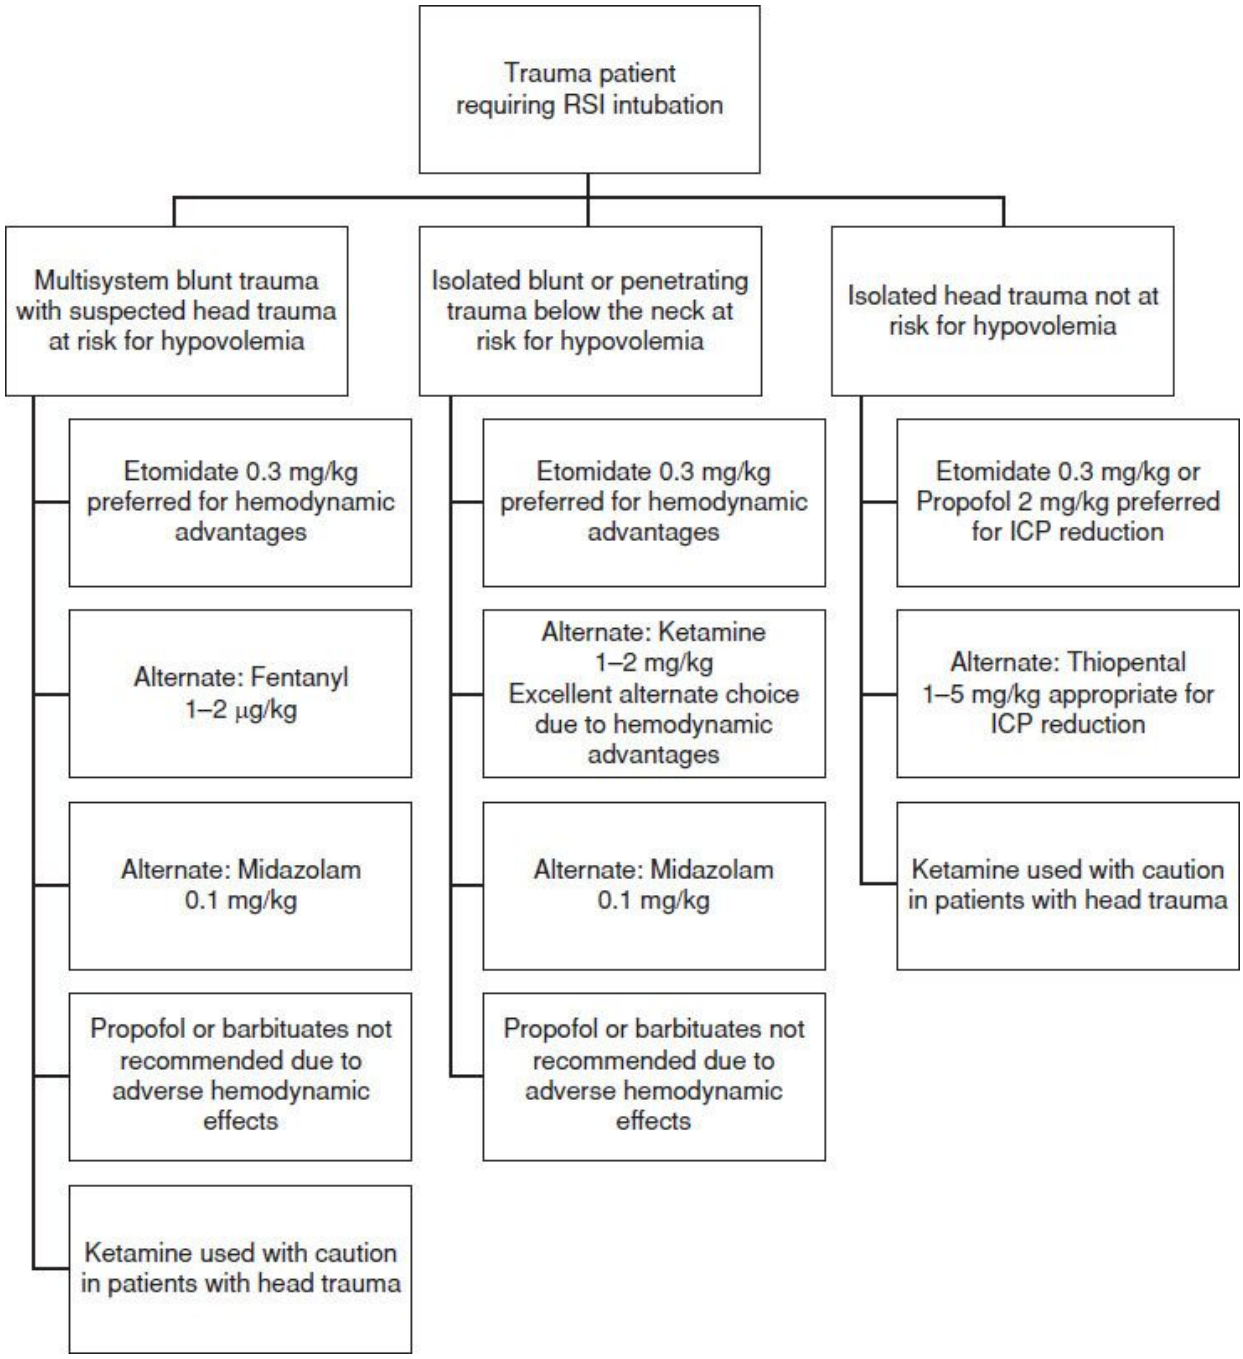


FIGURE 19.1 Algorithm for selection of induction agent in trauma airway management with preferred induction agent and alternate choices.

After intubation, small, frequent doses of midazolam (1 to 3 mg) and fentanyl (50 to 100 μg) are appropriate for sedation and are not

typically associated with major side effects. Longer-acting agents such as lorazepam and morphine may also be used.

Once significant hemorrhage or hemodynamic instability has been ruled out, more easily titrated agents such as propofol can be used in a continuous infusion for sedation. Continued paralysis while simultaneously providing analgesia and sedation, may be required to optimize resuscitation and diagnostic workup. Early removal of patients from spine immobilization boards, proper splinting of fractures, and application of local anesthetics to wounds significantly decrease the patient's discomfort.

Common Pitfalls

- Failure to consider occult hypovolemia, shock, and pre-existing disease states when choosing induction agents.
- Failure to maintain cervical spine stabilization during intubation in patients with suspected cervical spine injuries.
- Failure to have airway rescue adjuncts available for difficult airway situations.
- Failure to have a preplanned and prepared sequence of alternative airway approaches in case of failure of initial intubation attempts.
- Failure to provide adequate ongoing postintubation sedation and analgesia.

CHAPTER 20

Traumatic Shock

Christopher B. Colwell and Ernest E. Moore

Shock is the ultimate consequence of inadequate tissue perfusion, which may be manifested clinically by hemodynamic disturbances or organ dysfunction. At the cellular level, shock initially results from the insufficient delivery of required metabolic substrates, principally oxygen, to sustain aerobic metabolism. In the setting of trauma, shock is most often related to loss of circulating blood volume caused by hemorrhage, although inadequate oxygenation, cardiac dysfunction, neurologic dysfunction, or mechanical vascular obstruction may be either primary or contributing factors.

There are four general pathophysiologic types of shock: (a) hemorrhagic or hypovolemic, (b) cardiogenic, (c) neurogenic or vasogenic, and (d) septic. Hemorrhagic shock involves the loss of circulating intravascular volume caused by blood loss internally, externally, or both. Cardiogenic shock indicates a process that prevents the normal pumping of the heart and can be caused by pericardial tamponade that prevents normal ventricular filling, tension pneumothorax with vena caval compression and reduction in venous return to the heart, or direct cardiac damage with loss of contractile force (myocardial contusion).

Neurogenic or vasogenic shock may result from spinal cord injury with loss of peripheral vascular resistance. Major spinal cord injury results in acute vasodilatation but generally does not cause impaired tissue perfusion unless other injuries are present. Spinal cord injuries result in a loss of sympathetic tone and are, therefore, accompanied by bradycardia (spinal shock). Septic shock refers to a hyperdynamic response (elevated cardiac output and low systemic vascular

resistance), followed by decreased cardiac output and increased systemic vascular resistance, eventually resulting in organ function deterioration associated with the inflammatory mediators accompanying infection.

If the acute stress of the traumatic shock state is sufficiently severe or prolonged, organ dysfunction may also develop, including acute kidney injury (AKI), adult respiratory distress syndrome (ARDS), and multiple organ failure (MOF). These entities can develop within a few hours to several weeks after the acute injury.

Shock is a common and potentially treatable cause of death in injured patients. Traumatic shock usually results from one or more of the following mechanisms: (a) acute blood loss from solid organ injury, rib fractures, major vascular injury, pelvic fracture, or multiple long-bone fractures; (b) cardiac dysfunction from blunt cardiac injury, tension pneumothorax, or pericardial tamponade; (c) hypoxemia caused by airway compromise or pulmonary contusion; or (d) loss of vasomotor integrity (distributive) caused by neurologic injury and late overwhelming infection.

The pathophysiology of traumatic shock is largely related to an imbalance in oxygen supply and demand. In the early phase of acute trauma, this imbalance is often caused by hypoperfusion, although low arterial blood oxygen saturation may be a significant contributing factor. Aggressive resuscitation with fluids having low or no oxygen-carrying capacity in the setting of severe and ongoing hemorrhage may lead to a critically low hemoglobin concentration that further contributes to tissue oxygen debt.

Acute blood loss elicits compensatory hemodynamic changes that serve to maintain vital organ perfusion. These changes include increased heart rate and vasoconstriction primarily in the peripheral circulation and splanchnic vascular beds. The term *compensated shock* refers to varying degrees of tachycardia and peripheral vasoconstriction that maintain adequate critical organ perfusion. Arterial blood pressure in compensated shock states may be moderately low or within the normal range. The term *uncompensated shock* indicates inadequate vital organ perfusion.

Vasoconstriction in response to acute blood loss is a protective response that preserves perfusion to the vital organs at the expense of peripheral and abdominal organ perfusion. In the hypoperfused tissues, oxygen demand exceeds oxygen delivery, and the numerous cellular processes that depend on oxidative metabolism and subsequent production of adenosine triphosphate (ATP) begin to fail. Acidosis results when aerobic metabolism slows, as protons cannot be used to synthesize ATP from adenosine diphosphate (ADP); lactate cannot be converted to pyruvate and, therefore, lactate increases. If the pathologic processes are not corrected, cellular dysfunction and eventually organ failure result.

CLINICAL PRESENTATION

Initial findings in a patient with traumatic shock may include tachycardia, hypotension, signs of poor peripheral perfusion, and alteration in mental status. In response to a loss of circulating volume, the heart rate will increase to sustain normal cardiac output. Continued blood loss will eventually result in a decrease in blood pressure. Peripheral vasoconstriction and central venoconstriction shunt blood centrally and result in a narrowed pulse pressure. Clinically, decreases in peripheral perfusion manifest as cool, pale, clammy extremities with prolongation of capillary refill (Table 20.1).

TABLE 20.1
Classes of Hemorrhagic Shock

Class	Blood Volume Lost	Heart Rate (beats/min)	Systolic Blood Pressure	Respiratory Rate (breaths/min)	Central Nervous System/Mental Status
I	750 mL (15%)	<100	Normal	14–20	Slightly anxious
II	750–1,500 mL (15–30%)	>100	Normal	20–30	Mildly anxious
III	1,500–2,000 mL (30–40%)	>120	Decreased	30–40	Anxious, confused
IV	>2,000 mL (>40%)	>140	Markedly decreased	>35	Confused, lethargic

From American College of Surgeons Committee on Trauma. *Advanced Trauma Life Support: Providers' Manual.* Chicago, IL: American College of Surgeons, 2007.

The skin may become mottled in appearance, but cyanosis is not a common finding. The narrowed pulse pressure can make the pulse quality weak or thready. Alterations in mental status caused by hypoperfusion may be subtle initially and can be difficult to distinguish from associated head injury or intoxication. Therefore, altered mental status on presentation or a subsequent decline in mental status, especially in patients without head trauma, should raise concern of systemic hypoperfusion and impending circulatory collapse.

Shock may be present even in the setting of “normal” vital signs. Young, healthy patients with substantial blood loss may maintain a blood pressure within the normal range by compensatory vasoconstriction and increased heart rate. Heart rate can occasionally be in the upper normal range. In such patients, signs of peripheral hypoperfusion and subtle changes in mental status may be the only warning signs preceding rapid hemodynamic decompensation. Elderly patients may not develop a tachycardic response to blood loss because of pre-existing medical conditions or medications. In fact, a bradycardic response may occur with rapid blood loss that is believed to be vagally mediated. Conversely, hypotension and tachycardia may be exacerbated in a pregnant trauma patient for a given degree of blood loss caused by compression of the inferior vena cava by the gravid uterus, resulting in decreased venous return.

Decline in urine output caused by renal hypoperfusion and renal fluid reabsorption is an important manifestation of shock physiology. Monitoring urine output may be useful in the emergency department (ED); later, it is a critical parameter in the surgical intensive care unit. Therefore, a urinary catheter should be placed in patients who exhibit evidence of shock, and the bladder should be drained to begin urine-output monitoring and to check for hematuria.

DIFFERENTIAL DIAGNOSIS

The most common cause of postinjury shock is hemorrhage-induced hypovolemia. However, several pathologic entities must be considered as either potential contributors or primary causes of shock. These entities are listed in Table 20.2.

TABLE 20.2
Causes of Shock

Causes of Shock
Hemorrhage
Cardiac tamponade
Tension pneumothorax
Blunt cardiac injury
Myocardial infarction
Spinal shock
Toxicologic or pharmacologic agents
Air embolism

Pericardial tamponade is classically described as exhibiting the Beck triad of hypotension, distended neck veins, and muffled heart sounds. A pulsus paradoxus of >10 mm Hg may also be seen. However, not all of these markers may be present or detected. In a hypovolemic patient, the neck veins may be flat. Muffled heart sounds may be difficult to distinguish in a busy trauma resuscitation room, and detection of a pulsus paradoxus is not reliable. Pericardial tamponade should be considered whenever there is penetrating chest trauma, when there are rib fractures near the heart, or when there has been significant blunt trauma to the chest. The immediate availability of ultrasonography or echocardiography offers the best potential for rapid and accurate diagnosis.

A large pneumothorax or hemothorax can usually be detected by diminished breath sounds, although auscultation can be unreliable. Ultrasound (US) is useful for confirmation with a chest radiograph warranted if the US is equivocal. A tension pneumothorax may also result in deviation of the trachea away from the affected side, cardiac displacement, and hypotension related to inferior vena caval compression that limits venous return to the heart. However, tracheal deviation and cardiac displacement are late findings and may be difficult to detect by physical examination. Hypoxemia may be an earlier sign of a tension pneumothorax than hypotension. If a patient is hypotensive and has clinical evidence of a pneumothorax, placement of a chest tube before diagnostic imaging is appropriate.

Blunt cardiac injury (formally referred to as *myocardial contusion*) resulting in significant contractile dysfunction is a difficult diagnosis to make in the ED unless echocardiography is immediately available. Blunt cardiac injury should be suspected when blunt trauma involves the sternum and anterior left chest, particularly if ventricular ectopy, dysrhythmias, or electrocardiographic demonstration of ST-segment elevations (especially in the anterior precordial leads) are present. In addition, blunt trauma can result in valvular disruption and coronary artery dissection. Evidence of cardiogenic shock (hypotension, tachycardia, elevated central venous pressure) should alert the physician to the possible presence of a blunt cardiac injury or pericardial tamponade.

Spinal cord trauma with neurogenic shock may present with hypotension caused by loss of peripheral vascular resistance. In addition, because of the loss of sympathetic tone, these patients will not have the usual tachycardic response to hypotension but often demonstrate bradycardia instead. In this setting, the presence of neurologic deficits and lack of signs of peripheral vasoconstriction should arouse suspicion for this entity. Such patients generally have warm extremities and good urine output. Volume status must be carefully monitored, because excess fluid administration in patients with spinal shock may be detrimental.

Signs of shock in a trauma patient may not be a direct consequence of the injury. For example, a myocardial infarction may be the cause of a motor vehicle collision, or the physiologic stress associated with trauma may precipitate myocardial ischemia in a patient with underlying coronary artery disease. History, physical examination, or electrocardiographic findings consistent with myocardial infarction should arouse suspicion of combined medical and surgical processes. Another rare medical cause of hypotension in a trauma patient is anaphylaxis that may have preceded the trauma. Pharmacologic agents such as β-adrenergic blockers and recreational agents, such as ethanol and cocaine, may also significantly affect the clinical picture in the setting of acute trauma.

ED EVALUATION

The initial step in managing shock in the injured patient is prompt recognition. Effective management of the acutely injured patient exhibiting signs of shock requires that initial assessment and treatment begin simultaneously (1) with an emphasis on the airway, breathing, and circulation (ABCs). Assessment of airway patency, adequacy of ventilation (respiratory excursion and lung auscultation), hemodynamic status (pulse rate, central and peripheral pulse quality, blood pressure), and evidence of controllable hemorrhage should be immediately linked with interventions to (a) secure the airway while protecting the cervical spine, (b) enhance oxygenation, (c) provide ventilatory assistance, (d) limit further hemorrhage, (e) gain intravenous access, (f) initiate volume replacement, (g) obtain blood for laboratory and blood bank testing, and (h) perform US screening of the chest and abdomen (Fig. 20.1).

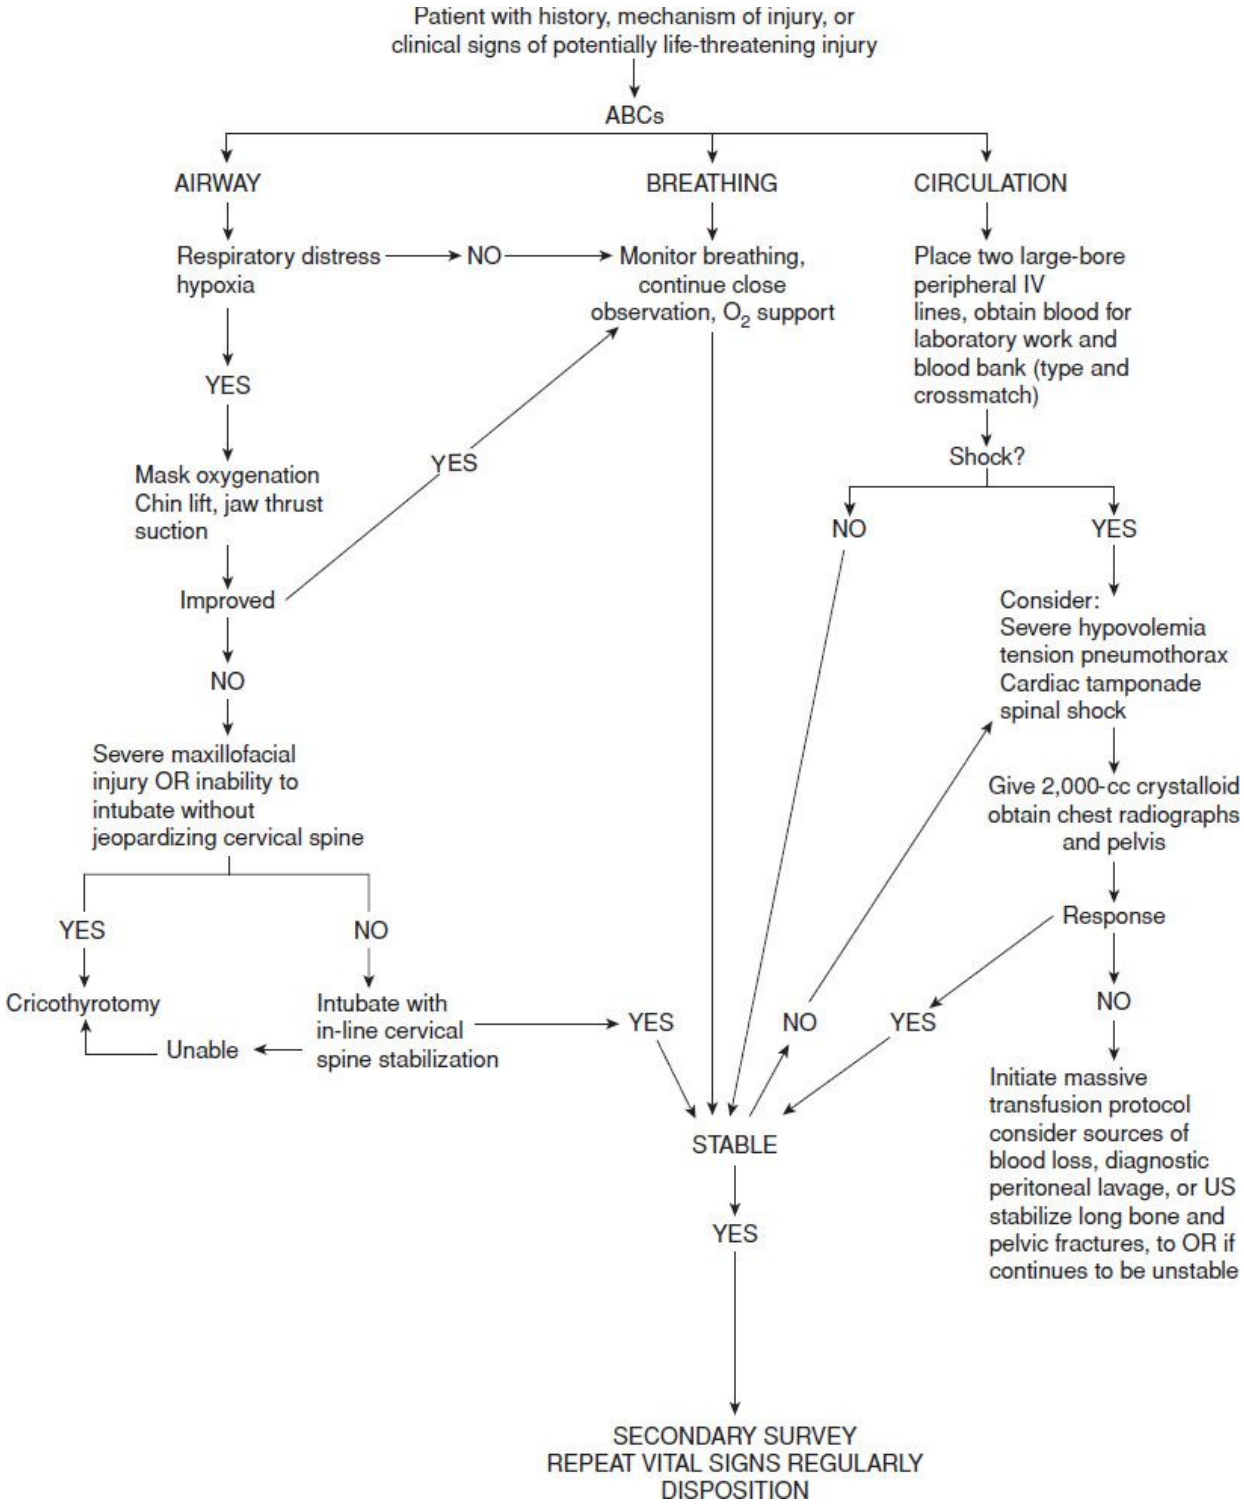

FIGURE 20.1 Treatment algorithm for traumatic shock.

After the primary assessment and initiation of treatment, a thorough secondary assessment should be conducted to identify

potential injuries to the head, neck, chest, abdomen, pelvis, back, extremities, neurologic, and vascular system. Hypothermia can depress hemodynamics and aggravate coagulopathy and should be aggressively treated. Acute trauma is a highly dynamic disease process that requires frequent and careful reassessment of ventilation, hemodynamic status, and physical examination to optimally adjust therapeutic interventions and identify evolving pathologic processes.

Initial laboratory studies in patients with major trauma should include (a) complete blood count (CBC); (b) arterial blood gases (base deficit); (c) electrolytes; (d) coagulation studies; (e) type and cross match for four units of packed red blood cells (PRBCs); and (f) toxicologic studies (Table 20.3). Urine should be obtained and checked for blood. Base deficit is a reliable early index of the magnitude of shock (2). Serum lactate has been advocated by some as an early predictor of morbidity and mortality, particularly in burn patients (3), but it appears to lag behind base deficit in the first 12 hours after injury (4).

TABLE 20.3
Initial Laboratory and Radiographic Studies in Major Trauma

Laboratory
Complete blood count
Arterial blood gases
Electrolytes (including BUN, creatinine, glucose)
Coagulation studies (Thermoelastography [TEG])
Type and crossmatch for four units of blood
Toxicologic studies (as indicated)
Serum lactate
Urinalysis
Ultrasound
Thorax
Pericardium
Abdomen
Radiographs
Chest x-ray, portable AP
Pelvis x-ray,[a] AP view

[a]In the stable patient who will undergo pelvic CT, pelvic x-ray is not needed.
BUN, blood urea nitrogen; AP, anteroposterior.

Initial radiographs have previously included the lateral view cervical spine, chest, and pelvis. With a number of studies suggesting that computed tomography (CT) scanning of the cervical spine is superior to plain films for detecting fractures (5), most centers are forgoing plain films of the cervical spine and going straight to CT. X-rays of the pelvis do not generally play a significant role in most trauma patients. Many of these patients will be getting a CT scan of the abdomen and pelvis and do not need a plain film unless they are unstable and may need to go directly to the operating room. In the unstable patient, a pelvic x-ray can determine the need for pelvic stabilization (by a bed sheet tied around the pelvis), as the patient is resuscitated initially or transferred to the operating room.

The initial chest radiograph will identify pneumothorax, hemothorax, pulmonary contusion, or a widened mediastinum, and the initial pelvic radiograph will identify major pelvic fractures as a potential cause of hypotension. Any patient with suspected spinal fractures or spinal shock should undergo radiographic evaluation once stabilized. The thoracic and lumbar spine can be evaluated by

CT scanning of the chest and abdomen, if these studies are indicated. Otherwise CT scans of the spine are appropriate in most situations.

US is part of the initial evaluation of the trauma patient. During the initial resuscitation, the focused assessment with sonography for trauma (FAST) examination should be performed to obtain views of the heart and abdomen to assess for pericardial effusion and intraperitoneal bleeding. Serial US examinations can be performed to increase the sensitivity for detecting intraperitoneal bleeding. In addition, US can be used for prompt detection of a hemothorax or pneumothorax. An alternative means of detecting intraperitoneal bleeding is diagnostic peritoneal lavage (DPL). The unstable trauma patient should undergo DPL when US is not available or if the US results are equivocal.

Monitoring of heart rate, respiratory rate, blood pressure, temperature, and pulse oximetry are important. Early placement of central venous pressure lines should be considered in patients who do not stabilize hemodynamically or are suspected of having cardiogenic or neurogenic shock components. Placement of a nasogastric or orogastric tube for decompression reduces the chances of aspiration and may improve ventilation if the stomach is distended with air.

A urinary drainage catheter should be placed after a search for potential urethral injury has been performed.

Urethral injury should be suspected in patients with pelvic fractures in the area of the symphysis pubis, anterior lacerations on rectal or vaginal examination, or abnormal position of the prostate gland. As noted, urine output becomes an important indicator of the adequacy of organ perfusion.

Quantitative end-tidal carbon dioxide ($ETCO_2$) monitoring is useful in intubated or sedated patients. $ETCO_2$ can help avoid hypoventilation, prevent excessive therapeutic hyperventilation, and detect decreases in cardiac output. Sequential assessment of hemoglobin/hematocrit and arterial blood gases during therapy for traumatic shock may be useful. These results should be interpreted together in terms of oxygen-carrying capacity and blood-oxygen content. In the trauma patient, the presence of metabolic acidosis in

the early phase of resuscitation indicates poor tissue perfusion and should be considered an indicator of inadequate volume resuscitation or ongoing hemorrhage.

Constant reassessment of ventilation and oxygenation, hemodynamic response to volume replacement therapy, and physical examination findings is crucial to detect clinical deterioration, adjust therapy, and identify previously missed injuries. Trauma resuscitations involve multiple individuals performing numerous tasks. During the process of resuscitation, tubes and catheters can become dislodged or disconnected, pneumothoraces can develop or enlarge, external or internal injuries may bleed again as blood pressure increases, pulmonary congestion or contusion may develop in response to volume therapy, core temperature may drop substantially in an exposed patient receiving large amounts of intravenous fluids, or the previously benign abdomen may become distended or rigid. These are examples of significant changes that can occur rapidly during the trauma resuscitation. Careful and constant attention with frequent reassessment is crucial to ensure optimal outcome.

KEY TESTING

- Type and cross
- Base deficit
- Thermoelastography (TEG)
- US of the thorax, pericardium, and abdomen
- Chest x-ray

ED MANAGEMENT

Walter Cannon wrote in 1923, “Since acidosis in shock indicates a deficient delivery of oxygen to active tissues, the rational move is not to treat the effect, but the cause, that is, to provide a better supply of oxygen by early and permanent improvement of the circulation” (6). This approach remains prudent today and is reflected in the ABCs. Initial treatment in traumatic shock occurs concurrently with initial evaluation and is focused on restoring adequate oxygen delivery.

Oxygen should be administered to all major trauma patients, regardless of presenting pulse oximetry readings. Early control of the airway in the patient with traumatic shock may be lifesaving and should take priority over all other interventions. Insertion of oral or nasal airways with assisted ventilation and endotracheal intubation are key components of the initial trauma resuscitation.

Gaining intravenous access rapidly is essential to begin volume replacement and support the hemodynamics of the patient in traumatic shock. The antecubital fossa is an excellent site to initiate intravenous access. Large-bore catheters (14 or 16 gauge) and high-flow intravenous tubing should be used to maximize delivery rate of fluids. At least two intravenous sites should be secured. If adequate intravenous access cannot be established within a few minutes, percutaneous femoral venous access, ankle venous cutdown, greater saphenous–venous cutdown at the proximal thigh, subclavian/jugular venous access, or intraosseous access should be considered.

Fluid therapy in trauma is an area of ongoing controversy. Intravascular volume replacement to compensate for blood loss and restore tissue perfusion has been accepted standard therapy for many years. The historical justification for aggressive intravenous fluid resuscitation was to maintain organ perfusion and improve survival. The enthusiasm for the approach was generated from experimental work employing controlled hemorrhage models and for decades, crystalloid loading to normalize blood pressure and heart rate was the standard. However, the Houston randomized clinical trial in 1994, showing no advantage to aggressive preoperative crystalloid resuscitation for penetrating torso wounds and reduced survival for cardiac wounds, prompted a reassessment of the resuscitation of the severely injured trauma patient. This often-cited clinical trial suggested higher survival rates in patients who underwent delayed fluid resuscitation at the time of operative intervention, instead of immediate fluid resuscitation starting in the field, but the benefit was limited to patients with pericardial tamponade (7). Although this trial initiated significant additional research and healthy debate, subsequent clinical trials have not been able to replicate the

advantage of hypotensive resuscitation found in the Houston study. Other studies have also suggested that aggressive fluid resuscitation in patients with uncontrolled or ongoing hemorrhage (prior to operative control) may increase blood loss and ultimately mortality. Research has questioned which intervention should take priority, reversal of hypovolemia or control of hemorrhage, when both cannot be achieved simultaneously. Restoring blood volume before active hemorrhage is controlled may result in increased blood loss caused by clot disruption, hemodilution, and loss of clotting factors. Although some studies have criticized aggressive fluid administration as being ineffective (8), others suggest that limited volume replacement, termed *hypotensive resuscitation,* which maintains minimally adequate organ perfusion, may result in improved outcome (9). The threshold for clot disruption appears to be about 90 mm Hg (10). It is important to remember that most clinical trials evaluating fluid administration have involved penetrating trauma victims. Whether the same principles can be applied to blunt trauma victims is not clear. In fact, this approach may be detrimental to blunt trauma patients with traumatic brain injury (TBI), because hypotension increases mortality in these patients (11). A clear endpoint of fluid therapy, in terms of an optimal blood pressure, has not been defined. Based on the current literature, it appears reasonable to have a goal of a systolic blood pressure of approximately 90 mm Hg for penetrating trauma patients and 100 mm Hg for blunt trauma patients with suspected TBI.

The optimal type of fluid for volume replacement has also been the subject of considerable debate. Crystalloid solutions, such as normal saline or lactated Ringer solution, have long been considered the standard. While hypertonic saline (HTS) is an appealing resuscitative agent, the recent large multicenter Resuscitation Outcomes Consortium (ROC) trial was terminated because of safety issues (12).

Replacing a significant percentage of the patient's blood volume with fluids that have not been warmed ("room temperature" is significantly cooler than body temperature) can render a patient hypothermic very quickly. Fluids may be warmed ahead of time or be administered through a fluid warmer. In an average-sized adult

showing signs of shock, infusion of 2 L of crystalloid and immediate reassessment of hemodynamics is a reasonable course of action (see Chapter 245 for pediatric resuscitation). The point in volume resuscitation at which blood transfusion is initiated has not been well defined. Factors that influence the decision to start blood transfusion include severity of shock, initial response to crystalloid, and anticipated ongoing bleeding. In general, if hemodynamics do not improve after administration of 3 L of crystalloid (or about 50 mL/kg) given rapidly, further volume replacement with blood should be considered. Certain patients may also require transfusion based on their initial injuries, such as those with major pelvic trauma.

The value of colloids in the treatment of traumatic shock remains to be established. Colloids, such as albumin, hetastarch, and dextran, can effectively increase intravascular volume and maintain plasma oncotic pressure at more normal levels compared with crystalloids. However, substantial data demonstrate that crystalloid and colloids are equally effective in resuscitation from hemorrhagic shock (13), and colloids have not been shown to improve outcomes despite higher cost. Furthermore, some evidence suggests that resuscitation with colloids may have deleterious effects. One study found that albumin was associated with significantly worse outcomes in patients with TBI (14) and another trial suggested starches might increase the risk of coagulopathy and AKI (15). Therefore, until well-designed clinical trials are performed showing an advantage to another approach, crystalloids remain the fluid of choice for the resuscitation of trauma patients in hemorrhagic shock (16).

Red blood cell (RBC) substitutes consisting of hemoglobin that has been modified by polymerization and biochemical alteration have been extensively studied in both animal and human trials. Studies have suggested that these RBC substitutes, with their ability to carry oxygen, may be superior to the current, more conventional methods of resuscitation from hemorrhagic shock (17). The USA Multicenter PolyHeme Resuscitation Trial enrolled 720 patients in 32 centers, but the results fail to demonstrate a clinical benefit (18).

Typed and cross-matched PRBCs are the best choice for blood transfusion, although this usually takes at least 30 minutes to obtain.

If transfusion is required more urgently, type-specific blood (usually available in 10 to 20 minutes) is an appropriate alternative. Type-specific blood has ABO compatibility with the patient's blood type but has not been tested for antibody compatibility. If traumatic shock is severe and immediate transfusion is critical, type O Rh-positive blood for males and type O Rh-negative for girls and women of childbearing age should be used until type-specific or typed and cross-matched blood is available. Type O Rh-negative blood should be immediately available in the trauma room, if there is appropriate prehospital notification.

If early blood transfusion is required to manage profound hypovolemia or if there is ongoing massive hemorrhage, fresh-frozen plasma (FFP) and platelets may be needed to restore the coagulation system. If a massive transfusion is anticipated (persistent hypotension with presumed active torso hemorrhage), some clinical studies have suggested a preemptive FFP:RBC ratio of 1:1 although a survival benefit has not been clearly defined. Others have suggested a 1:2 ratio may be more effective (19). A suggested definition of massive transfusion is 10 or more units of RBC in a 12-hour period. Initial large studies have suggested a significant survival benefit, but the role of tranexamic acid (TXA) remains controversial and the clinical benefit has not yet been clearly established (20). Conventional coagulation studies (PRR, INR) and platelet counts generally do not reflect the coagulation status of the critically injured. Point of care measurements, such as thermoelastography (TEG), that allow for early diagnosis of primary fibrinolysis, are now being implemented (21). Recombinant factor VIIa is a hemostatic agent originally developed to treat bleeding in hemophiliacs. Several authors have suggested that factor VIIa may be beneficial in severely bleeding trauma patients. However, two large randomized clinical trials have failed to identify a benefit (22).

Pneumothorax or hemothorax should be managed by the placement of a chest tube (18 French for pneumothorax, 28 French for hemothorax) in the lateral chest with the tube oriented toward the apicoposterior chest wall. While traditionally large chest tubes have been used in these situations, some authors have argued the

smaller pigtail catheters (14 French) perform just as well, even for a traumatic hemothorax (23). If a tension pneumothorax is suspected and the patient is hypotensive, the chest tube should be placed immediately even if a drainage system is not available.

If pericardial tamponade is suspected and the patient is hypotensive and worsening despite volume resuscitation, pericardiocentesis is indicated. A pericardiocentesis needle is inserted in the left subxiphoid area and directed 45 degrees toward the left shoulder or sternal notch, whereas suction is maintained through an attached syringe. Although the subxiphoid approach has been described as the "classical" approach for performing pericardiocentesis, the para-apical or parasternal approach with US guidance has been advocated in more recent studies (24). No controlled trials have compared the approaches in trauma patients. If a particular view by US (subxiphoid or parasternal) offers evidence of significant fluid accumulation, it is prudent to take that approach with the pericardiocentesis needle. Blood in the pericardium often forms clots, thus limiting the value of pericardiocentesis, particularly with right ventricular or atrial injuries. If the patient is profoundly hypotensive or has lost a detectable blood pressure in the trauma bay, an emergency left lateral thoracotomy should be performed to open the pericardium. Patients who have not shown signs of life after sustaining blunt trauma are poor candidates for ED thoracotomy (25).

Intra-abdominal injury is a common source for postinjury shock. The clinical presentation and response to initial therapy dictate the subsequent assessment of the abdomen. Hemodynamically unstable patients with physical examination or US evidence of abdominal injury should undergo exploratory laparotomy. Patients with suspected abdominal trauma who have exhibited transient hemodynamic instability should undergo a FAST examination, which can identify free intra-abdominal fluid. DPL is an alternative method of detecting intraperitoneal hemorrhage, if US is not available. Hemodynamically stable patients with potential abdominal trauma are candidates for abdominal CT scanning.

A quick maneuver to treat the hypotensive pregnant trauma patient is to place the patient in the left lateral decubitus position or tilt the backboard up 15 degrees on the right to move the gravid uterus off the inferior vena cava. This positioning improves venous return and may normalize the blood pressure.

In general, vasopressors and inotropic agents are not used in the ED management of traumatic shock except for cases of neurogenic or vasogenic shock (e.g., spinal cord injury) in which peripheral vasodilatation causes or contributes to hemodynamic instability. Agents such as dopamine or norepinephrine may be useful after fluid resuscitation. From the ED perspective, shock rarely occurs from isolated head trauma except in the young child. In cases of myocardial infarction associated with trauma or significant myocardial contusion, inotropic support may be appropriate.

CRITICAL INTERVENTIONS

- Recognize and treat shock aggressively before hypotension develops. Remember that shock may exist in a patient with "normal" vital signs.
- Wrap potentially unstable pelvic fractures with a sheet prior to transfer or extended diagnostic testing.
- When possible, place the hypotensive pregnant trauma patient in the left lateral decubitus position to relieve possible compression of the inferior vena cava.
- Isolated head trauma rarely causes hypotension; search for other causes.

DISPOSITION

Definitive management of the patient with traumatic shock often requires emergency surgery. Consultation with a surgeon should be initiated as soon as possible in all victims of significant trauma who might require operative or critical care interventions. If information from prehospital care providers indicates potentially serious injury, the surgeon (or trauma team) should be notified before the patient arrives in the ED. If transfer to another hospital is required, early

mobilization of resources (ambulance, staff, or air medical transport service) should be initiated concurrently with assessment and stabilization.

The criteria for transfer to a trauma center include lack of an experienced trauma surgeon, lack of adequate critical care or support services, and lack of adequate resources to manage a patient's injuries. The use of scoring systems such as the Trauma Score (TS), Revised Trauma Score (RTS), and the Glasgow Coma Scale (GCS) for triage may be helpful in identifying patients with severe injury. Patients with a TS <12, an RTS of ≤ 8, or a GCS <10 generally have serious injuries and should be managed within an organized trauma system. The emergency physician must determine which interventions and diagnostic studies are essential before transfer. These decisions are affected by mode of transport, distance to the trauma center, and the capabilities of the referring hospital. For example, delaying transfer to obtain a head and abdominal CT scan or plain radiographs is of no benefit if there is no neurosurgeon, general surgeon, or orthopedist available or if no immediate intervention will take place at the referring hospital. On the other hand, if a head, chest, or abdominal CT scan is indicated and can be obtained while waiting for the ambulance or helicopter to arrive (and will not cause a delay in transfer), it is best to proceed with these studies.

Common Pitfalls

- Failure to recognize shock; normal vital signs can be misleading.
- Failure to realize that altered mental status is a sign of shock, particularly when there is no evidence of head trauma.
- Failure to monitor trauma patients carefully and to perform serial examinations to detect changes in clinical status and response to interventions. An initial favorable response to volume replacement should not mislead the physician to be less vigilant, as adequate initial resuscitation can temporarily mask significant ongoing hemorrhage.
- Delaying surgical consultation or transfer to a trauma center.

- Missing subtle injuries, especially in patients with severe multisystem trauma.

CHAPTER 21 Wound Management

Judd E. Hollander and Adam J. Singer

Nearly 9 million patients with traumatic lacerations are treated annually in emergency departments (EDs) in the United States (1). The ultimate goals are to restore the physical integrity and function of the injured tissue in a cosmetically pleasing manner and to reduce the risk of infection. Treatment of these wounds involves a series of decisions that determine the methods of evaluation, wound preparation, wound closure, and postoperative care most likely to help attain these goals.

CLINICAL PRESENTATION

Lacerations occur predominantly in young adults; the majority of patients with lacerations are males (2). Most wounds are located on either the head or neck (50%) or the upper extremity (35%), usually involving the fingers or hands. The most common mechanism of injury is application of a blunt force, such as bumping the head against a coffee table. Such contact crushes the skin against an underlying bone, causing the skin to split. Other causes of injury include sharp instruments, glass, and wooden objects (2). While mammalian bites continue to receive much attention, they are a relatively infrequent cause of puncture wounds and lacerations (2).

ED EVALUATION

Evaluation of the patient with a traumatic wound begins with an expeditious, comprehensive assessment of the patient. This assessment can be divided into primary and secondary surveys, following advanced trauma life support algorithms. Unless the

wound compromises the ABCs, formal wound evaluation and management occur during the secondary survey and management phase of the trauma evaluation.

Proper wound management begins with a thorough patient history. It is important to determine hand dominance and occupation. Host factors such as the extremes of age, diabetes mellitus, chronic renal failure, obesity, malnutrition, and the use of immunosuppressive medications all increase the risk of wound infection and can impair wound healing. Wound healing can also be impaired in the presence of inherited and acquired connective tissue disorders. The tendency of patients to form keloids should be ascertained because the development of keloids can result in a scar with less than acceptable cosmesis. Black and Asian populations are more prone to keloid formation (3).

Identification of the mechanism of injury is essential to help ascertain the presence of potential wound contaminants and foreign bodies that might result in chronic infection and delayed healing (3). Failure to diagnose foreign bodies in wounds is a leading cause of litigation against emergency physicians. Missed tendon and nerve injuries and failure to prevent infection are other common wound-related causes of litigation. In patients with scalp lacerations, a history of loss of consciousness and any neurologic complaints should be obtained. In patients with hand injuries, a history of neurologic deficits should be obtained to help predict the presence of tendon or nerve injury.

A careful history can also predict the likelihood of foreign bodies. Most organic and inorganic components of soil potentiate infection. However, sand grains are relatively innocuous. The black dirt on the surface of highways appears to have minimal chemical reactivity.

Crush injuries that tend to cause greater devitalization of tissue are more susceptible to infection than are wounds resulting from the more commonly seen shearing forces. Impact injuries with low energy levels may not result in division of the skin; they can, however, disrupt vessels and produce a hematoma and ecchymosis.

The presence of allergies to local anesthetics, latex, and antibiotics should be determined. The tetanus status of all patients should be

assessed, and patients should receive immunization in accordance with current Centers for Disease Control and Prevention recommendations (Table 21.1). Before inspecting the wound, the emergency physician should question the patient regarding the time and mechanism of injury. The amount of time elapsed since the accident may influence treatment decisions.

TABLE 21.1
Recommendations for Tetanus Prophylaxis

	Clean Minor Wounds		All Other Wounds	
History of tetanus immunization	Td	TIG	Td	TIG
<3 or uncertain doses	Yes	No	Yes	Yes
≥3 doses				
Last dose within 5 yrs	No	No	No	No
Last dose within 5–10 yrs	No	No	Yes	No
Last dose >10 yrs ago	Yes	No	Yes	No

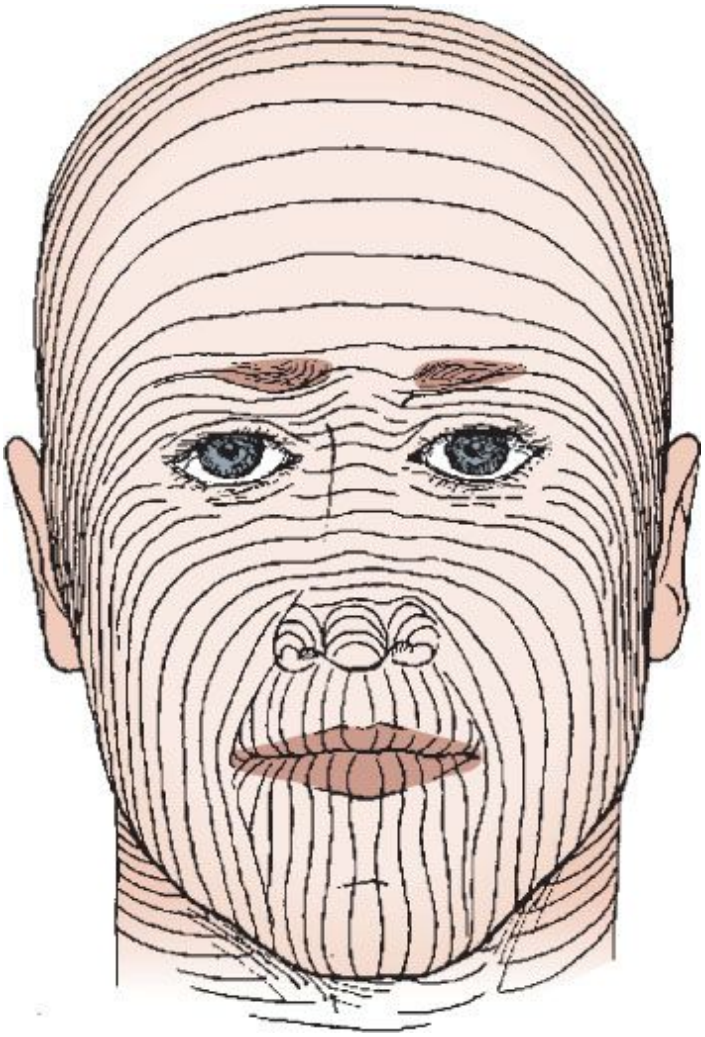
Td, tetanus–diphtheria toxoid; TIG, tetanus immune globulin.
Note: For example, contaminated wounds, puncture wounds, avulsions, burns, crush injuries.
From Singer AJ, Hollander JE, Quinn JV. Evaluation and management of traumatic lacerations. *N Engl J Med*. 1997;337:1142–1148.

Adequate wound examination should always be conducted in a field where bleeding has been controlled. One way to minimize the possibility of missing an injury to a vital structure is to start the wound examination with a careful neurovascular assessment of pulses, motor function, and sensation distal to the laceration. Finger tourniquets or a blood pressure cuff may then be used to obtain a bloodless field, but they should not be used for more than 30 to 60 minutes.

Moist areas of the body, such as the axillae, perineum, toe webs, and intertriginous areas, harbor millions of bacteria per square centimeter. Lacerations of the oral cavity are usually heavily contaminated with facultative species and obligate anaerobes. Wounds with fecal contaminants run a high risk of infection despite therapeutic intervention.

Wounds located on highly vascular areas, such as the face and scalp, are less likely to be infected than are wounds located in less vascular areas, such as the extremities (2). Lacerations of the scalp and face have a very low infection rate regardless of the intensity of cleansing (4).

Wound location also contributes to the cosmetic appearance of the scar by affecting static and dynamic skin tensions (eFig. 21.1). Lacerations over joints are subject to large, dynamic skin tensions and will have a wider scar than will similar lacerations subject to less tension. Wounds that run perpendicular to the lines of minimal skin tension will also be prone to the development of wider and more visible scars.



eFIGURE 21.1 Langer lines of least skin tension.

eTABLE 21.1
Advantages and Disadvantages of the Common Wound-Closure Techniques

	Advantages	Disadvantages
Suture	Time-honored	Requires removal
	Meticulous closure	Requires anesthesia
	Greatest tensile strength	Greatest tissue reactivity
	Lowest dehiscence rate	Highest cost
		Slowest application
Staples	Rapid application	Less meticulous closure
	Low tissue reactivity	May interfere with some older-generation imaging techniques (CT, MRI)
	Low cost	
	Low risk of needlestick	
Tissue adhesives	Rapid application	Lower tensile strength than sutures
	Dehiscence over high-tension areas (joints)	Not useful on hands
	Resistant to bacterial growth	Cannot bathe or swim
	No need for removal	
	Low cost	
	No risk of needlestick	
	Patient comfort	
Surgical tapes	Least reactive	Frequently falls off
	Lowest infection rates	Lower tensile strength than sutures or adhesives
	Rapid application	
	Patient comfort	Highest rate of dehiscence
	Low cost	Requires use of toxic adjuncts
	No risk of needlestick	Cannot be used in areas of hair
		Cannot get wet

CT, computed tomography; MRI, magnetic resonance imaging.

eTABLE 21.2
Characteristics of Nonabsorbable Sutures

TABLE 21.2
Properties of Commonly Used Local Anesthetics

Agent	Trade Name	Local Anesthetic Class	Concentration	Maximal Safe Dose	Onset	Duration
Procaine	Novocaine	Ester	0.5–1%	7 mg/kg	2–5 min	15–45 min
With epinephrine				9 mg/kg		30–90 min
Lidocaine	Xylocaine	Amide	0.5–2%	4.5 mg/kg	2–5 min	1–2 hrs
With epinephrine				7 mg/kg		2–4 hrs
Bupivacaine	Marcaine	Amide	0.125–0.25%	2 mg/kg	2–5 min	4–8 hrs
With epinephrine				3 mg/kg		8–16 hrs

Suture	Knot Security	Tensile Strength	Tissue Reactivity	Workability
Nylon (Ethilon)	Good	Good	Minimal	Good
Polypropylene (Prolene)	Least	Best	Least	Fair
Silk	Best	Least	Most	Best

eTABLE 21.3
Characteristics of Absorbable Sutures

TABLE 21.3
Suture Selection Based on Anatomic Location

Location	Suture Size[a]
Face	6-0 or 7-0
Oral mucosa	4-0 or 5-0
Scalp	4-0
Chest	3-0 or 4-0
Back	3-0 or 4-0
Forearm	4-0 or 5-0
Fingers	4-0 or 5-0
Hand	4-0 or 5-0
Lower extremity	4-0 or 5-0
Foot	4-0 or 5-0

[a]Larger suture sizes may need to be used for wounds with higher tension.

Suture	Knot Security	Tensile Strength	Wound Security (50% Tensile Strength)	Tissue Reactivity
Surgical gut	Poor	Fair	5–7 d	Most
Chromic gut	Fair	Fair	10–14 d	Most
Poliglecaprone (Monocryl)	Good	Fair	10–14 d	Least
Polyglactin (Vicryl)	Good	Good	30 d	Minimal
Polyglycolic acid (Dexon)	Best	Good	30 d	Minimal
Polydioxanone (PDS)	Fair	Best	45–60 d	Least
Polyglyconate (Maxon)	Fair	Best	45–60 d	Least

KEY TESTING

- The majority of lacerations require no diagnostic testing besides a history and physical examination.
- Depending upon the likelihood of a retained foreign body or fracture from the injury, radiography, ultrasound, or computerized tomography may be necessary.

ED MANAGEMENT

Aseptic Technique

The use of sterile gloves makes common sense, despite the lack of clinical evidence supporting their use (5,6). Though the practice of universal precautions is recommended in all patients, double gloving is recommended when caring for patients who can transmit serious infections (human immunodeficiency virus or hepatitis) to the healthcare provider.

Latex Allergy

Severe reactions in latex-sensitive individuals have resulted in fatalities. Populations that appear to be at increased risk for allergic reactions to latex include patients who have undergone multiple

operations, patients with atopic disease, children with spina bifida, and medical personnel with frequent latex exposures.

Wound Examination

Wound examination should always be conducted under optimal lighting conditions and with bleeding in the field controlled. Wound examination should begin with a neurovascular assessment of pulses, motor function, and sensation distal to the laceration.

Bleeding should be controlled with direct pressure. When lacerations continue to bleed despite reasonable pressure, placement of a sphygmomanometer cuff proximal to the injury, with inflation to a pressure greater than the patient's systolic blood pressure, will help contain bleeding to allow proper examination. Palpation of the bones adjacent to the injured site may detect tenderness, a defect, or instability consistent with an underlying injury. Radiography should be used to detect fractures. Detection of an open fracture will dictate a change from usual management because it will require the administration of systemic antibiotics and may require irrigation in the operating room. Wounds occurring adjacent to a joint should be carefully evaluated for joint violation. If in doubt, sterile fluid should be injected into the joint, and the physician should look for communication to verify violation of the joint space.

Amputated parts should be cared for as outlined in the chapters on hand injuries and replantation emergencies (Chapters 41 and 47). Digits should be covered with a protective saline-soaked dressing, placed within a waterproof bag, and then placed in a container of ice water for preservation and consideration of future reattachment.

Complicated injuries involving most open fractures, joint penetration, flexor tendon injuries, nerve injuries, or arterial injuries are often treated in the operating room. In most other cases, wound repair will occur in the ED.

The ultimate appearance and function of a scar can be predicted by the static and dynamic skin tensions on the surrounding skin (see eFig. 21.1). The most aesthetically pleasing scar occurs when the long axis of the scar is parallel to the direction of minimal tension, because the static skin tensions continually pull on the wound edges

even after wound closure. The ultimate width of the scar is proportional to the magnitude of the static skin tensions.

An appreciation of the effects of various dynamic tensions can be used to determine the need for tension-relieving absorbable sutures in addition to the nonabsorbable skin closure.

Wound Anesthesia

Most lacerations will require some form of anesthesia prior to wound closure. All visibly contaminated wounds and wounds that will require anesthesia for closure should receive anesthesia prior to cleansing so that adequate mechanical removal of bacteria, soil, and other debris can be more readily accomplished.

Local Infiltration

The most common form of anesthesia for traumatic injuries is local infiltration. Unfortunately, local anesthesia is painful. To reduce the pain associated with local infiltration, several strategies can be employed. The addition of sodium bicarbonate to lidocaine (pK_a, 7.9) in a 1:9 ratio increases the ratio of uncharged to charged ions and results in more rapid diffusion of anesthetic agent into nerve endings. It reduces the pain associated with local infiltration without altering the ability of host defenses to prevent infection (7). The use of warm anesthetic solutions, small needles, slow rates of infiltration, injection through the wound edges in noncontaminated wounds, and pretreatment with topical 4% tetracaine or lidocaine, epinephrine, and tetracaine (LET) are additional strategies that can be used to decrease the pain of infiltration (3,8).

For injection of local anesthesia, a 27- to 30-gauge needle attached to a 10-mL syringe should be used. The needle should be passed into the wound edge rather than the intact skin because wound edge injections are less painful. Full anesthesia to pinprick is present 5 to 6 minutes after subdermal injection. The local anesthetic agent should be instilled slowly to decrease the pain that accompanies tissue infiltration. The needle should be passed through the dermal tissue initially; then the anesthetic agent can be injected as the

needle is slowly withdrawn. This technique minimizes distention and pain by providing a potential space for the anesthetic solution. Aspiration of the syringe before injection is recommended to prevent inadvertent intravascular injection.

Because the duration of local anesthesia induced by bupivacaine is nearly four times longer than that of lidocaine, bupivacaine (0.25%) should be used when longer durations of anesthesia are desirable (Table 21.2).

Vasoconstrictors such as epinephrine can be used as adjuncts to the local anesthetic agents. They will reduce bleeding and oozing within the laceration, which will make exploration and closure easier to accomplish. The addition of epinephrine also delays systemic absorption and increases the therapeutic window. Clinical studies have not found that the vasoconstriction associated with epinephrine use results in differences in infection rates. While traditionally these agents have been avoided in fingers, toes, and the penis owing to the risk of vasospasm and subsequent necrosis, more recent evidence suggest that their use is safe (9).

Regional Anesthesia

When the nerve supply to a wound is easily accessible, a regional nerve block is a valuable alternative to local anesthesia. The use of regional nerve blocks will prevent distortion of the wound edges, facilitating approximation and increasing the likelihood of an excellent cosmetic result. Regional nerve blocks can be accomplished by only one or two needle passages through skin proximal to the injury site. Regional nerve blocks of the supraorbital, infraorbital, and mental nerves are useful for facial lacerations; however, they are more painful and less reliable than local infiltration (10). Median, radial, and ulnar nerve blocks may be useful for lacerations of the hand. Digital or metacarpal nerve blocks can be used for finger lacerations. Regional nerve blocks can also be used for lacerations of the feet. Field blocks can be considered for more proximal extremity injuries.

A 27- or 25-gauge needle is preferred to a 30-gauge needle for a regional nerve block, because either one is more resistant to

deflection during passage through tissue. The duration of sensory analgesia can be significantly prolonged when epinephrine (1%) is added to the anesthetic solution. When the needle puncture site is the mucous membrane, anesthetizing the mucous membrane with a topical anesthetic agent makes the introduction of the needle painless.

Topical Anesthesia

Topical anesthesia eliminates needle use and the risk of inadvertent needle sticks while allowing the application of painless anesthesia. Various combinations of lidocaine (1% to 4%), adrenaline (1:1,000 to 1:2,000), and tetracaine (0.5% to 2.0%) are as effective as eutectic mixture of local anesthetic cream (EMLA) (11,12). An EMLA has a slower onset of action, is more expensive than LET, and is not approved for use on injured skin; therefore, it is not recommended for use in the ED.

Preparation of Skin

Removal of the hair surrounding a laceration may facilitate meticulous wound closure. Because many bacteria normally reside in hair follicles, shaving the hair prior to repair may increase wound infection rates. Reduced damage to hair follicles may be achieved by using hair clippers instead of a razor. Removal of the eyebrow hair should be avoided because it does not always grow back. Additionally, the presence of hair serves as a guide to approximation of wound edges during laceration repair.

The skin surrounding the wound should either be cleansed with normal saline or disinfected with an iodophor (such as Betadine) or chlorhexidine; the physician should avoid contacting the wound itself with disinfectant. A recent study in the operating room demonstrated significantly reduced wound infection rates after skin preparation with chlorhexidine (13). Although these agents can reduce the bacterial concentration on intact skin, they appear to damage wound defenses, making the wound more susceptible to

development of infection. Consequently, any contact of these agents with the wound should be avoided.

Debridement

Appropriate debridement is an important factor in the management of contaminated wounds. Retained devitalized soft tissue, fat, muscle, and skin can damage wound defenses and increase the likelihood of infection through the promotion of bacterial growth and the inhibition of phagocytosis. Identification of the exact limit of devitalized tissue in wounds may be difficult. Evaluation of the color, consistency, contraction, and circulation is useful.

In some anatomic sites, such as the trunk, debridement is best accomplished by complete excision of the skin and deep tissues. Heavily contaminated wounds with serpiginous defects in these regions can be converted to clean wounds by more generous tissue excision. When a heavily contaminated wound contains specialized tissues, such as the nerves or tendons that perform important physical functions, complete excision often is not feasible. In such instances, mechanical wound cleansing followed by excision of all fragments of tissue that are not clearly viable is indicated.

The benefits of debridement must be weighed against the consequences of excision of the tissue. Debridement of skin and underlying tissue leaves a significant soft tissue defect that makes reapproximation more difficult.

Assessment for Foreign Bodies

Metal, bone, teeth, pencil graphite, certain plastics, glass, gravel, sand, some fish bones, some wood, and some types of aluminum are visible on plain radiographs. Almost all glass fragments 2 mm or larger are visible on radiographs (14). If the wound was caused by metal or glass and no foreign body is found on wound exploration or on plain films, it is unlikely that a foreign body exists. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful for identifying and locating objects that have densities similar to soft

tissue. Sonography may also be useful, particularly for wooden foreign bodies.

Cleansing the Wound

The two basic methods of wound cleansing are hydraulic forces (irrigation) and direct contact (scrubbing).

Irrigation

Some debate exists over both the optimal method of irrigation and the preferred solution. The efficacy of wound irrigation is correlated with the pressure at which the irrigant is delivered to the wound. High-pressure irrigation (>7 pounds per square inch) successfully cleans wounds of small particulate matter, such as bacteria and soil. Such cleansing has reduced the infection rate of experimentally contaminated wounds. In contrast, low-pressure syringe irrigation, even with large volumes of fluid, demonstrates negligible capability for removing small particles (bacteria) but removes large particulate matter, such as detached devitalized tissue.

High wound impact pressures can be easily obtained using a 30- to 60-mL syringe and a 19-gauge needle or Zerowet splash shield (15). However, it must be noted that sustained high- pressure irrigation can result in tissue damage. As a result, at very high pressures, infection rates may actually increase.

For relatively clean wounds in highly vascularized areas containing loose areolar tissue, such as the eyelid, high pressures should be avoided. In fact, high-pressure irrigation has not been found to offer any advantages for cleansing clean, noncontaminated facial lacerations (4). Conversely, high-pressure irrigation is clearly indicated for contaminated wounds of the lower extremity. The choice of irrigation solution is relatively straightforward. Normal saline compares favorably with more expensive, less readily available alternatives. Because of their tissue toxicity, detergents, hydrogen peroxide, and concentrated forms of povidone–iodine should not be used to irrigate wounds. Irrigation of wounds with tap water results in comparable infection rates versus irrigation with sterile saline (16). Irrigation volume should be individualized based on patient

characteristics and such wound characteristics as location and etiology. Use of a device designed to reduce splatter will minimize the healthcare provider's risk of exposure to potentially infectious materials.

Scrubbing

Direct scrubbing of the wound with gauze or a sterile surgical brush helps remove both bacteria and particulate matter, which potentiate the risk of wound infection. However, scrubbing also contributes to the tissue damage and reduces the ability of the wound to resist infection. Therefore scrubbing should be reserved for highly contaminated wounds.

Use of Drains

The potential benefits of the use of surgical drains in a clinical setting must be weighed against its harmful effects. Drains evacuate potentially harmful collections of pus and blood from wounds. When no definite localized fluid collection exists, drains must be considered prophylactic, and their potentially harmful effects become more important. The general use of drains is not indicated in the management of most wounds in the ED.

Open Wound Management

The technique of wound closure largely depends on whether the wound has lost tissue and the risk of wound infection. With *primary closure,* the wound is immediately closed. Primary closure results in a reduction in healing time in comparison with other closure methods. It also may reduce the bleeding, inconvenience, and discomfort often associated with open wounds. *Secondary wound closure,* in which the wound is left open and allowed to close on its own, is particularly well suited for highly contaminated or infected wounds. Though this method may reduce the risk of infection, it is relatively slow and uncomfortable. *Delayed primary* (or *tertiary*) *closure* combines the advantages of both primary and secondary closures. The wound is left open for a period of 3 to 5 days, after which it may be closed if no infection supervenes. For wounds with associated significant

tissue loss, grafts or flaps are often required to close the defect. These procedures are usually performed in the operating room.

Though there is a direct relationship between the time interval from injury to laceration closure and the risk of subsequent infection, the length of this "golden period" is highly variable (3). A study of forearm lacerations found that closure within 4 hours had a lower infection rate than later closure (17). A large series of pediatric patients (2,834 patients) with lacerations did not find a difference in infection rate for lacerations closed within or >6 hours from the time of injury (18). Facial lacerations healed well regardless of the time to closure. In contrast, trunk and extremity lacerations exhibited lower rates of healing if they were closed more than 19 hours from the time of injury (63% to 75%) as compared to earlier (75% to 91%) (19).

On the basis of these data, it seems appropriate to consider each laceration separately, taking the time from injury until presentation into account, along with laceration location, degree of contamination, risk of infection, and importance of cosmetic appearance, before deciding whether to perform primary wound closure. Wounds that are not closed primarily owing to a high risk of infection should be considered for delayed primary closure after 3 to 5 days, when the risk of infection decreases.

Wound Closure

Careful handling of tissues and judicious use of electrocautery are necessary to reduce further trauma that may lead to poor cosmetic outcome (20). The optimal wound-closure technique varies with the clinical situation. Sutures are the most commonly employed wound-closure technique. Tissue adhesives can be used in up to one-third of ED laceration repairs. Staples and surgical tapes can be used in selected situations. The advantages and disadvantages of various wound-closure techniques are summarized in Table 21.4.

TABLE 21.4
Advantages and Disadvantages of the Various Suture Techniques

Suture Type	Advantages	Disadvantages	Frequent Uses
Interrupted percutaneous	Excellent approximation	Time-consuming May strangulate tissues	Low-tension wounds May be used with deep sutures for high-tension wounds
Continuous percutaneous	Rapid closure Accommodates edema	Less meticulous closure than interrupted sutures If a single knot unravels the wound may dehisce (if no deep sutures placed)	Percutaneous closure in conjunction with deep sutures
Interrupted dermal	Reduces tension on wound surface Allows early removal of percutaneous sutures avoiding hatch marking May reduce scar width	May increase infection in contaminated wounds	High-tension wounds Closure of dead space
Continuous dermal	Rapid Reduces tension on wound surface Allows early removal of percutaneous sutures avoiding hatch marking May reduce scar width	Technically difficult Less accurate approximation than interrupted sutures If a single knot unravels, the wound may dehisce	High-tension wounds require interrupted dermal sutures Closure of dead space
Vertical mattress	Excellent wound edge eversion Combines advantages of deep and superficial sutures	May cause tissue strangulation	Thin or lax skin with little dermal or fascial tissues High-tension areas (e.g., extremities)
Horizontal mattress	More rapid than simple interrupted sutures Excellent wound edge eversion	May cause tissue strangulation	Bleeding scalp wounds Initial approximation of high-tension wounds
Half-buried horizontal mattress	Less compromising to flap perfusion	Time-consuming Technically difficult	For corner stitches and flaps

Sutures

The choice of suture technique should be determined by the configuration and biomechanical properties of the wound, in combination with an assessment of its risk of infection. Percutaneous sutures pass through the epidermal and dermal layers of the skin. They are used alone for low-tension lacerations and in combination with deep dermal sutures for higher tension lacerations. The dermal suture reapproximates the divided edges of the dermis without penetrating the epidermis. Often, dermal and percutaneous sutures are used together.

Most often, percutaneous sutures are performed with nonabsorbable sutures, such as nylon and polypropylene. Both nylon and polypropylene retain most of their tensile strength for more than 60 days and are relatively nonreactive (3). Removal of nonabsorbable sutures is required. Percutaneous sutures of either monofilament nylon or polypropylene exert the least damage to the wound defenses.

Nonabsorbable sutures made from natural fibers potentiate infection more than synthetic nonabsorbable sutures, correlating with the reaction of tissue to these sutures in clean wounds. The incidence of infection in contaminated tissue containing

monofilament sutures is lower than in those containing multifilament (braided) sutures. Although use of absorbable sutures is generally reserved for dermal closures, more rapidly absorbing forms can be used to close skin in children and avoid the discomfort and inconvenience of suture removal.

Dermal closures are generally accomplished with absorbable sutures. Chromic gut lasts for up to 2 weeks, but it is associated with increased tissue reactivity. Polyglactin (Vicryl) and polyglycolic acid (Dexon) maintain tensile strength for 20 to 28 days and have less tissue reactivity. Some synthetic absorbable sutures, such as polydioxanone (PDS) and polyglyconate (Maxon), retain their tensile strength for as long as 2 months. They are particularly useful in areas with high static and dynamic tensions. These sutures should be used only in the deeper areas, because they can become extruded after long periods of time. Antibiotic-impregnated absorbable sutures (such as Vicryl Plus and Monocryl Plus) have in vitro antibacterial actions against a wide variety of bacteria. They should be considered especially in contaminated wounds.

The use of dermal sutures relieves skin tension, decreases dead space and hematoma formation and, theoretically, should improve cosmetic outcome. Research in experimental animal models has found that deep sutures increase the risk of infection in highly contaminated wounds, but they do not do so in clean, noncontaminated lacerations (3). Deep sutures should not be placed in adipose tissue and in contaminated wounds. No studies of traumatic lacerations have demonstrated any benefit to the use of deep sutures (21). Many practitioners prefer to use deep sutures in gaping lacerations and in cosmetically important lacerations despite a lack of evidence. Deep sutures should not be used in the hand as they may inadvertently cause damage to important structures such as nerves and tendons.

Undermining the wound margin decreases the forces required for wound closure. Theoretically, it should limit the width of the ultimate scar. However, this benefit must be weighed against its potential damage to the skin blood supply, which may increase the likelihood of infection. Consequently, undermining should be

reserved for clean, noncontaminated wounds subjected to strong static and dynamic tensions.

The magnitude of the suture's damage to the local tissue defenses is related to the quantity of the suture within the wound. As a result, the narrowest diameter suture (5-0 or 6-0) that is strong enough to resist disruption of the skin should be used (Table 21.3). Approximation of the midportion of the laceration first, with subsequent bisection of the remaining portion, will enable the use of the least amount of suture. Interrupted dermal sutures placed in each quadrant of the wound subjected to strong static and dynamic skin tensions may provide sufficient strength to permit early suture removal.

Careful attention to the following details may help ensure proper wound edge eversion and an optimal cosmetic outcome after suturing. The needle should enter the wound at an angle of 90 degrees. This will result in a wider "bite" at the depth of the wound than at its surface, helping to achieve wound eversion. This is best accomplished by maximally pronating the hand that is holding the needle holder. It is also important to match corresponding layers of the skin on either side of the wound by taking equally sized bites.

The choice of a particular suture technique is based upon the specific wound, its location, tension, and advantages and disadvantages of the various suture techniques (Table 21.4). *Simple interrupted* sutures are commonly used for low-to-moderate tension wounds. For long linear lacerations, *continuous* sutures may be used to save time and distribute the tension more evenly. *Continuous subcuticular* (or *intradermal*) sutures can be used instead of percutaneous sutures to avoid the need for suture removal. However, this method is more time-consuming and technically challenging. A *half-buried horizontal mattress* suture (or *corner* stitch) is most appropriate for narrow corners and flaps, as it does not compromise tissue perfusion. *Vertical mattress* sutures help achieve maximal wound edge eversion, but they may result in tissue strangulation. They are best reserved for closure of high-tension wounds in thin skin where placement of deep dermal sutures is difficult. Whatever method is used, the sutures should be tied tightly enough to achieve

complete apposition of the wound edges. However, care should be taken not to tighten the suture too tightly, as this may compromise perfusion and result in necrosis and sloughing of the wound edges.

Topical Skin Adhesives

The only topical skin adhesives that are strong enough to close wounds are the cyanoacrylate polymers. A growing number of butylcyanoacrylate, octylcyanoacrylate, or combination topical skin adhesives are now available. The topical skin adhesives also have the advantage of forming a microbial barrier to prevent wound contamination (22).

Several clinical studies have compared the use of 2-octylcyanoacrylate to 5-0 and 6-0 sutures. Quinn et al. (23) found the long-term cosmetic outcomes to be equivalent. The use of 2-octylcyanoacrylate was faster and less painful than the use of sutures. The largest study to date enrolled 818 patients who were randomly assigned to receive skin closure with either 5-0 or 6-0 sutures or 2-octylcyanoacrylate (24). Of the 818 patients enrolled, 333 had subcuticular or subcutaneous sutures placed prior to laceration closure. Comparing the group of patients who received 2-octylcyanoacrylate with the group of patients who received skin closure with sutures, the 3-month cosmetic outcomes, short-term infection rates, and wound dehiscence rates were all similar. The time to wound closure was reduced by more than 50% in the group treated with 2-octylcyanoacrylate. Subgroup analysis of patients from both adult and pediatric EDs found equivalent 3-month cosmetic outcomes (25,26).

Although in vitro and in vivo studies have found that cyanoacrylate tissue adhesives possess gram-positive antimicrobial properties, it is imperative that clinicians adhere to standard wound preparation and wound-cleansing procedures. Meticulous wound cleansing is essential regardless of wound closure method. Although wound cleansing can sometimes be accomplished without the use of local anesthesia, the decision to close wounds with tissue adhesives should not, in and of itself, lead the clinician to avoid the use of anesthesia when needed for wound cleansing.

The application of tissue adhesives is rapid and relatively painless. Adhesives also have the advantage that they do not require later removal, as do sutures. They will usually slough off in 5 to 10 days as the keratinized layer of epithelium sloughs. They should be used only topically, not placed within the wound margins. The topical skin adhesives are needleless alternatives to sutures for the closure of most facial lacerations, providing an excellent cosmetic appearance, comparable to that provided by sutures.

Topical skin adhesives can be used in locations that could otherwise be closed with 5-0 or 6-0 nonabsorbable sutures. Topical skin adhesives should only be used in higher-tension areas if subcutaneous or subcuticular absorbable sutures are placed to relieve tension on the skin. They should not be used over high-tension areas or areas involved in repetitive movement, such as joints, unless the wound is splinted and tension-relieving sutures are used. When tissue adhesive application leads to a suboptimal wound edge apposition, antibiotic ointment, petroleum jelly, or bathing can be used to accelerate removal.

For the repair of very small facial lacerations, the butylcyanoacrylates are equivalent to 5-0 and 6-0 sutures or octylcyanoacrylates. In general, the butylcyanoacrylates are more brittle and friable than octylcyanoacrylates and do not allow the same degree of movement and flexibility of the skin.

Staples

Staples can be applied more rapidly than sutures. Staples are associated with a lower rate of foreign body reaction and a lower infection rate. In general, staples are considered particularly useful for scalp, trunk, and extremity wounds (3). They can also be used when time is limited, such as in situations of mass casualties or multiple trauma. On the other hand, they do not allow as meticulous a skin closure as sutures, and their use is limited when cosmetic appearance is of utmost importance. They are slightly more painful to remove than sutures. In experimental animal models, staples have shown lower rates of bacterial growth and lower infection rates than

sutures, although these effects appear to have limited clinical significance.

Adhesive Tapes

Linear wounds in skin subjected to minimal static and dynamic tensions are easily approximated by tape. The relatively lax skin of the face and abdomen is amenable to wound closure by tape. With tape closures, patients are spared the discomfort of suture removal and the development of suture puncture scars. An additional benefit of this technique is that patients need not be subjected to the painful injection of the local anesthetic agent required for suturing.

Surgical tapes are intrinsically less reactive than staples. However, adhesive tapes require the use of adhesive adjuncts (e.g., tincture of benzoin), which are tissue toxic. Although the various surgical tapes have different degrees of adhesion, porosity, breaking strength, and elasticity, tapes alone will not maintain wound integrity in areas subject to tension. They are seldom recommended for primary wound closure in the ED but are often used after suture removal to decrease tension on the wound until they fall off. The outcome of highly select, small, short, linear, low-tension facial lacerations that are closed with surgical tape is comparable to closure with a tissue adhesive (27).

Complex Issues in Wound Care

Bite Wounds

An estimated 1 to 2 million animal bites are treated each year in the United States. The most frequent complication from bites is infection. Dog bites have an infection rate of 1.4% to 30%, cat bites 15.6% to 50%, and human bites 9% to 18% (14). Most bite wounds are minor. Local wound care always begins with a thorough evaluation of the injury. The location, number, type, and depth of wound are noted. The wound is also assessed for signs of infection. Bite wounds are frequently puncture wounds. Meticulous examination is of utmost importance, as they are notoriously deceptive and may be more

extensive than they initially appear to be. The physician should evaluate all bite wounds for injuries to deep structures such as tendons, joint capsules, blood vessels, nerves, and bone. Local or regional anesthetic should be used to facilitate wound exploration, and a proximal tourniquet may be used when necessary to create a bloodless field. If bony involvement or foreign body is suspected, a plain radiograph should be obtained. Meticulous cleansing, irrigation, and debridement are the essential components of all bite wound care. Irrigation of puncture wounds is controversial. Their small openings do not allow the irrigant solution to drain out appropriately. This may result in infiltration of the tissue. Surgical debridement may be necessary to remove compromised or necrotic tissue that may contain embedded organisms, soil, and clots that cannot be removed by irrigation alone.

Primary closure generally should not be performed for human or extremity bites. Primary closure of dog bite wounds is controversial. Recent studies support primary closure of selected dog bite wounds (28). In one study, 145 head and neck dog bite wounds underwent primary closure without the use of antibiotics, and the wound infection rate was only 1.4% (29). Dog bite wounds to the head and neck that are more than 1.5 cm long can be closed primarily with sutures. Small bite wounds (<1.5 cm) behave like puncture wounds and should be left open to allow for drainage. Patients with bite wounds that require reconstructive surgery should be immediately referred to the appropriate specialist. Hand wounds should be managed without primary closure. However, for cosmetic reasons, facial wounds should be repaired. Other bite lacerations can be closed using delayed primary closure techniques. All injured extremities should be immobilized and elevated. Bites are tetanus-prone wounds, and the recommendations for immunoprophylaxis should be followed (Table 21.1). Domestic and wild animal bite victims should be assessed for the need for rabies postexposure immunoprophylaxis (see Chapter 375).

Puncture Wounds

The feet are the most common site for puncture wounds. There are many different views on the management of plantar puncture wounds (14,30). Some physicians prefer expectant therapy, reacting to complications as they develop. Others pursue invasive exploration for and removal of foreign bodies with subsequent antibiotics in the hope of preventing unusual but devastating infections that can develop.

Infections of plantar wounds can often have serious consequences and lead to disability or amputation. Osteomyelitis, osteochondritis, and septic arthritis are the worst of the complications. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the most common isolates from plantar puncture wound infections. *Pseudomonas* infections are associated with puncture wounds through tennis shoes.

Exploration of plantar puncture wounds for foreign bodies is technically difficult. Foreign bodies that penetrate the plantar fascia are almost impossible to locate through a narrow puncture wound. Irrigation of deep puncture wounds may not be beneficial because the irrigant does not completely drain out of the wound. Some authors recommend enlarging the puncture wound to allow for deeper irrigation and exploration, especially if bone or joint involvement is suspected. Others believe that removing a block of tissue down to the subcutaneous layer allows adequate visualization of accessible foreign bodies and removal of most of the contaminated tissue. Still others simply trim jagged epidermal skin edges. Blind probing and grasping have unknown false-negative rates and may force foreign bodies deeper into the wound. If a wound infection is present, the risk of foreign body is very high, and imaging or exploration is mandated.

Another controversy involves the use of prophylactic antibiotics for this type of injury. Many experts do not recommend the use of antibiotics for new plantar puncture wounds. They argue that antibiotics will not compensate for inadequate initial wound care, they are ineffective in wounds with retained foreign bodies, they may contribute to a gram-negative infection, and wound infections that do not have a retained foreign body respond quickly to initiation of antibiotics. Owing to the difficulty of cleaning and exploring

plantar puncture wounds, physicians should reevaluate these wounds for infection within 2 to 3 days of initial presentation. If infection develops, they should be aggressively explored for a foreign body.

Facial Lacerations

Owing to their cosmetic significance and proximity to important structures, several points concerning the repair of facial lacerations are noteworthy. Because of their rich vascular supply, facial lacerations have a relatively low rate of infection. The risks of high-pressure irrigation (edema making it more difficult to perfectly approximate wound edges) should be weighed against the benefits (cleansing), and individual decisions regarding the use of wound irrigation should be made accordingly. For example, an upper eyelid laceration resulting from a blunt impact with the corner of a table requires minimal irrigation, whereas a contused cheek laceration resulting from a fall onto a rough and dirty surface requires larger volume irrigation.

Whether nongaping facial lacerations require deep sutures is a subject of ongoing debate, but at least one study suggests that nongaping lacerations do not benefit from layered closure (21). Gaping lacerations as well as those in which underlying muscle are involved should be repaired in multiple layers. Meticulous wound approximation should follow important anatomic landmarks such as the forehead or nasolabial creases, the eyebrow, and the vermilion border. When these structures are within a laceration, initial placement of key sutures aligning the landmarks is crucial. Eyebrows should never be removed because they may not grow back.

With lip lacerations, it is important to exclude any underlying dental injuries. If a fractured tooth is not found, careful exploration of the lip wound should be performed to rule out an embedded tooth fragment. Through-and-through lacerations of the lips should be closed in three layers. The first layer should be placed within the oral labial mucosa using a 4-0 or 5-0 absorbable suture. The laceration should then be recleansed now that it is sealed off from the oral flora. The second layer should be placed in the muscle using a 5-0 absorbable suture, and the third layer should be placed in the skin

using a 6-0 nonabsorbable suture. The first suture in the skin should be placed at the vermillion border. Patients should be advised to eat a soft diet and carefully rinse out their mouth after each meal. Prophylactic use of oral antibiotics for lacerations of the oral mucosa that cover oral anaerobes is recommended.

With ear lacerations, it is important to identify any underlying injuries to the cartilage. A field block performed at the base of the ear is helpful with extensive ear injuries. With simple lacerations, primary repair of the overlying skin, ensuring complete coverage of the cartilage, suffices using nonabsorbable 6-0 sutures. Large or gaping lacerations of the cartilage may be closed with a 6-0 monofilament nonabsorbable suture. Any hematoma beneath the skin needs to be evacuated, and a compressive dressing should be placed to ensure adequate contact between the skin and the cartilage. Due to its relative avascularity, necrosis of the cartilage with subsequent formation of a "cauliflower" ear may result if the cartilage is deprived of its vascular supply. With exposure of cartilage, prophylactic oral antibiotic coverage for staphylococcus and pseudomonas is recommended.

With eyelid lacerations, it is crucial to exclude any injury to the lacrimal duct or the tarsal plate. These lacerations, as well as those involving the lid margins and inner surface, should be repaired by a specialist. Bulging of subcutaneous fat suggests violation of the tarsal plate and, along with the presence of ptosis, should always prompt referral. See Chapter 25.

Post Repair Wound Care

Post repair wound care should optimize healing. It must be tailored to both the type of wound and method of wound closure. Sutured or stapled lacerations should be covered with a protective nonadherent dressing for 24 to 48 hours until enough epithelization takes place to protect the wound from gross contamination. Maintenance of a moist wound environment increases the rate of reepithelization. When possible, the site of injury should be elevated above the patient's heart to limit the accumulation of fluid in the wound interstitial spaces.

Topical antibiotic ointments may help reduce infection rates and prevent scab formation. Patients whose lacerations are closed with topical skin adhesives should not have topical ointments applied. They will loosen the adhesive and result in dehiscence.

Prophylactic systemic antibiotic administration should not be used as a regular adjunct to wound care. Several studies and a meta-analysis have found no benefit in prophylactic antibiotics for routine laceration repair (31). Use of antibiotics should be individualized on the basis of the degree of bacterial contamination, the presence of infection-potentiating factors (e.g., soil), the mechanism of injury, and presence or absence of host predisposition to infection. In general, decontamination is far more important than antibiotics. Antibiotics should be used in most human, and extremity bites; intraoral lacerations; open fractures and open joints; or tendon lacerations (3). Additionally, patients with soft tissue lacerations who are prone to the development of infective endocarditis, patients with prosthetic joints and other permanent “hardware,” and patients with lymphedema should receive antimicrobial therapy. Intravenous antibiotics can be given prior to wound care in patients at high risk for systemic complications of infected soft tissue injuries.

Sutured or stapled wounds should be kept clean but can be washed (14). Patients with tissue adhesives may shower, but they should avoid bathing and swimming; prolonged moisture may loosen the adhesive bond. Gentle blotting should be used to dry the area, as wiping could result in dehiscence. Splinting may prove helpful in areas subject to high tension (e.g., in lacerations across joints). Patients should be instructed to observe the wound for erythema, warmth, swelling, and drainage, as these findings, as well as fever, may indicate infection. Use of standardized wound care instructions improves patient compliance and understanding.

Sutures or staples in most locations should be removed after approximately 7 days (Table 21.5). Facial sutures should be removed sooner (within 3 to 5 days) to avoid the formation of unsightly sinus tracts. Sutures subject to high tension (e.g., in joints, hands) should be left in for 10 to 14 days. When tissue adhesives are used, patients should be advised to avoid picking or scrubbing the area and to

avoid exposure of the wound to water for more than brief periods until the previously noted times. When tissue adhesives remain on the skin for prolonged periods, antibiotic ointment, petroleum jelly, or bathing can accelerate removal. Acetone can be used when more rapid removal is required. Patients should be told when and with whom to follow up for suture removal or wound examination. Most wounds do not require scheduled wound checks as patients can be told to watch for the signs and symptoms of infections.

TABLE 21.5
Optimal Time from Placement of Sutures Until Suture Removal

Location	No. of Days
Face	3–5
Oral mucosa	3–5
Scalp	7
Chest	8–10
Back	10–14
Forearm	10–14
Fingers	8–12
Hand	8–10
Lower extremity	8–12
Foot	10–12

Abraded skin and wounds may develop permanent hyperpigmentation after exposure to the sun. Consequently, they should be protected with a sun-blocking agent for at least 6 to 12 months after injury.

Prevention of Tetanus

Two-thirds of the recent tetanus cases in the United States have followed lacerations, puncture wounds, and crush injuries. Proper immunization plays the most important role in tetanus prophylaxis. Recommendations on tetanus prophylaxis are based on the condition of the wound and the patient's immunization history. A summary guide to tetanus prophylaxis of the wounded patient, as recommended by the Centers for Disease Control, is outlined in Table

21.1. As noted, passive immunization with tetanus immunoglobulin is indicated only under specific conditions.

The only contraindication to tetanus and diphtheria toxoids is a history of neurologic or severe hypersensitivity reaction after a previous dose. Local side effects do not preclude repeated use. Local reactions, generally erythema and induration with or without tenderness, are common after the administration of vaccines containing diphtheria, tetanus, and pertussis antigens. These reactions are usually selflimited and require no therapy. If a systemic reaction is suspected to represent allergic hypersensitivity, immunization should be postponed until appropriate skin testing is undertaken. If the use of a tetanus toxoid is contraindicated, passive immunization against tetanus should be considered in a tetanus-prone wound. In those patients who have not completed a primary tetanus immunization series, appropriate follow-up should include referral to a physician who can complete active immunization.

CRITICAL INTERVENTIONS

- Obtain a tetanus immunization history and administer tetanus toxoid if it has not been given within the past 10 years (5 years if the wound is tetanus prone).
- Perform and document a neurovascular assessment distal to the laceration.
- Perform and document a careful wound exploration to exclude foreign bodies and tendon lacerations.

DISPOSITION

The appropriate surgical specialist should be consulted for patients with open fractures of long bones, nerve or vascular injuries, flexor tendon disruptions, repair of specialized structures such as the parotid or lacrimal duct, replacement of skin loss by a flap or graft, or extensive debridement.

Few patients with lacerations will require admission to the hospital. Even those patients requiring surgical intervention can

often be discharged with appropriate follow-up arrangements. Often, definitive repair can be accomplished via same-day surgery.

If the initial receiving hospital does not have the appropriate emergency or surgical specialist, transfer is necessary. The patient should be transferred in the most expeditious manner possible.

Common Pitfalls

- Failure to detect sensory, motor, and vascular complications or injuries to specialized tissues.
- Failure to detect and remove foreign bodies.
- Removing hair with a razor, because it may increase the infection rate.
- Using antiseptic agents such that there is contact between the agent and the wound.
- Using drain placement as a replacement for meticulous hemostasis; drains should be reserved for removal of harmful collections of fluid.
- Using tissue adhesives without appropriate cleansing and exploration.
- Using tissue adhesives in high-tension wounds or over joints.

PART 2 • SPECIFIC INJURIES

CHAPTER 22 Head Injuries

James F. Holmes and Cindy H. Chang

Traumatic brain injury (TBI) is the most common trauma-related cause of death and disability. Blunt head trauma results in more than 5 million emergency department (ED) visits annually, with more than 500,000 of these patients ultimately hospitalized. Although males of age 15 to 40 make up nearly half of all ED visits for blunt head trauma (1), the prevalence of TBI is bimodal, with peaks in the young and in the elderly (1). Traffic accidents (40%) and falls (30%) are the most common mechanisms. Medical and surgical improvements during the past 30 years have resulted in reduced mortality from TBI. Nevertheless, TBI continues to place a heavy cost burden on society (>$60 billion/year) as well as family and caregivers, because surviving patients of moderate to severe TBI frequently require long-term care.

TBI is typically categorized as primary or secondary brain injury. Primary brain injury refers to the irreversible brain damage occurring at the time of initial impact. Injury prevention and education are the primary tools to reduce the incidence of primary brain injury. These interventions include motorcycle and bicycle helmet laws, seatbelt laws, and alcohol preventive measures. Secondary brain injury includes the insults that occur following the initial impact, such as tissue ischemia, hypoxia, reperfusion injuries, and infection that occur minutes to days later. Both prehospital and hospital interventions are designed to prevent or limit the degree of secondary brain injury.

CLINICAL PRESENTATION

The Glasgow Coma Scale (GCS) is the standard method to describe head-injured patients (Table 22.1). The GCS was initially described in 1974 as a tool to standardize the intensive care unit (ICU) description of patients with significant TBI. This scale has subsequently been modified, including the use of a summation score and application in both prehospital and ED evaluations. Intubated patients should be assigned a "T" in the summation score (e.g., GCS = 7 T) to reflect the inability to assign a verbal score. Patients are categorized by their GCS into mild (GCS 14 to 15), moderate (GCS 8 to 13), and severe (GCS <8) head injury classifications. Some authors include a GCS score of 13 in the mild head injury category, but this is more appropriately categorized as moderate head injury, with up to 25% of patients having TBI on cranial computed tomography (CT). The GCS score is crude and current work is aimed at better classification of patients with TBI (2).

TABLE 22.1
Glasgow Coma Scale

Best Eye Opening	
Spontaneously	4
To verbal command	3
To painful stimuli	2
None	1
Best Verbal Response	
Alert and oriented	5
Disoriented	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Best Motor Response	
Follows verbal commands	6
Localizes pain	5
Withdraws from pain	4
Flexure (decorticate) posturing	3
Extension (decerebrate) posturing	2
No movement	1

Patients with TBI frequently have additional injuries that require prompt diagnosis and treatment. Patients should be maintained in cervical spine immobilization until such injury is ruled out. Patients with TBI are at increased risk of having “delayed diagnosis” of their nonhead injuries, as the physical examination is not reliable. Thus, liberal radiographic evaluation is often warranted in those patients with decreased GCS scores.

Epidural hematomas (EDHs) most often occur following damage to an epidural artery (often the middle meningeal artery), typically adjacent to a skull fracture. Injuries to the middle meningeal vein, diploic veins, and venous sinuses can also cause EDH, but these mechanisms are less common. EDH appears as a convex collection of blood on CT scan, resulting from blood dissecting the dura from the inner skull table (Fig. 22.1). The clinical presentation is classically that of a patient who sustains a blow to the head with a brief loss of consciousness (LOC) followed by an awake, lucid interval and then a progressive decline in mental status as the EDH expands. This classic scenario is the exception rather than the rule, however. Patients with EDH require prompt neurosurgical evaluation. Although small EDHs may be managed conservatively with very close observation, symptomatic EDHs require prompt drainage. Morbidity and mortality increase as neurologic symptoms occur.

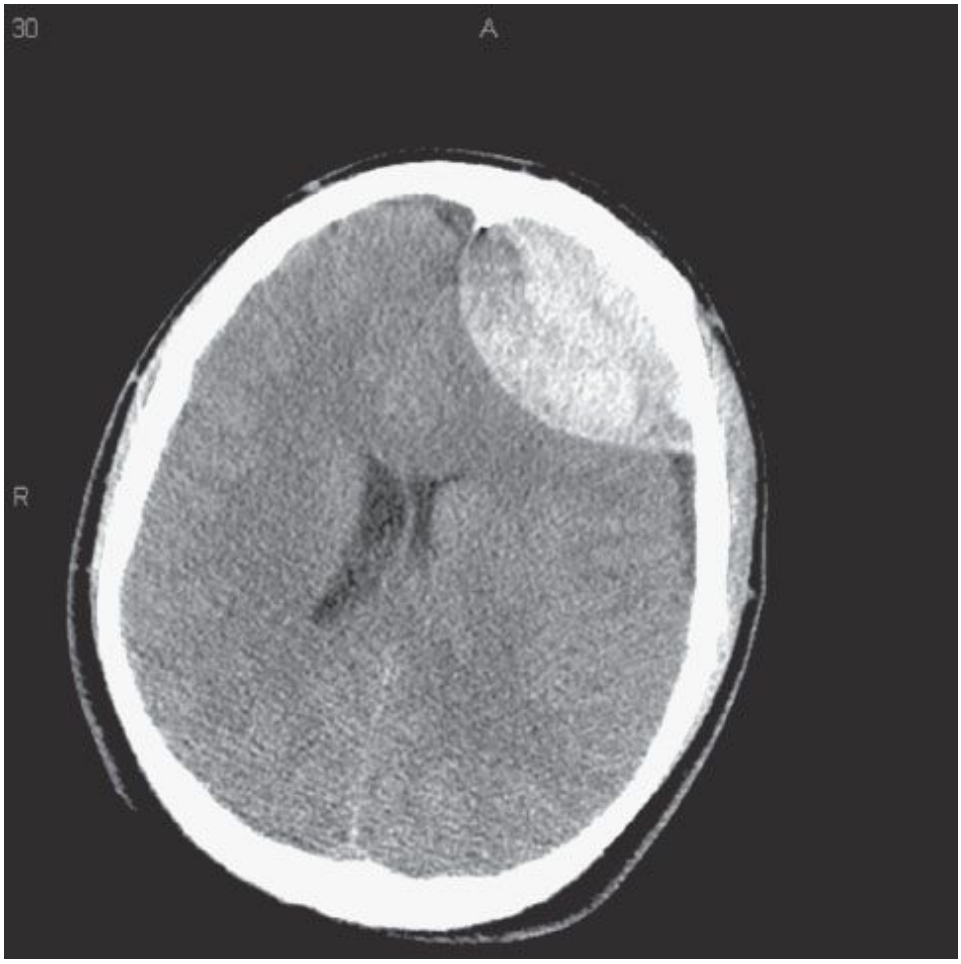

FIGURE 22.1 Left frontal epidural hematoma appears convex as it is restrained in its expansion by the dural membrane. This patient presented with a decreased mental status and decreased movement of his right side.

Subdural hematomas (SDHs) occur with greater frequency than EDHs. The injury is a collection of blood in the subdural space, appearing concave on cranial CT scan (Fig. 22.2). Patients with brain atrophy (particularly alcoholics and the elderly) are at increased risk for SDH because the bridging veins in the subdural space are stretched as brain size decreases. These "stretched" bridging veins are at risk of injury even with minor head trauma. Of all TBIs, SDHs are most likely to have delayed presentations (Fig. 22.3A,B) or present without a history of a significant traumatic event. Some SDHs are managed conservatively, but symptomatic SDH requires

prompt evacuation of clot. As with most TBIs, mortality from SDH increases with increasing patient age. On CT scan, fresh blood from an SDH (and other injuries) appears hyperdense in comparison to brain tissue. From 7 to 14 days after the event, blood becomes isodense with the brain tissue and may be missed if the CT scan is not carefully studied (Fig. 22.3A). Older SDHs appear hypodense compared to brain tissue (Fig. 22.3B).

FIGURE 22.2 Right subdural hematoma appears concave as it tracks below the dural membrane. Note the compression of the right lateral ventricle and the mass effect exhibited by the hematoma as it shifts the brain structures to the patient's left.

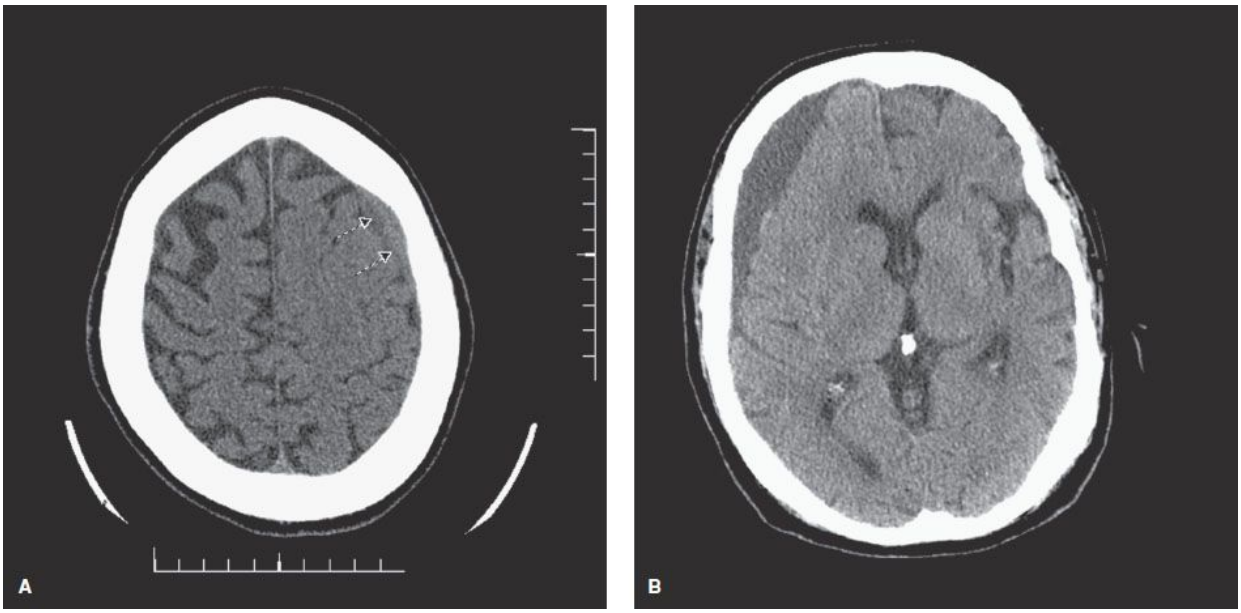

FIGURE 22.3 **A:** Subacute subdural hematoma. The *arrows* outline the isodense collection of blood in the subdural space. Blood becomes isodense on CT scan 1 to 2 weeks after injury. This finding is easily missed if the CT scan is not carefully inspected. **B:** Chronic subdural hematoma. The hypodensity in the right frontal region represents a chronic subdural hematoma. Blood becomes hypodense on CT scan 2 weeks after the injury. Note the small area of hyperdensity within the chronic subdural hematoma. This area represents acute hemorrhage within the chronic subdural hematoma.

Parenchymal contusion is the most common traumatic finding on CT scan following head trauma (1). Contusions are highly variable in size, location, and consistency. They are located anywhere in the brain but are most common in the frontal, temporal, and occipital regions where the skull base has an irregular contour. Size ranges from punctuate (1 mm) hemorrhages to areas several centimeters in diameter. The consistency of the contusion may vary from edematous tissue to necrotic brain tissue to frank hemorrhagic contusion. Contusions frequently evolve throughout time, such that the initial CT scan may show minimal to no contusion, but repeat cranial CT imaging demonstrates the development of a substantial contusion (Fig. 22.4A,B). In addition, contusions can develop over the opposite side of skull impact; these are termed *contrecoup* injuries.

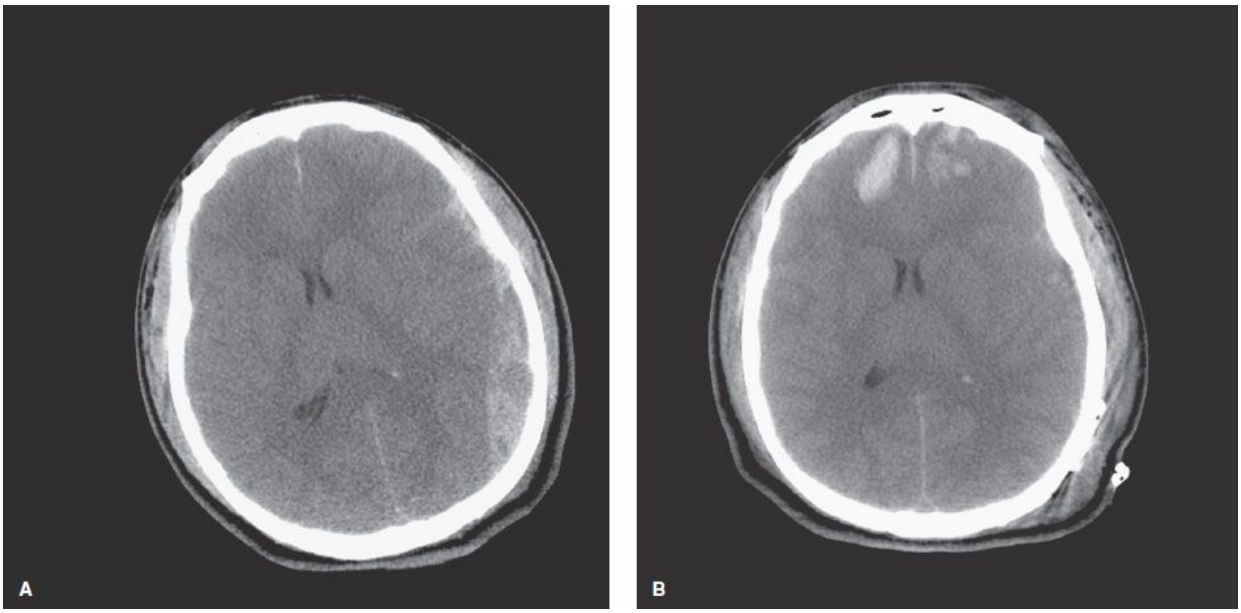

FIGURE 22.4 **A:** Initial cranial CT scan in the ED after acute injury. There is an epidural hematoma (EDH) adjacent to the posterior temporal bone that compresses portions of the left lateral ventricle. **B:** Repeat cranial CT scan in the ICU after craniotomy. The image taken 11 hours after the initial cranial CT scan reveals new bilateral frontal parenchymal hemorrhagic contusions. The previously noted EDH was drained by neurosurgery. Hemorrhagic contusions frequently evolve throughout the initial 24 hours after injury.

Subarachnoid hemorrhage (SAH) is the second most common traumatic finding on CT scan (1). Because the blood disperses within the subarachnoid space, this injury does not usually result in a mass effect. However, coexisting TBIs are frequently present, and the presence of SAH increases the likelihood of morbidity and mortality from these injuries. Cerebral vasospasm occurs 2 to 3 days after traumatic SAH but is generally less frequent and less severe than vasospasm following spontaneous SAH.

Diffuse axonal injury (DAI) occurs when deceleration and rotational shearing forces disrupt axons in the white matter of the brain. The clinical presentation ranges from brief LOC without other clinical symptoms of head injury to coma. This injury is underdiagnosed, as the CT scan is often normal, although cerebral edema and loss of the gray/white junction may be identified.

Magnetic resonance imaging (MRI) is better at characterizing the extent of the injury, although it too may underestimate the degree of injury if there is only limited edema. DAI can be devastating, and no specific treatment beyond supportive care is currently available.

Intraventricular hemorrhage (IVH) is rare and occurs when blood collects within one of the ventricles. In isolation, this injury is unlikely to have clinical implications and can be observed without intervention.

Skull fractures occur after direct blows to the skull and are best identified on CT scan when viewed using a bone window setting (Fig. 22.5). Skull radiographs also demonstrate such fractures, but this radiologic technique has become obsolete with the introduction of CT scanning. Skull fractures are commonly divided into linear, depressed, and basilar types. Basilar skull fracture encompasses the spectrum of fractures occurring along the skull base and is often a clinical diagnosis as CT scanning frequently does not demonstrate the fracture. The temporal bone is the most commonly involved bone, and fractures may be best identified by thin-cut CT scanning. Patients with basilar skull fracture extending into the carotid canal are at increased risk of carotid artery injuries, and CT angiography is thus warranted in these cases. Skull fractures frequently present with associated pneumocephalus (air within the skull) (Fig. 22.5); however, pneumocephalus on cranial CT does not require specific intervention.

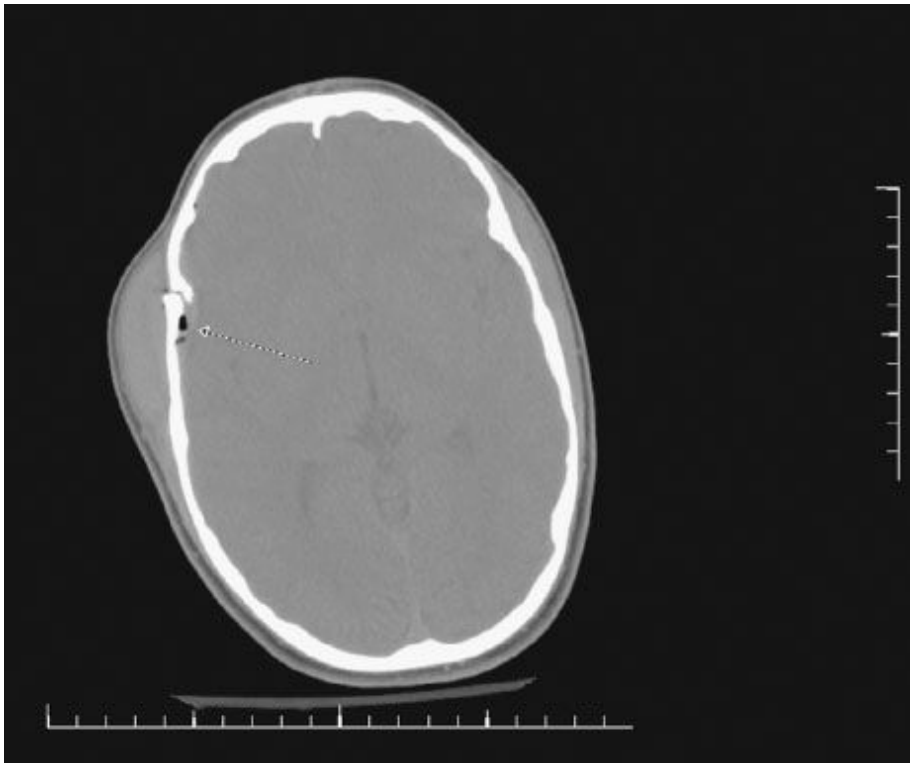

FIGURE 22.5 Cranial CT scan viewed with bone windows. A large cephalohematoma is visible in the right temporal region. The *arrow* identifies a slightly depressed skull fracture and pneumocephalus below the cephalohematoma. The presence of skull fractures and pneumocephalus are best identified with bone windows.

Concussion is the most common type of head injury, often occurring during sports activities. The diagnosis is often given to patients with signs or symptoms of TBI but normal cranial CT scans. Concussive symptoms include traumatic amnesia, headache, nausea, blurry vision, vertigo, sleep disturbance, emotional lability, and difficulty concentrating. Postconcussive syndrome refers to the continuation of these symptoms and may last from weeks to months. The American Academy of Neurology has developed a grading scale and treatment regimen for athletes with concussions (Table 22.2) and recently expanded and updated their recommendations regarding concussion (3). It is imperative that patients sustaining a concussion avoid further head trauma, because repeated concussions pose additive risks. In addition, the Centers for Disease Control

recently developed detailed care plans for patients with concussions (4).

TABLE 22.2
Grading and Treating Concussions in Athletes

	Clinical Description	Treatment
Grade I	Transient confusion, no LOC	
	Concussive symptoms last <15 min	Athlete may return to action once no symptoms for 15 min
Grade II	Transient confusion, no LOC	
	Concussive symptoms last >15 min	Athlete can no longer play in game, may return to contact if no symptoms for 1 wk
Grade III	LOC of any duration	Requires ED evaluation; for brief LOC (<1 min), may return to contact if no symptoms for week; if LOC is prolonged (>1 min), must wait 2 wks without symptoms before return to contact

LOC, loss of consciousness; ED, emergency department.
Adapted from Giza CC, Kutcher JS, Ashwal S, et al. Summary of evidence-based guideline update: Evaluation and management of concussion in sports: Report of the Guideline Development Subcommittee of the American Academy of Neurology. *Neurology.* 2013;80(24):2250–2257 and Practice parameter: The management of concussion in sports (summary statement). Report of the Quality Standards Subcommittee. *Neurology.* 1997;48(3):581–585.

Traumatic sinus thrombosis is a rare occurrence after injury. Traumatic sinus thrombosis is suspected based upon cranial CT findings and confirmed with MRI and magnetic resonance angiography (MRA). Treatment is controversial but includes heparin if there are no contraindications to such therapy.

Brain herniation is an ominous finding. Transtentorial herniation occurs when a space-occupying mass depresses brain tissue (usually the uncus) below the tentorium. The third cranial nerve is also compressed, resulting in pupillary dilation (“blown pupil”) on the side of the lesion. Subfalcine herniation involves midline shift of the cingulate gyrus, compressing the anterior cerebral artery and producing brain ischemia.

Penetrating head injury occurs most frequently with firearms. Immediate cranial CT scanning is imperative to identify the path of the penetrating object and associated injuries. Shock waves associated with high-velocity bullets damage tissue beyond the bullet's actual path, requiring careful observation for further swelling of the tissue around the tract. Mortality from gunshot wounds to the head is >50% and increases significantly if the bullet crosses the midline. Objects such as knives and nails that are impaled into the skull require cranial CT scanning and neurosurgical consultation to determine the appropriate location for removal (operating suite vs. the ED).

DIFFERENTIAL DIAGNOSIS

The ED presentation of patients with TBI is usually straightforward. Standard protocols for the evaluation and management of the trauma patient are followed, but one must always consider the contribution of underlying medical illnesses to the patient's presenting condition. Careful consideration of both traumatic and nontraumatic causes for decreased mental status will minimize the risks of failing to reach a correct diagnosis. Stroke, seizure, hypothermia, hyperthermia, hypoglycemia, electrolyte disturbances, alcohol intoxication, and drug overdose may all result in decreased mental status and mimic TBI, especially if the patient has some evidence of head trauma. Furthermore, the physician should always consider a medical cause as the precipitant of the traumatic event. Frequently, a complete and reliable history cannot be obtained, and proper management requires maintenance of a broad differential diagnosis and systematic exclusion of medical conditions through appropriate and thoughtful diagnostic testing.

ED EVALUATION

The evaluation of head injured patients starts with prehospital management and transportation to an appropriate facility. The Brain Trauma Foundation developed guidelines for the prehospital management of patients with TBI (5). Prehospital providers typically institute spinal immobilization, oxygenation, and immediate

transport. Although intravenous (IV) access and fluid resuscitation is controversial in the hypotensive patient with penetrating trauma, the hypotensive patient with a blunt mechanism should receive fluid resuscitation to support the blood pressure and minimize secondary brain insults. Prehospital airway management is controversial, as evidence is conflicting (5–8). Reasons for adverse outcomes with prehospital intubation include a combination of hypoxic episodes during intubation attempts and hyperventilation or hypoventilation after definitive airway establishment (7,8). Prehospital rapid sequence intubation is not recommended for patients with short transport times who are spontaneously breathing and are not hypoxic (5). Those prehospital systems electing to include prehospital intubation in trauma protocols must ensure that paramedics have adequate airway experience and that end-tidal CO_2 monitoring is not only available but followed to assure normocarbia.

Prehospital triage protocols should function to match patient needs with the resources available at the destination hospital. Patients with prehospital GCS scores <14 require transportation to the nearest designated trauma center. The hospital destination for patients with minor head injuries (GCS ≥ 14) is more controversial. At a minimum, these patients require transportation to a center with immediate CT scanning capabilities and the ability to rapidly transport if neurosurgical consultation is needed but not available.

Initial ED trauma evaluation centers on the primary and secondary trauma surveys. Proper assessment of the airway, breathing, and circulatory status is critical, as a single episode of hypotension (systolic blood pressure <90 mm Hg) nearly triples the mortality risk and an episode of hypoxia (O_2 saturation $<90\%$) doubles this risk (9). Thus, aggressive evaluation and treatment is essential to prevent complications related to hypotension and hypoxia. Hypotension secondary to brain herniation is an ominous finding and suggests impending death. Cushing reflex (hypertension with bradycardia) also suggests impending death and indicates the need for rapid treatment. Neurologic components assessed in the primary survey include an initial GCS score and identification of any obvious motor deficits (i.e., confirming movement in all extremities).

A detailed head examination and neurologic examination is performed and documented in the secondary survey, although it may not be possible to perform these well in severely injured patients. Care is taken not to delay diagnosis and treatment to perform a detailed examination. However, findings pertinent to patients with head injuries should be documented, including all abrasions and lacerations, violations of the galea and/or the skull, contusions and hematomas, and findings suggestive of basilar skull fracture. Basilar skull fracture is primarily a clinical diagnosis confirmed by the presence of raccoon's eyes (periorbital ecchymosis), Battle sign (mastoid ecchymosis), hemotympanum, or cerebrospinal fluid (CSF) drainage from the nares. Battle sign, and to a lesser degree, raccoon's eyes, are late findings that generally appear 12 to 24 hours after injury. CSF is often difficult to differentiate in patients with epistaxis. The "halo test" aids in the identification of CSF rhinorrhea. Bloody fluid from the nares is dropped on a sheet of filter paper, and a positive "halo test" occurs if a clear halo forms around this fluid, suggesting the presence of CSF. Neurologic examination includes pupillary size and response to light, cranial nerve function, motor and sensory function, deep tendon reflexes, and proprioreception. A focal neurologic deficit suggests a space-occupying brain lesion (Fig. 22.1). All penetrating injuries are identified and documented, as this aids in determining the trajectory of the object. Determining entrance and exit wounds is difficult and does not alter initial patient care.

Brainstem function should be tested in patients with coma. The corneal reflex is tested by lightly brushing the cornea with a sterile cotton swab. Patients with an intact brainstem blink, whereas no response indicates absence of brainstem function. The oculovestibular reflex is tested using the cold caloric test. Injecting ice water against an intact tympanic membrane induces nystagmus; if the eyes fail to move, the brainstem is not functioning.

The secondary survey also includes a detailed history. Alternative sources (family, friends, other witnesses, and paramedics) are sought when the history is not obtainable from the patient. Certain events (e.g., syncope, seizure) may guide the need for a medical evaluation

in addition to the trauma evaluation. The identification of potential risk factors for TBI and thus the need for CT scanning are sought from awake patients and include traumatic amnesia, LOC, headache (location and severity), nausea, seizure, vomiting, neurologic complaints, and visual changes. The patient's past medical history is critical and must include current medications, especially the use of anticoagulants. Patients who take anticoagulants, especially clopidogrel and warfarin, are at increased risk of TBI and its complications. Prompt evaluation, laboratory testing, and cranial CT scanning are critical in all patients on clopidogrel or warfarin, regardless of how minor the head trauma may appear (10). Physicians should be aware of new oral anticoagulants available (Dabigatran, Rivaroxaban, and Apixaban), as the risk for intracranial hemorrhage after blunt head trauma is believed increased but not formally studied.

Radiographic evaluation is central to the ED evaluation and treatment of patients with head injuries. Cranial CT scanning allows rapid identification of TBI and skull fractures so that educated management decisions can be made. The prevalence of TBI on cranial CT scan increases as the GCS decreases, ranging from 2% to 5% in patients with GCS scores of 15% to >90% in patients with GCS scores of 3. There are several CT grading scales, but the Marshall CT grading system is most commonly used and predicts mortality when combined with age and the GCS score (11).

Trauma cranial CT scanning is performed without IV contrast. Thus, cranial CT scanning is obtained prior to any contrast study (chest CT, abdominal CT, angiography), as residual IV contrast mimics SAH on CT. A 4- to 6-hour delay after a contrast study is recommended before undergoing a noncontrast cranial CT scan. However, if the patient's mental status rapidly deteriorates cranial CT should not be delayed, as large space-occupying masses are identified regardless of prior contrast administration.

The indications for cranial CT scanning after blunt head trauma have been the subject of significant research efforts in recent years. Appropriate selection of patients for CT should decrease both the rate of missed TBI and the rate of negative cranial CT scanning.

Cranial CT has inherent risks including radiation-induced malignancy, time, and cost, although these risks should not limit its use in the patient at risk for TBI. Patients with GCS scores <15 require immediate cranial CT scanning. Although some have suggested that selective cranial CT scanning be employed in those with GCS scores of 14, these patients have a risk of TBI on CT scan that approaches 15% and should thus undergo immediate cranial CT scanning (12).

Cranial CT scanning in patients who have GCS scores of 15 is more controversial. The New Orleans Cranial CT rule was developed in patients with ED GCS scores of 15 and a history of LOC (13). This rule had a sensitivity of 100% (95% CI 95, 100%) for TBI on CT scan but a specificity of only 25% (95% CI 22, 28%). The rule's criteria for obtaining a CT scan included headache, vomiting, age >60, drug or alcohol intoxication, deficits in short-term memory, and physical evidence of trauma above the clavicles. The variable "physical evidence of trauma above the clavicles" was the least helpful, and most patients with this variable as their only abnormal finding did not benefit from CT scanning. The Canadian Cranial CT rule was developed on a multicenter population of patients with initial ED GCS scores ≥ 13 and a history of LOC or traumatic amnesia (14). The "moderate risk" criteria using this rule consist of failure to reach a GCS score of 15 within 2 hours, open skull fracture, evidence of basilar skull fracture, vomiting two or more episodes, age ≥ 65, amnesia before impact >30 minutes, and a dangerous mechanism of injury. The rule had a sensitivity of 98% (95% CI 96, 99%) and specificity of 50% (95% CI 48, 51%) for predicting clinically important TBI on CT scan. The dangerous mechanism of injury variable consists of 10 descriptive mechanisms, making it difficult for the busy clinician to remember and use. The NEXUS Cranial CT rule was derived on a multicenter population of patients undergoing cranial CT scanning in the ED (15). This rule was designed to identify a population at such low risk for TBI that cranial CT scan is *not* indicated. The rule consists of age <65, no evidence of skull fracture, no scalp hematoma, no neurologic deficit, normal alertness, normal behavior, no coagulopathy, and no persistent vomiting. The

rule had a sensitivity of 98% (95% CI 97, 99%) and a specificity of 14% (95% CI 13, 14%). Validation of these rules has been difficult but the Canadian CT rule appears to perform best. Unfortunately, implementation of these rules has been challenging and has the potential to increase rate of cranial CT scanning.

KEY TESTING

Together, these and other studies suggest that patients undergo cranial CT scanning in the ED for the following high-risk findings:

- GCS <15
- Head trauma on anticoagulation (i.e., clopidogrel, warfarin)
- GCS of 15 with LOC/amnesia and any of the following
  - Vomiting
  - Age >60
  - Abnormal mental status
  - Evidence of any type of skull fracture

Patients who have a GCS score of 15 and a LOC/traumatic amnesia are also considered for CT scanning, as there is still a small but increased risk of TBI if the patient has any of the following:

- Headache
- Deficits in short-term memory
- Dangerous mechanism of injury
- Alcohol intoxication

With the introduction of CT scanning, skull films have fallen out of favor because of the high false-negative rate and are now limited only to the youngest patients. MRI provides more detail about the extent of TBI, especially parenchymal contusions, DAI, and brainstem and posterior fossa injuries. CT scanning provides better definition of SAH and skull fractures, but MRI is otherwise more sensitive. MRI is more time consuming, expensive, and complicated, and thus it is not routinely used in the ED evaluation of head-injured patients.

Investigators have recently attempted to identify neuro-biomarkers to aid in both appropriate cranial CT utilization and predicting adverse outcomes in those with TBI. S-100B, a protein produced by certain astrocytes, is most studied and levels <0.1

μg/L within 4 hours of injury suggest a very low risk of intracranial hemorrhage on CT. It has, however, failed to demonstrate improvement from clinician judgment and currently, along with other neuro-biomarkers, remains experimental.

ED MANAGEMENT

A definitive airway with a cuffed endotracheal tube is required for patients who are unable to maintain their airway or who have GCS scores ≥ 8. Recommendations for airway management in TBI patients include the use of potentially cerebroprotective agents. Fentanyl and defasciculating dosages of paralytics are recommended, although fentanyl may carry a small risk of inducing hypotension in patients with tenuous volume status. Pretreatment with lidocaine (1 mg/kg IV) to blunt the rise in intracranial pressure (ICP) associated with laryngoscopy and succinylcholine administration is controversial, but the downside of this intervention is minimal (16,17). Oxygenation should be maximized by preoxygenating the patient prior to intubation and providing supplemental oxygen to those who are not intubated. The ventilated patient requires close monitoring of tidal volumes to prevent hypercapnia and hypocapnia; CO_2 levels can be followed with end-tidal CO_2 monitoring or arterial blood gas measurements.

The patient's volume status should be continuously assessed, and fluid resuscitation with crystalloid and blood is provided to support blood pressure. Normal saline is preferred, as lactated Ringer solution is hypo-osmolar and might theoretically worsen cerebral edema. Hematocrit measurements and blood transfusion are indicated to maximize the patient's oxygen-carrying capacity. Recent evidence suggests a target hemoglobin level of 9 to 10 g/dL is warranted in TBI patients. Additional laboratory measurements should include platelet count, coagulation studies, a chemistry profile, ethanol level, toxicologic screen, type and screen, and rapid glucose assessment.

The Brain Trauma Foundation provides evidence-driven treatment guidelines for patients with significant TBI (18). Medical and surgical

treatment in patients with TBI should maximize cerebral perfusion pressure (CPP), which is calculated as mean arterial pressure (MAP) minus ICP (CPP = MAP − ICP). Ideally, CPP is maintained between 50 and 70 mm Hg. Unfortunately, ICP is not initially available in the ED, and treatment must thus be based on clinical findings and cranial CT scan results. Once ICP monitoring is established, treatment is guided by the CPP.

Mannitol is an osmotic diuretic that can be used to reduce ICP. The dosage ranges from 0.25 to 1 g/kg IV as a bolus (not a continuous infusion because of the risk of concentrating mannitol in brain tissue and subsequent worsening of cerebral edema). Mannitol's positive effect on ICP is twofold: (a) immediate plasma expansion, with improvement in red blood cell membrane deformability and subsequent increased cerebral blood flow and (b) increased plasma osmolarity and an osmotic diuresis, leading to a decrease in cerebral edema that is noted by 30 minutes after administration and lasts 90 minutes to 6 hours. Indications for mannitol prior to CT or ICP monitoring include signs of transtentorial herniation or progressive neurologic decline from TBI. Because of its osmotic effect and the risk of hypotension, mannitol should not be administered in patients whose volume status has not been optimized.

Patients with TBI have an increased risk of both early ($\geq$7 days) and late (>7 days) posttraumatic seizures. The prevalence of early posttraumatic seizures ranges from 4% to 25%. Seizures increase ICP and cerebral metabolism, and prophylaxis is thus recommended to prevent their occurrence. Risk factors for posttraumatic seizures include a GCS score <10, EDH, SDH, cortical contusion, and depressed skull fracture. Patients with significant TBI should receive a 7-day course of antiseizure medications. Phenytoin (18 mg/kg IV load), levetiracetam (1 g IV), and carbamazepine (100 mg orally [PO] tid) are preferred instead of valproic acid because of concerns of higher mortality with valproic acid in TBI patients. Seizure prophylaxis is not recommended for the prevention of late posttraumatic seizures, as studies have not shown that it confers a benefit.

Recognition and prompt treatment of coagulopathy, either preexisting or as a result of brain injury, is critical in TBI patients. Patients on warfarin with TBI on cranial CT scan require immediate treatment with plasma once the diagnosis is made. Many centers now administer low-dose recombinant factor VIIa (40 μg/kg IV) or prothrombin complex concentrates to immediately reverse coagulopathy in TBI patients. Trauma-induced coagulopathy occurs in nearly 20% of patients with TBI, as thromboplastin that is released from damaged brain tissue activates the clotting cascade (19). Patients with moderate to severe TBI are at increased risk of coagulopathy, and careful monitoring and aggressive treatment, if necessary, are warranted to prevent progression of the intracranial hemorrhage.

Adequate analgesia and sedation are important in patients with severe TBI. Options include morphine (4 to 10 mg/h), fentanyl (2 to 8 μg/kg/h), midazolam (2 to 5 mg/h), and propofol (20 to 75 μg/kg/min). Propofol improves ICP but has not been shown to improve mortality or 6-month outcomes. Barbiturate coma is only recommended for patients who fail standard medical and surgical treatment.

Isolated linear skull fractures can be observed and may not require hospitalization. Depressed skull fractures may require operative therapy to elevate the depressed bone fragment, and thus neurosurgical consultation is indicated for these injuries. Fractures that are depressed more than the thickness of the skull bone are most often repaired. Basilar skull fractures involving the temporal bone require ears, nose, and throat (ENT) consultation, as the auditory bones may be disrupted, resulting in varying degrees of hearing loss. Meningitis is a rare complication ($<5\%$) in these patients; prophylactic antibiotics are not believed to be effective. Direct measurement of the ICP through a ventriculostomy catheter is recommended in patients with GCS ≥ 8 and traumatic findings on cranial CT scanning although a recent trial questions the benefit of ICP monitoring (20). Some centers employ ICP monitoring in comatose patients with normal cranial CT if the patient is >40 years, has neurologic posturing, or is hypotensive. Treatment is instituted

when ICP is >20 mm Hg. There is no evidence that prophylactic antibiotics at the time of catheter insertion prevent infection. The procedure can be performed in the ED by experienced personnel.

Craniotomy can be lifesaving in patients with TBI. Indications for craniotomy include an expanding mass lesion (EDH or SDH), significantly depressed skull fracture, or penetrating injuries with signs of preserved brain function. Patients with EDH or SDH who have decreased mental status (GCS <13), focal neurologic findings, clinical signs of herniation, or shift on CT require emergent craniotomy for hematoma drainage. Signs predicting the need for craniotomy in TBI patients with an initial GCS score of 15 include vomiting, restlessness, a decline in GCS, severe headache, confusion, and temporal bone trauma (21).

Hyperventilation was once a standard initial therapy for patients with severe TBI because it causes a decrease in ICP. More recent evidence suggests that hyperventilation can be harmful. Routine hyperventilation to a partial pressure of arterial carbon dioxide ($PaCO_2$) of 25 mm Hg is thus no longer recommended, and hyperventilation is avoided during the initial 24 hours of resuscitation. Currently, hyperventilation is recommended only as a final effort to control ICP after other interventions have failed. Steroids have long been used to treat malignancy-induced cerebral edema. However, multiple studies, including a large randomized controlled trial of 10,008 patients (22), have demonstrated increased mortality in TBI patients who receive steroids.

Studies evaluating prophylactic hypothermia for severe TBI have yet to identify a population or specific regimen that reduces morbidity or mortality. Current evidence suggests that hypothermia must be maintained for at least 48 hours followed by slow rewarming to have an impact on mortality. Rapid rewarming is to be avoided as it causes cerebral edema. Additional research is required before this treatment can be accepted. Use of hypertonic saline (3% to 7.5% saline) may improve outcomes in head-injured patients, but a large randomized controlled trial demonstrated no benefit when given in the field. Thus, definitive recommendations await further investigation. Hypertonic saline causes an osmotic shift of free water

from brain tissue, thus potentially reducing cerebral edema in patients with intact blood–brain barriers. Finally, recent work failed to show benefit of administering progesterone in patients with moderate to severe TBI. An ongoing multinational study is currently evaluating tranexamic acid in patients with GCS scores <13 or TBI on CT scan.

CRITICAL INTERVENTIONS

- Determine the need for cranial CT in patients with minor head trauma.
- Establish and maintain a definitive airway, and prevent hypoxia (maintain O_2 saturation $>90\%$) in patients with severe head injury.
- Use adequate volume resuscitation to maintain systolic blood pressure >90 mm Hg.
- Maintain cervical spine protection, and perform appropriate radiologic evaluation (CT scan).
- Administer seizure prophylaxis in patients who are at risk.
- Obtain immediate neurosurgical consultation, and ensure appropriate disposition of patients with significant TBI.

DISPOSITION

Patients with intracranial hemorrhage on their cranial CT scan warrant surgical consultation. The elderly (>65 years) and those with GCS scores <15 are hospitalized in ICUs for close neurologic observation. Disposition of patients <65 years with GCS scores of 15 and intracranial hemorrhage on CT, however, is highly variable (23). Risk for intervention in this population is very low and many can be managed with ward admission or in an ED observation unit, thus saving intensive care resources. Facilities without neurosurgical capabilities must safely transfer patients with intracranial hemorrhage on CT to appropriate treating facilities. Such patients should be transferred expeditiously and should not undergo extensive diagnostic testing that may delay their transfer. Cranial CT scan images, if obtained, must be sent with the patient at the time of

transfer. With expanded electronic and Internet capabilities, cranial CT images can now be digitally transferred to neurosurgeons at the accepting facility.

Patients with mild head injury may be safely discharged home following normal cranial CT scans (24). Appropriate discharge instructions for head-injured patients are essential, especially if the patient is on warfarin or has not undergone CT scanning. Because of the risk of delayed hemorrhage, the most conservative trauma centers may admit patients on warfarin for close observation despite normal cranial CT scans, although the risk of delayed hemorrhage is less than 1% (10). Appropriate ED discharge involves assessing how well the patient can be observed outside the ED and how reliably he or she can be returned to the ED if signs and symptoms of TBI develop. Both the patient and the caretaker should be made aware of the signs and symptoms of progressing TBI (e.g., increasing headache, vomiting, alterations in mental status, and seizure).

Appropriate information and follow-up should be provided to patients with concussions. Athletes with concussions are advised to follow up with a physician and must be asymptomatic for at least 1 week before they are allowed to return to contact sports (Table 22.2) (3,25).

Common Pitfalls

- Failure to recognize the need for cranial CT scanning in patients with minor head injury who are at risk for TBI.
- Failure to identify other causes for decreased mental status in the trauma patient, including alcohol or drug (narcotic) intoxication, medication overdose, hypoglycemia, seizure, hypothermia, hyperthermia, electrolyte disturbances, and stroke.
- Inadequate airway protection in patients with moderate to severe TBI and failure to appropriately fluid resuscitate the hypotensive or marginally stable head-injured patient.
- Inappropriate hyperventilation of patients with TBI. Hyperventilation is a last-ditch effort after other interventions have failed.

- Failure to give appropriate discharge instructions to patients with minor head injury.

CHAPTER 23 Maxillofacial Injuries

Katie Sprinkel and Stephen Colucciello

There is substantial regional variation in the etiology of facial trauma, and in the developed world interpersonal violence has surpassed motor vehicle collisions (MVCs) as the most common cause of facial fractures (1). The use of seat belts as restraint devices in vehicles has been repeatedly shown to result in a decreased incidence of facial lacerations and fractures, whereas the protective effect of airbags is less clearly established in facial trauma (2). Other causes include falls, sports injuries, and gunshot wounds, with gunshot wounds and MVCs resulting in the highest injury severity (1). The most frequently fractured facial bones in descending order are the nasal bones, orbital floor, zygomaticomaxillary complex, maxillary sinuses, and mandibular ramus (1).

CLINICAL PRESENTATION

The presentation of maxillofacial trauma depends largely on the mechanism of injury; understanding the mechanism of injury can aid in predicting the severity and risk for associated injuries. Patients who sustain significant blunt trauma (e.g., MVC) often suffer multiple injuries, and their initial evaluation and stabilization should follow a standard trauma protocol. Neglecting potentially serious chest, abdominal, or pelvic injuries in the multiple-trauma patient with distracting facial deformity is a dangerous error. Facial injuries in women in particular are a marker for intimate partner violence, which is underreported and should be investigated when taking the patient's history. Studies estimate between 1/3 and 2/3 of women who present with facial trauma are victims of intimate partner

violence (IPV), and the most common injuries are to the midface (3). Overall, assaults most frequently involve young males as the perpetrators with alcohol being the main contributing factor. Mandibular, orbital floor, nasal, and zygomaticomaxillary complex fractures most commonly result from assault, whereas MVCs tend to cause more complex midface injury patterns (1).

Victims of penetrating maxillofacial trauma are less likely to have serious injuries to distant organ systems but may experience injury to the globe, brain, or neck. High-velocity injuries have a high rate of airway compromise, with nearly a third requiring urgent airway control, either intubation or a definitive surgical airway (4). The emergency physician must be particularly attuned to both central nervous system (CNS) and vascular injury in penetrating trauma as well.

Airway compromise and management of hemorrhage are the most urgent concerns in maxillofacial injury. Airway problems can result from a posteriorly displaced tongue, dislodged teeth, oral hemorrhage and vomitus, or injury to the soft tissues surrounding the airway. A decision for definitive airway control is based on the patient's level of consciousness, severity of injury, risk for aspiration or airway obstruction by delayed edema, and hematoma formation (5). Clinicians who elect to perform blind nasotracheal intubation should be aware of the rare risk of intracranial placement of the endotracheal tube (6). The risk of delayed airway compromise has prompted some authors to recommend intubating patients who present with significant intraoral blood or moderate-sized hematomas in the neck or face, although definitive support in the literature is lacking (7). For patients who require transfer for definitive care, the emergency physician should consider the risk of developing airway compromise en route to the trauma center and complications may increase with the length of transport. When in doubt, it is best to obtain a definitive airway prior to transport. Given the significant vascularity of facial structures, maxillofacial trauma may infrequently result in enough blood loss to cause hypotension and, rarely, exsanguination. The incidence of severe hemorrhage ranges from 1% to 11%, with the highest incidences

occurring in patients with midfacial fracture (8,9). The tamponade effect of the facial musculature combined with the relative accessibility for direct pressure makes life- threatening hemorrhage in adults relatively uncommon.

DIFFERENTIAL DIAGNOSIS

The sometimes dramatic appearance of facial trauma may distract the examining physician from more serious injuries. Once the airway is ensured and brisk facial bleeding controlled, other life threats must be quickly and systematically excluded. Then, the emergency physician should attempt to specifically address bony and soft tissue facial injuries.

Brain injury is the most common associated injury, occurring in up to 79% of patients with single facial fracture, and 88% of patients with two or more facial fractures (10). Previously, some suggested that facial fractures may decrease the risk for intracranial injury. Recent evidence supports the contrary, noting that patients with facial fractures, especially involving the midface, actually have an increased risk of traumatic brain injury (10). This link suggests that the clinician should have a low threshold for performing head computed tomography (CT) in patients with any facial fracture, especially those who have altered mental status, neurologic deficit, or perhaps a worrisome mechanism of injury. The converse is also true. In one study, 10% of comatose blunt trauma victims had significant unsuspected facial bone fractures that were diagnosed by routine facial CT (11).

The incidence of concomitant cervical spine fracture in the setting of facial fracture is not insignificant, reports range from 1% to 8% with that number increasing with number of facial fractures (10,11). The use of the Nexus or Canadian Cervical Spine Rules provides evidence-based guidelines for cervical radiography and the presence or absence of a facial fracture alone should not determine the need for cervical spine imaging unless it is considered a “distracting injury.” See Chapter 28, “Cervical Spine Fractures” (12). There is some data to suggest that facial fracture is a risk factor for injury to the carotid or vertebral vessels, which is more frequent in blunt

trauma than previously recognized. Recent guidelines recommend imaging (CT angiography) to screen for cerebrovascular injury if the patient has displaced midface or complex mandibular fractures (13).

Loss of vision is another significant concern, occurring in as high as 6% of maxillofacial trauma. Visual testing and red color perception are the most useful tests but not always possible in the unconscious patient. Pupillary size and shape, reactivity to light, lid lacerations and globe tension to palpation may also reveal important clues to ocular or periorbital injury (14,15).

ED EVALUATION

Aside from airway concerns, maxillofacial injuries are seldom life threatening. However, other organ system injuries carry significant morbidity and potential mortality. *After* resuscitation and addressing significant injuries to other organ systems, the emergency physician should perform a thorough and directed examination of the face. Anatomic complexity, swelling, lacerations, pain, and altered level of consciousness pose challenges to an optimal physical examination. A systematic approach can help surmount these challenges.

A complete history, including specifics about the mechanism of injury, should be obtained, ensuring that certain injuries are not overlooked. High-yield general questions include the presence of loss of consciousness, facial numbness, weakness, and visual disturbances. Specifically, for periorbital injuries, the emergency physician should ask about blurred vision, pain on extraocular motion, and diplopia. Monocular diplopia indicates a problem with the lens or retina in a single eye; binocular diplopia that involves eye movement suggests nerve palsy, muscle injury, or entrapment. For midface and jaw injuries, ask about dental malocclusion and trismus.

The emergency physician should begin with inspection and evaluate the patient from multiple perspectives. This should include both the “bird’s eye view” as well as the “worm’s eye view,” which involves inspection from above and below to reveal subtle facial asymmetries. Loss of contours, edema, ecchymosis, and hemorrhage are clues to soft tissue and underlying bony injuries (eFig. 23.1). Facial elongation in the frontal plane can occur with high-grade Le

Fort fractures (“donkey” facies) (16). Ecchymoses around the eyes (raccoon eyes) and over the mastoid areas (Battle’s sign) are associated with basilar skull fractures. Raccoon eyes, which usually take several hours to develop, are nonspecific and may be associated with nasoorbitoethmoid (NOE) injuries, Le Fort, orbital, and frontal bone fractures. Facial function is tested by examining the muscles of facial expression. Patients should be asked to close their eyes tightly, raise their eyebrows, purse their lips, smile, and frown. Fractures of the temporal bone may be associated with a posttraumatic Bell palsy with weakness of the facial muscles on the affected side (16). Difficulty with opening and closing the mouth may be secondary to jaw muscle spasm, or it is less commonly associated with fractures of the mandible, zygoma, or maxilla. Evaluating extraocular motions is just as important as testing facial function. Inability to gaze upward or downward, exophthalmos, or enophthalmos can be associated with periorbital fractures. Pain with extraocular movements suggests an occult periorbital fracture. The eye examination should encompass visual acuity, examination of the anterior chamber and pupil, extraocular motions, ptosis, periorbital sensation, and the swinging flashlight test to assess for a Marcus Gunn pupil (see Chapter 25). The ear canal is inspected for any lacerations or clear fluid leak that may represent cerebrospinal fluid (CSF). Using an otoscope, the tympanic membrane is examined for evidence of rupture or hemotympanum, seen as a purplish bulge of the membrane. This finding is associated with basilar skull fracture and fractures of the mandibular condyles. The external ear is examined for otohematomas, which can result in chronic deformity called “cauliflower ear.” In the nose, the most important findings include septal hematoma and CSF rhinorrhea. A septal hematoma is a bluish colored, bulging septal mass that is tender and boggy to palpation.

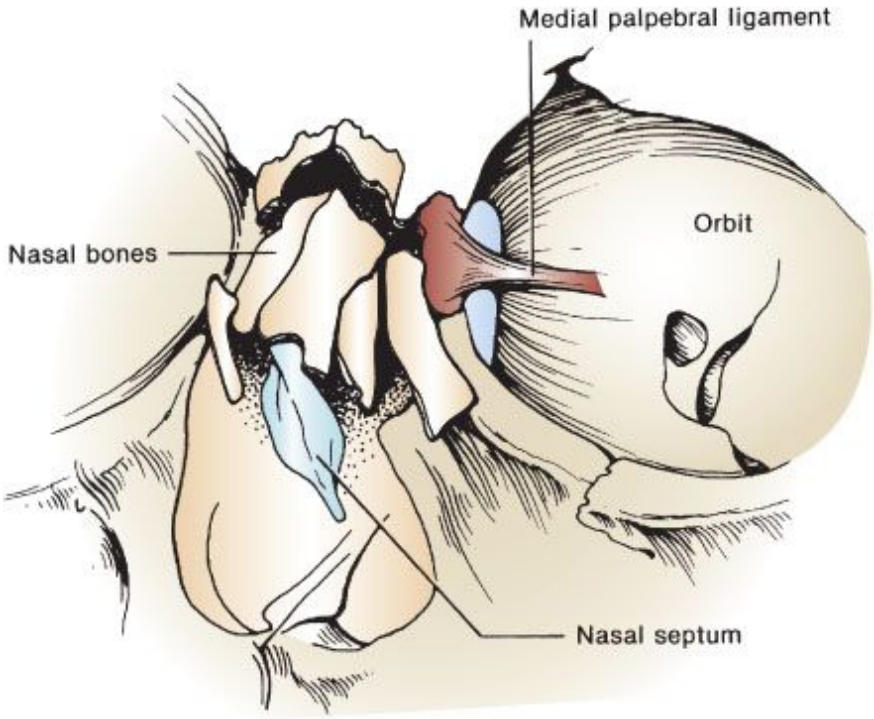

FIGURE 23.1 Nasoethmoidal fractures.

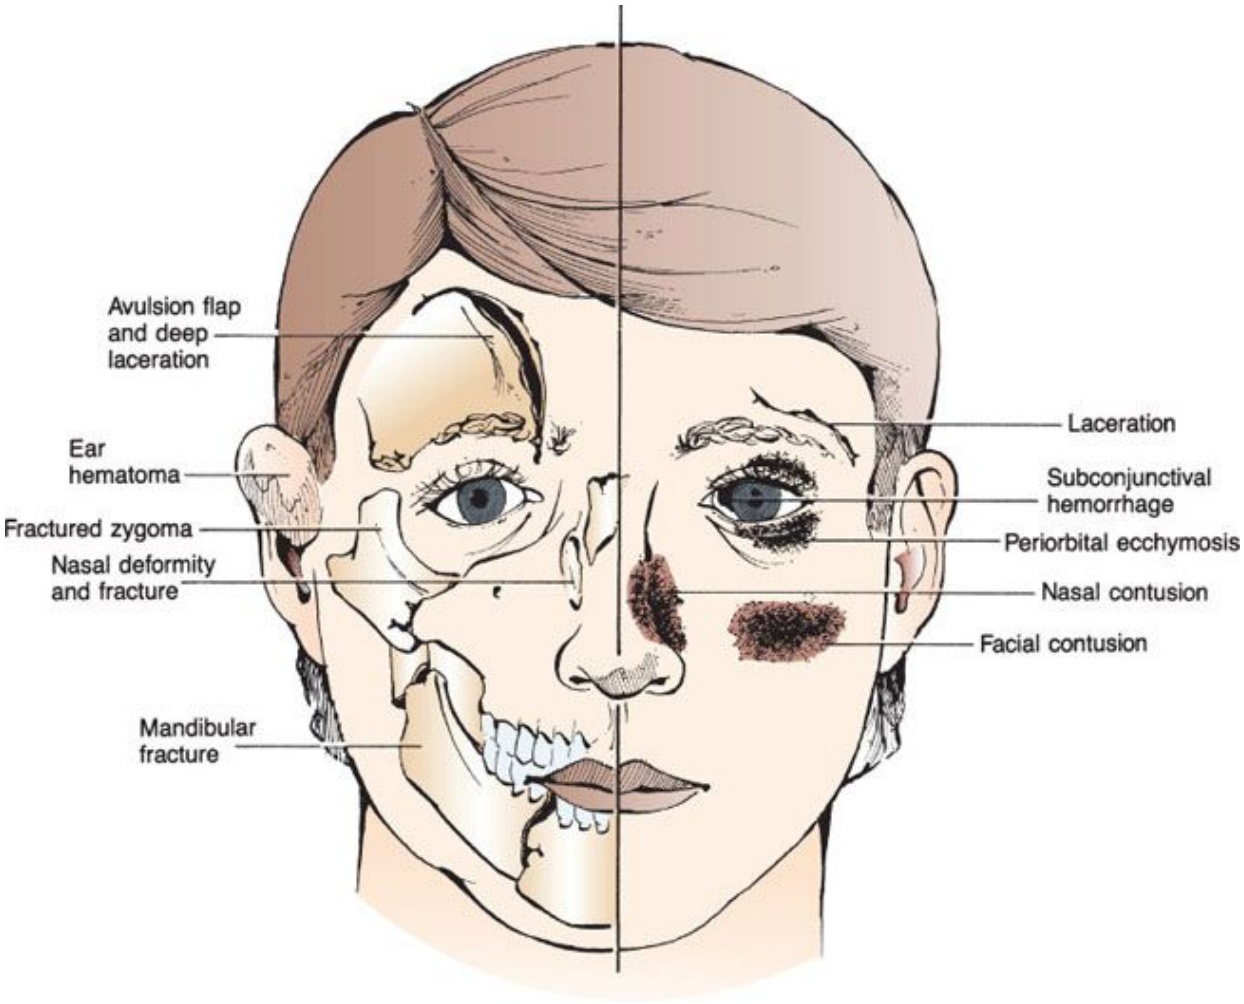

eFIGURE 23.1 Superficial facial injuries provide important visual clues to underlying soft tissue and bony injuries.

The emergency physician should consider testing bloody nasal discharge for CSF. A drop of the bloody fluid containing CSF will demonstrate a target or "halo sign" when placed on a paper towel or bed sheet, because the CSF migrates farther and faster than blood. This test can produce false-negative results with non-CSF fluids mixed with blood, whereas glucose and β-2 transferrin testing are more specific for CSF (10).

Palpation is another important part of the physical examination. The entire face should be palpated for tenderness, step-offs, bony crepitus, and subcutaneous air (often present with fractures involving the sinus). Facial stability is tested by placing a gloved hand in the

patient's mouth, grasping the hard palate, and rocking back and forth while the other hand simultaneously palpates the central face. The physician should be careful to not rock the teeth themselves if dental trauma exists, as dental avulsion may occur.

The final part of the examination of the face is a test for sensation. The branches of the trigeminal nerve are commonly disrupted or contused during facial injury and can cause sensory deficits to the face. The V1 branch of the trigeminal nerve is particularly susceptible to injury in the supraorbital notch. Damage to this nerve can result in anesthesia of the upper nose, eyebrow, and forehead. The infraorbital nerve can be disrupted as it courses through the floor of the orbit and is frequently damaged with orbital or zygomatic fractures. This results in ipsilateral numbness of the lower eyelid, side of the nose, upper lip, gums, and hard palate. Finally, the mental nerve can be injured when there is a mandibular injury resulting in ipsilateral anesthesia to the chin. The presence of facial anesthesia does not necessarily confirm a facial fracture; contusion to the nerve alone can produce similar numbness.

While plain radiographs (e.g., a Waters view, or occipitomental view, for midface fracture) may be effective as a screening tool for some facial fractures, there has been a gradual shift away from this modality (17). Ultrasound has been shown to have diagnostic value, recognizing its limitations with nondisplaced and complex fractures, especially in posterior orbital floor and mandibular condyle where sensitivity is especially low. Data is most impressive for nasal bone fractures, with a sensitivity of 90% to 100% and specificity of 98% to 100% with ultrasound (18). CT, however, is the gold standard for imaging in cases where there is concern for facial fracture with superior sensitivity, speed, cost, and utility in surgical planning (17). Interestingly, several studies have shown that the noncontrasted head CT ordered primarily for ruling out intracranial trauma, has the added advantage of evaluating for orbital, maxillary, and zygomatic fractures, citing sensitivities of 90% to 100% (19,20). The decision to add facial CT to a patient already undergoing head CT can be augmented by specific physical examination findings. Aid in the decision to add a facial CT to a patient's planned head CT may come

from the knowledge that 12% of trauma patients who require a head CT will have facial fractures as well as the fact that complicated orbital fractures may not be fully delineated on isolated head CT (21).

KEY TESTING

- Airway assessment and attention to hemorrhage take precedent, vision-threatening injury should also be evaluated with an ocular examination.
- If suspicion for facial fracture exists based on physical examination, facial CT is the gold standard imaging modality (17).
- Ultrasound shows promise in the diagnosis of facial fracture, in particular there is data showing nasal bone fractures, orbital fractures, anterior maxillary wall, and zygomatic arch fractures can be readily detected (18).
- Head CT should be strongly considered in any patient with facial fracture given the high incidence of concomitant intracranial injury.
- Facial fracture is also a marker of increased risk for cervical spine fracture in trauma, adherence to clinical decision rules is appropriate to determine need for cervical spine imaging.
- CT angiography (16-slice scanner) is recommended to screen for cervical vessel injury with displaced midface and complex mandible fractures (13).

ED MANAGEMENT

Fractures, bleeding, edema, and foreign bodies (such as loose teeth) may occlude the airway and distort anatomy minutes to hours after injury. Thus, it may be prudent to prophylactically secure the airway in patients with evidence of progressive swelling using rapid-sequence orotracheal intubation or an awake intubation. In patients with significant facial trauma, equipment for “backup” cricothyrotomy should be readily available as several factors may qualify them as “difficult airways.” These factors should be assessed

prior to any intubation attempt, including the potential for poor mask seal precluding effective bag-valve-mask ventilation, cervical spine immobilization, and loss of normal landmarks with bony, soft tissue, and vascular injury.

The patient's position on the stretcher dramatically affects the airway. Sitting up and leaning forward is the "position of life" as it clears the airway of blood and displaces any fractured bones or loose tissue forward. The patient can even self-suction blood with one or two Yankauer suction catheters. However, this position is not an option if there is significant concern for cervical spine injury.

Maxillofacial trauma can compromise the airway at the nasal, oropharyngeal, or laryngeal level. If collapse of the nasal airway results from posteroinferior displacement of maxillary fractures, definitive control may be achieved by pulling the face forward using anterior traction on the maxilla (38). The maxillary arch should be grasped above the front teeth to avoid pulling them out of their loosened sockets. If a prolapsed tongue is occluding the oropharyngeal airway (often seen in central mandibular fractures), the tongue can be pulled forward with a traction suture or towel clip. Maxillofacial trauma may also occur in conjunction with direct trauma to the neck, causing airway collapse at the level of the larynx. Cricothyrotomy is possible if the level of injury is above the larynx. In patients with injuries at or inferior to the larynx, endotracheal intubation under direct laryngoscopy may be attempted, but emergency tracheostomy may be necessary. If tracheal injury is inferior to a level at which tracheostomy will provide an adequate airway, emergent consultation with an ENT or thoracic surgeon is warranted (22).

Once the airway is secure and breathing is stabilized, the "C" of the trauma ABCs must be addressed. Although some patients with maxillofacial trauma may be hypotensive, isolated facial injuries rarely cause shock (8). Hemodynamic compromise should be ascribed to other injuries until proven otherwise. The blood supply to the face involves both branches of the external and internal carotid arteries with several anastomoses between each. Generally, if there is ongoing hemorrhage, direct pressure should be applied both

internally to the anterior nares and externally where indicated. Immediate manual reduction of fracture fragments or dislocations may also slow the bleeding. If there is continued blood loss despite these maneuvers, particularly if there is massive nasopharyngeal bleeding, hemorrhage control may be achieved by using posterior nasal packing with either gauze, Foley catheter, or a commercially available nasal balloon (8). Care should be taken with posterior nasal packing to avoid the risk of intracranial placement. The McKesson prop, which is a rubber stopper placed in between the upper and lower teeth to push the midface upward, has also been proposed as a temporizing measure to tamponade bleeding from severe midface fractures (17). Seldom, with maxillary fractures, the posterior pharynx may need to be packed after endotracheal intubation. If hemorrhage continues, arterial ligation or embolization should be pursued (8).

Frontal Bone Fractures

The frontal bone is the strongest bone in the face, consisting of a thick anterior wall that can tolerate as much as 2200 lb of force, and a relatively thin posterior wall. Two-thirds of frontal bone fractures involve both anterior and posterior tables, and given the tremendous amount of force required to break these bones, the incidence of concomitant intracranial and other facial injury is high. These fractures also carry significant potential for infection (23). Therefore, patients with known or strongly suspected frontal bone fractures should undergo head CT scanning and meticulous evaluation for associated injuries, including orbital, nasal, and ethmoid fractures (24).

Frontal sinus injuries are often not obvious; suspicion is based on mechanism of injury (person's head hits the dash of a car or assault with a heavy blunt object such as a brick). On inspection, the emergency physician should look for any depression of the forehead. Glabellar depression indicates fracture of the anterior wall of the frontal sinus. The presence of subcutaneous air indicates sinus disruption, and the supraorbital rims should be palpated for step-off or deformity. Palpation with a sterile gloved finger can help detect

fractures that underlie open wounds. Though rare, posterior wall fractures may result without an anterior wall fracture (24). When testing sensation, it is important to realize that numbness in the distribution of the supraorbital nerve (forehead) may herald an occult fracture. CSF rhinorrhea, if present, indicates involvement of both the posterior wall and meninges (24). Some patients may present with postnasal drip as CSF may preferentially enter the oropharynx. Finally, all patients with frontal bone fractures deserve a thorough ophthalmologic examination due to high rate of concomitant injury.

Although plain films such as Waters and Caldwell views of the face can screen for fracture, if there is significant concern for fracture, axial and coronal CT is indicated to delineate the status of the posterior table and the nasal frontal outflow tract (14). Pneumocephalus is another significant finding which indicates dural violation (25).

Repair of the anterior wall of the frontal sinus can often be delayed; however, fracture of the posterior table requires urgent neurosurgical consultation. When the frontal sinus is fractured, prophylactic antibiotics are generally given. Commonly prescribed antibiotics include first-generation cephalosporins, erythromycin, trimethoprim–sulfamethoxazole, and amoxicillin-clavulanate. However, choice of antibiotics and when to start them is often left to the consultant. In addition, the presence of CSF rhinorrhea associated with frontal bone fractures usually prompts antibiotic prophylaxis by the consultant, although there has been conflicting evidence to the utility of this practice.

Orbital Fractures

Trauma to the orbital regions may range from simple soft tissue swelling around the eye to blindness. Immediate blindness from trauma is rare and is generally permanent, but delayed loss of vision is possible (15). A majority of blindness results from globe rupture; however, damage to the optic nerve (directly or indirectly) and retinal detachment can also lead to a loss of visual acuity. In addition, direct ocular trauma can produce a traumatic iritis. Injuries

occurring as a result of trauma to the globe are discussed in detail in Chapter 25.

Fractures of the orbit are either “pure” or “impure.” Pure fractures affect only the internal orbit without orbital rim involvement, whereas impure fractures include the orbital rim. The blow-out fracture (eFig. 23.2) is a pure internal orbital fracture, usually involving the floor and medial portion of the orbit (24). These fractures occur with either direct force to the orbital rim or when a blunt force strikes the globe. Blow-in fractures consist of fractures and collapse of the orbital roof, which are strongly indicative of intracranial injury. If the fracture propagates to the orbital apex, it can place the optic nerve in jeopardy. This is called *orbital apex syndrome* and is an emergency if there are clinical or radiographic signs of optic nerve impingement (23).

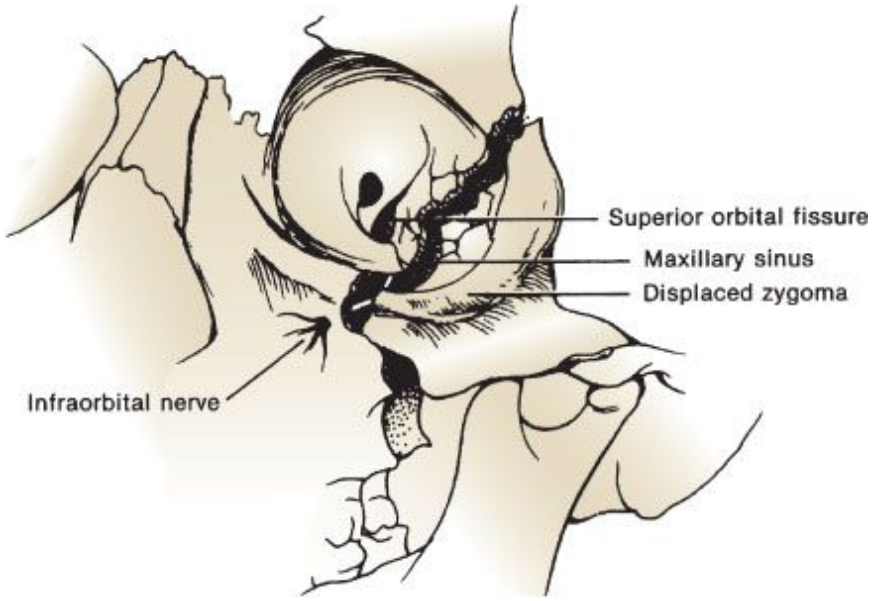

FIGURE 23.2 Zygomaticomaxillary complex fractures.

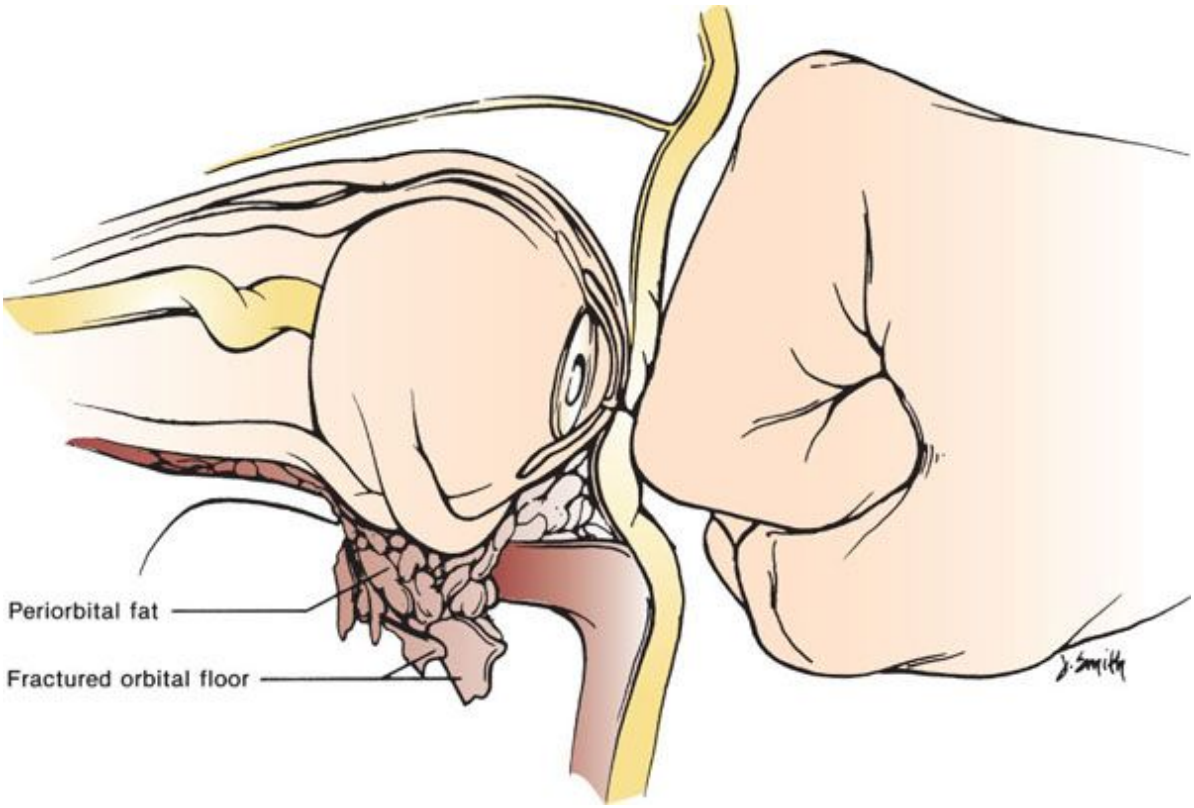

eFIGURE 23.2 Blow-out fracture.

The patient's orbital region should be inspected for eyelid edema, lacerations, ecchymosis, enophthalmos (sunken globe), hypoglobus, proptosis, or obvious inability of the patient to deviate the involved eye. If the patient cannot look up or complains of diplopia on upward gaze, inferior rectus muscle entrapment associated with orbital blow-out fractures should be considered (26). However, most diplopia is a result of muscle hematoma or nerve injury and not a result of true muscle entrapment. The orbital rims should be palpated for bony step-offs or crepitus, which may indicate a fracture involving the sinuses. When palpating for irregularities, the unaffected side should be palpated for comparison, because the supraorbital and infraorbital nerve foramina can masquerade as fractures (24). Finally, the patient should be asked about numbness of the cheek, maxillary teeth, or upper lip. Paresthesias in these areas suggest a contusion or disruption of the infraorbital nerve (24). When there are findings consistent with fracture in the orbital region, the emergency physician's first step is a meticulous

evaluation of the globe. The ocular examination takes precedence because certain injuries (e.g., globe rupture) benefit from early diagnosis and management, and an adequate examination may be impossible as swelling progresses. In a patient with acute orbital trauma, the two most important ophthalmologic functions to evaluate are visual acuity and extraocular muscle mobility. If the eyelid is too swollen to allow for retraction and therefore an evaluation of visual acuity, light perception should be documented to ensure optic nerve integrity. When in doubt, involvement of ophthalmology is prudent. Retrobulbar hematoma, or more rarely, subcutaneous emphysema creating ocular compartment syndrome, must also be addressed emergently if a tense proptotic globe with decreasing visual acuity is identified. Lateral canthotomy should be performed in consultation with an ophthalmologist to prevent optic nerve ischemia, and mannitol, acetazolamide, and steroids may further decrease the possibility of optic nerve ischemia in the presence of increased intraocular pressure (26). Once ocular injuries have been identified, attention shifts to imaging of the orbital region. Plain radiographs are no longer recommended as screening tools as CT is the preferred test (27). Classic radiologic signs include the "hanging teardrop," which appears when orbital fat herniates into the maxillary sinus, and air/fluid levels in the maxillary sinus.

Management of orbital blow-out fractures remains controversial but phone consultation with plastic surgery on call provides crucial follow-up. In addition to consultation, the following guidelines provide a reasonable basis for decision making in the emergency department (ED). In cases associated with minimal displacement, no entrapment, and no diplopia, the patient may be treated as an outpatient with head elevation, ice, pain medication, and surgical follow-up within several days (28). Absolute indications for surgery include acute enophthalmos, hypophthalmos, or muscular entrapment with mechanical gaze restriction, even despite lack of extraocular muscle entrapment on CT (23). Contraindications for urgent surgery include hyphema, retinal tears, and globe perforation, as soft tissue injuries of the eye may be aggravated by surgery for blow-out fractures. Timing of surgery is also controversial especially

in the multiply injured patient and is a decision to be made by the consultant(s). Patients should be refrained from nose blowing, which can increase the risk for rare, but significant, orbital subcutaneous emphysema (29). If there is significant subcutaneous emphysema or other evidence of fracture into the maxillary sinus, some physicians prescribe prophylactic antibiotics against sinus pathogens, although the utility of this practice has not been studied in a prospective manner (23). First-generation cephalosporins, trimethoprim–sulfamethoxazole, or amoxicillin–clavulanate are often employed.

Nasal Fractures

Nasal bone fractures are the most common facial fracture, and can result in chronic deformity and nasal obstruction (30). Isolated nasal bone fractures typically do not require emergent treatment unless there is significant epistaxis or septal hematoma. A more severe injury involves trauma to the bridge of the nose and includes fractures of the medial orbital wall. This is termed a *NOE fracture* and can involve disruption of the cribriform plate with associated CSF rhinorrhea or intracranial injury (22).

Evaluation begins with a detailed history. The patient should be asked about previous nasal fractures and whether the nose looks normal, as nasal deformity can be secondary to either old or new trauma. Another important question regards difficulty breathing through the nose.

The nose should be inspected for swelling, ecchymoses, and deformity and palpated for crepitus. The emergency physician should move the nasal pyramid to both sides to detect any mobility. Using a nasal speculum inside each naris, the physician should note the position of the nasal septum and examine for lacerations and septal hematoma, which will appear as a bulging blue mass that is boggy to palpation with a finger or cotton swab. Any fluid from the nose should be tested for CSF.

Nasal bone fractures are often diagnosed by history and physical examination alone. Nasal bone radiographs have no clinical utility as they do not affect management (31). If there is no misalignment of the nose, the only treatment includes ice packs and analgesia. If the

patient presents immediately with deformity and significant swelling has not developed, closed reduction using local anesthesia and manual pressure with or without forceps can be attempted according to the comfort and experience of the emergency physician. More often, soft tissue edema precludes adequate examination and the patient should be referred to ENT or plastic surgery as an outpatient. Often, open or closed reduction will be performed within 5 to 7 days, after swelling has subsided. Indications for immediate treatment include CSF rhinorrhea, the presence of septal hematoma, and lacerations with exposure of the underlying bony or cartilaginous elements (30).

Septal hematomas, if not drained in the ED, can lead to abscess formation or necrosis of the nasal cartilage, with resultant saddle nose deformity especially if the hematoma is bilateral. To drain a septal hematoma, the nasal mucosa is anesthetized with a topical anesthetic, and a no. 11 blade is used to make a mucosal incision through the inferior portion of the hematoma, excise a small amount of mucosa. The clot should be suctioned and the area irrigated before the nostril is packed in similar fashion to that for anterior epistaxis. The patient should be put on broad spectrum antibiotics and packing can be removed when there is no hematoma for 24 hours (32).

Nasoorbitoethmoid Fractures

NOE fractures result from significant forces to the bridge of the nose or medial orbital wall and rarely occur as isolated events. These injuries involve the central portion of the midface (the nasal bones, frontal processes of the maxilla, and ethmoid bones) (Fig. 23.1) and may result in a fracture of the cribriform plate with subsequent CSF leakage (22). In addition, these fractures may be associated with dural tears or lacrimal disruption.

A thorough history of the mechanism of injury can be helpful in making the diagnosis typically this will be high-energy blunt trauma. On examination, asymmetry or widening of the nasal bridge between the eyes should be noted (telecanthus) as this is the most troublesome permanent defect resulting from these fractures. The distance between the medial canthi is normally about half the

interpupillary distance (approximately 32 to 35 mm for Caucasians). An increase in this distance suggests an NOE fracture. Also characteristics of NOE fractures are a flattened nasal bridge, enophthalmos, and epiphora (tears pouring over the eyelid) (33). These findings are increasingly difficult to detect as swelling progresses. Palpation of the medial orbital rim especially at the medial canthus may reveal crepitus, tenderness, or movement of bony fragments.

Plain radiographs are not useful in the diagnosis of NOE fractures because of thin bones and complex anatomy. Radiographic assessment should be performed with a facial CT scan with fine-cut axial and coronal images.

The emergency physician's role in management of the patient with an NOE fracture is to make the diagnosis and to rule out associated lacrimal system injury or dural tear. NOE fractures should be repaired no later than 10 to 14 days, but if an NOE injury is identified, the patient will generally be admitted by a facial surgeon.

Zygomatic Fractures

The zygoma is a prominent bone in the lateral portion of the facial skeleton that attaches to the maxillary, frontal, and temporal bones. Occasionally, the zygoma is fractured exclusively through its body. However, because of the thickness of this bone, fractures often extend through weaker areas of the orbit and maxilla. Fractures through the suture lines where the zygoma attaches to the three adjacent bones are termed *tripartite, tripod,* or *zygomaticomaxillary* fractures, whereas fracture through the arch of the zygoma are termed (not surprisingly) *zygomatic arch fractures* (Fig. 23.2).

History and physical examination reliably detect most zygomatic fractures. The mechanism of this injury is usually a direct blow to the cheek with a bat or fist. The patient may complain of pain with, or difficulty in, opening the mouth, which can be a result of impingement of the bone fragment on the temporal muscle or coronoid process The patient's range of mouth opening should be >30 mm; if it is less than this or there is cheek pain with jaw movement, a zygoma fracture should be suspected (26). Inspection of

patients with zygomatic injuries may reveal flattening of the cheek or a downward orbital tilt secondary to disruption of the lateral canthal ligament. Lateral subconjunctival hemorrhage may be an important clue to an associated zygoma injury. Further examination may reveal binocular diplopia secondary to damage of the extraocular muscles or entrapment. Up to 90% of patients with blunt zygoma trauma will have hypesthesia in the infraorbital nerve distribution (26,34). Palpation of the zygomatic arch is accomplished by the intraoral approach (the index finger is placed along the outside of the upper rear molars to palpate the arch intraorally). A crushed arch may not permit an examining finger to slip under the arch on the involved side as compared to the opposite side (26).

If an isolated arch fracture is suspected, a submentovertex view, or "jug-handle" radiograph, may aid in diagnosis. If a tripod fracture or other complex fracture is suspected, a facial CT with fine cuts through the maxilla and orbit is indicated. Surgical consultation for possible open reduction and internal fixation should be obtained for these fractures, but treatment is often delayed until swelling has subsided and a complete evaluation can be preformed. In patients with isolated fractures of the zygomatic arch, ED management is limited to analgesia and surgical follow-up within several days. All patients with suspected fractures of the zygoma should avoid nose blowing to decrease the incidence of subcutaneous emphysema (26).

Maxillary Fractures

Maxillary fracture is the most common finding in patients who sustain penetrating facial trauma. In blunt trauma, maxillary fractures are often associated with other significant traumatic injuries, as these bones require considerable force to break. The Le Fort classification system is used to describe maxillary fractures and by definition all involve the pterygoid plate. In actual practice, pure Le Fort fractures are much less common than unilateral or bilateral mixed maxillary fractures (e.g., left Le Fort I with right Le Fort II).

- Le Fort I
  - Transverse line separates the hard palate from the surrounding bone (Fig. 23.3).

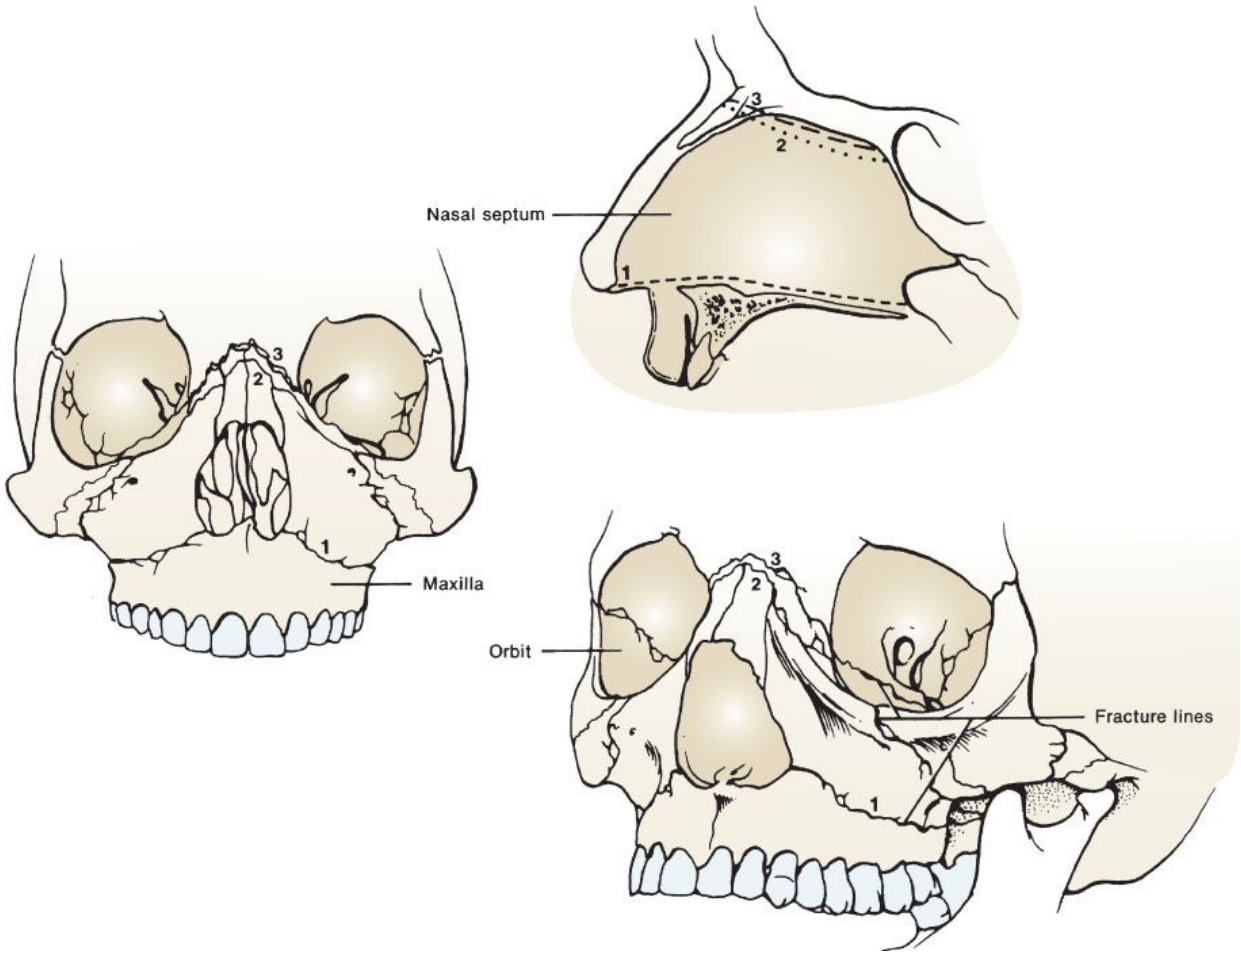

FIGURE 23.3 Lines of fracture in Le Fort I, Le Fort II, and Le Fort III fractures are shown from different views.

- "Floating palate," may involve dental mobility but nose does not move.

- Le Fort II
  - Pyramidal fracture line extends into the orbital floor and inferior orbital rim, separates central maxilla and palate from the rest of the face
  - Mobility of maxilla and hard palate is appreciable.
- Le Fort III (Craniofacial dysjunction)
  - NOE, zygomas, and maxilla are separated from calvarium.
  - Maxillary excursion reveals facial mobility, globes are kept in place by the optic nerve.
- Le Fort IV

• Le Fort III with associated frontal bone fracture.

Fractures of the maxilla are often associated with significant facial edema and bleeding, which may make diagnosis by inspection difficult. The emergency physician should note any asymmetry or loss of contour; an elongated oval or donkey face may be seen with high-grade maxillary fractures. Orbital ecchymosis, lengthening, and edema of the middle third of the face, and malocclusion are also present with Le Fort type II and III fractures. Facial nerve injury may also accompany maxillary fractures, with resultant facial muscle paralysis, and sensory deficits in the infraorbital distribution should be noted. When there is trauma to the lateral midface, the physician should carefully examine cheek wounds for clear or pink fluid leakage (saliva), representing possible parotid duct damage. Alternatively, blood may be expressed from the parotid duct located adjacent to the maxillary molars when the parotid gland is massaged. Providers should also be vigilant for CSF leaks presenting with rhinorrhea with Le Fort type II and III fractures.

Palpation of the maxillary structures follows inspection with special attention given to bony crepitus and abnormal mobility of the face upon stress maneuvers. To stress the face, the examiner firmly grasps the upper palate and rocks back and forth, checking for abnormal midface mobility with the other hand (eFig. 23.3). In patients with facial mobility, the fracture is further characterized by delineating the mobile portions of the face.

eFIGURE 23.3 Checking for abnormal midface mobility.

Severe epistaxis is commonly associated with maxillary fracture, with the internal maxillary artery being the most frequent culprit. Anterior and posterior nasal packing and fracture reduction can often decrease facial hemorrhage, although care should be taken with posterior nasal packing as intracranial placement of a Foley or commercial packing material could occur (2). If basic measures to tamponade have failed and life-threatening hemorrhage continues, arterial ligation or transcatheter arterial embolization are the next steps to address ongoing hemorrhage (8).

CT scan is required to delineate the extent of bony and soft tissue injury if there is suspicion for midface fracture, plain films are not sufficient. Penetrating trauma to the midface can involve injury to the brain and major vascular structures in the head and usually requires CT of the brain and occasionally diagnostic angiography. Multislice CT angiography have been recommended in cases of

displaced midface fracture to screen for cerebrovascular injury (13). Surgical specialists should be consulted early when significant maxillary fractures are identified, early versus late repair will be determined by coexistent injuries.

Mandible Fractures

After nasal bone fractures, the mandible is the most commonly fractured facial bone. Because of its ring shape, the mandible is frequently broken in more than one place; one series found that more than half of mandibular fractures occur in at least two locations (35). Areas of the mandible that are most commonly fractured are the mandibular condyle, body, and the angle (Fig. 23.4).

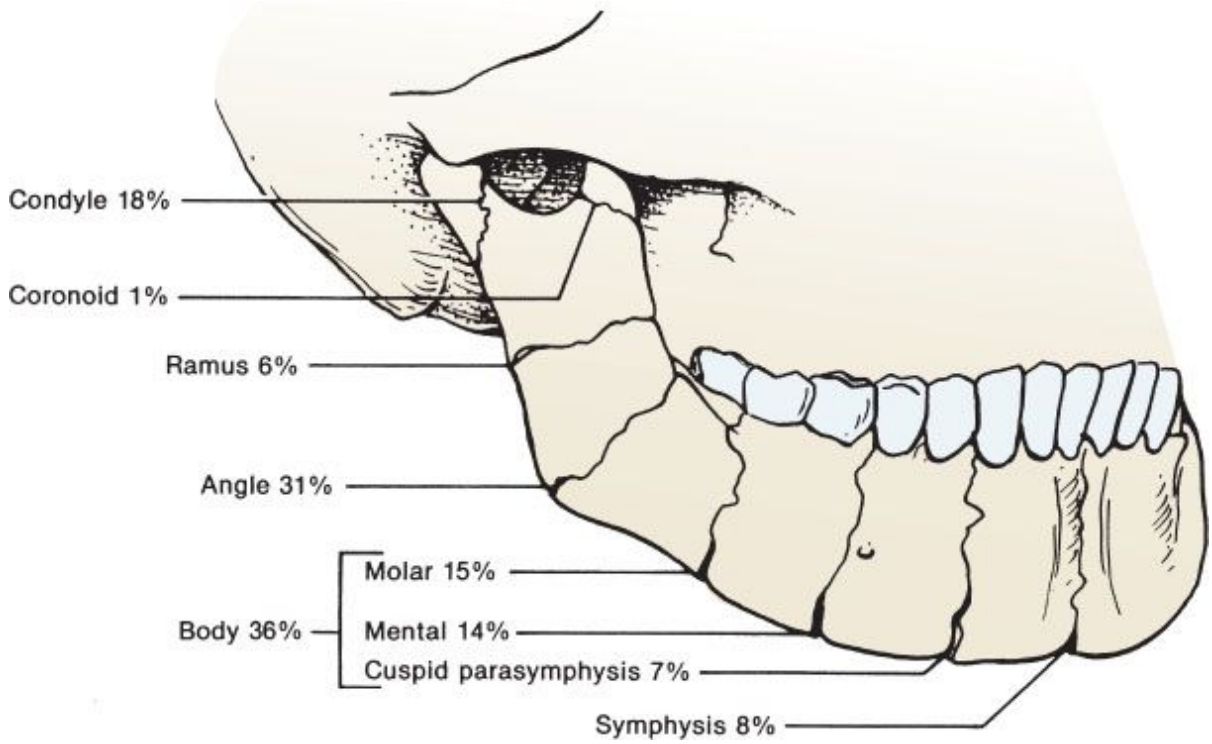

FIGURE 23.4 Mandible fractures: sites and incidence.

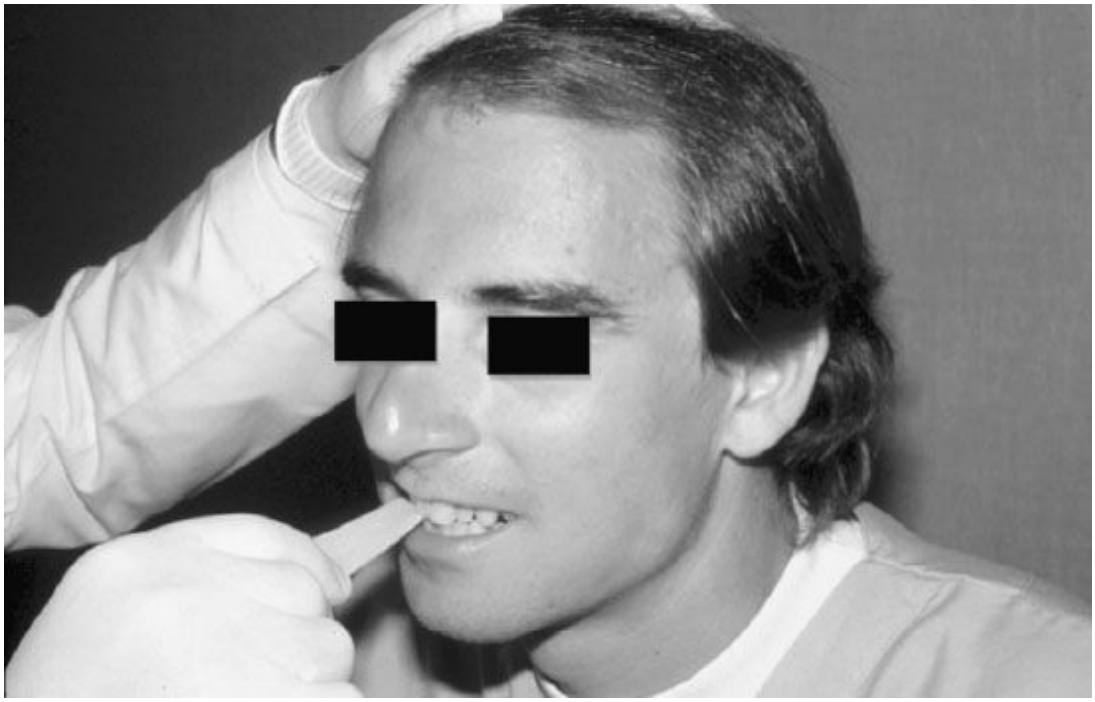
Patients should be asked whether their teeth fit together normally, as many fractures of the mandible or maxilla result in malocclusion. The proprioceptive receptors of the teeth allow for detection of as little as 1 to 2 mm of bite discrepancy (34). Then, the patient should be asked whether there is jaw pain with opening or closing of the

mouth, and sensation should be assessed in the mental nerve distribution of the lower lip and chin. During the physical examination, the patient's jaw is inspected for asymmetry. When a fracture is present, the chin is often deviated toward the injured side; with a unilateral dislocation, the jaw is deviated away from the injured side. Traumatic dislocation from acute blunt trauma is rare; fractures are far more common. Edema, bleeding, and hematomas can also provide evidence of fracture. Particularly, preauricular swelling or bleeding from the external auditory canal may indicate a condylar fracture, which can be notoriously difficult to identify on plain radiographs. A careful intraoral examination is of paramount importance to evaluate for open fracture, including any tenderness or irregularities in the contour of the mandible or altered dentition. A sublingual hematoma, although not common, is strongly suggestive of mandibular fracture. Normal condylar excursion should be assessed by placing the examiner's fingers into the external ear canals and instructing the patient to open and close the mouth. In the patient with pain but without obvious fracture, the tongue depressor test has been shown to be a useful clinical tool to rule out mandible fracture with a sensitivity of 95% (36). A positive test, suggestive of possible fracture, is elicited when the patient reflexively opens his mouth when a tongue depressor clenched between the teeth on the side of the fracture is twisted by the examiner. Normally, a patient should be able to break the tongue blade when it is twisted between the teeth (eFig. 23.4).



eFIGURE 23.4 Tongue blade test.

CT scan has surpassed plain radiographs as the gold standard for diagnosis of mandibular fractures and have been shown to have greater sensitivity and utility in operative planning (14,37). The panoramic radiograph (Panorex) still holds some utility in defining dentition even after CT. Although evidence for prophylactic antibiotics in mandibular fractures is poor, standard practice is to give intravenous antibiotics for open mandibular fractures to cover oral pathogens (38). Penicillin G (2 to 4 million units IV) is the drug of choice, with clindamycin (600 to 900 mg IV) and first-generation cephalosporins serving as alternatives. Open fractures require admission for operative treatment, whereas most closed mandibular fractures can be treated on an outpatient basis with open reduction and internal fixation 3 to 5 days after injury to allow for swelling to decrease if patient comfort allows. A Barton bandage (Ace bandage wrapped around the head and jaw) and soft or liquid diets are helpful in cases of delayed repair.

Mandibular Dislocations

The temporomandibular joint is also subject to dislocation; this may occur during yawning, singing, or other movements that involve opening the mouth very widely. Dislocation can also occur during seizures, dystonic drug reactions, dental procedures, or more rarely after blunt trauma. Dislocation is often recurrent.

With mandibular dislocation, the history is often difficult to obtain because the patient has difficulty speaking. During inspection, asymmetry of the jaw is a clue to the diagnosis. A unilateral dislocation will often cause deviation of the mandible away from the affected side. A bilateral dislocation of both condyles will give the patient an underbite appearance (bottom teeth more anterior than upper teeth). The teeth will not occlude normally, and speech is often affected. Often there is significant masseter muscle spasm that can make reduction difficult.

Mandibular dislocations can be reduced by the emergency physician, sometimes requiring benzodiazepines or local anesthetic to relax the masseter or pterygoid muscles. Occasionally, conscious sedation may be required. There are two simple reduction techniques that are most often employed. In the first technique, the clinician faces the patient with thumbs wrapped in gauze to avoid being bitten. The physician's thumbs are then placed under the posterior molars or on the mandibular ridge and the inferior surface of the mandible is grasped placing downward pressure on the molars. This will free the condyles and allow them to be pushed forward into place (28). In the second technique, the clinician stands behind the patient with gauze-wrapped thumbs on the posterior molars and fingers grasping the mandible anteriorly. Pressure is exerted downward and forward until the joint snaps into place (eFig. 23.5). An alternating rocking motion between right and left sides may help in reduction.

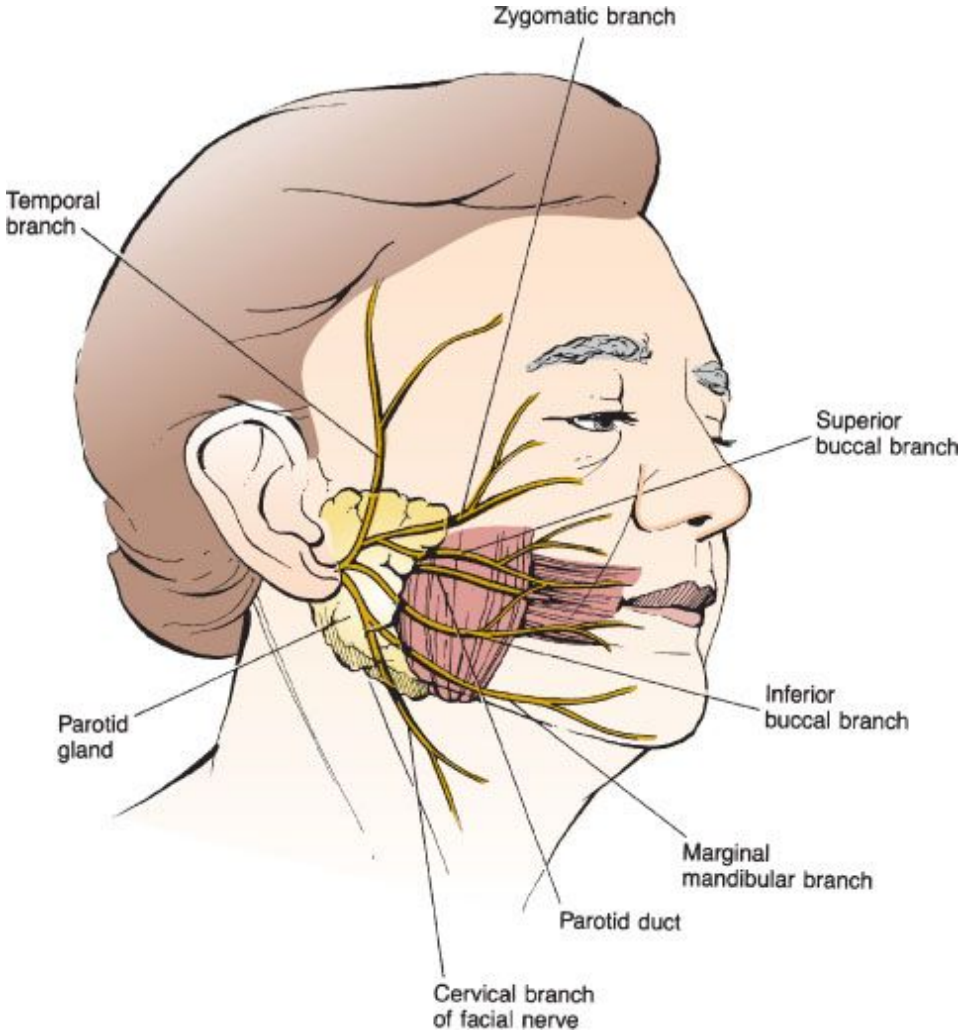


FIGURE 23.5 Important soft tissue structures of the face.

eFIGURE 23.5 Method for reduction of a mandible dislocation from behind.

Rarely, neither of the foregoing techniques will work, and reduction under general anesthesia may be required. Once reduction is accomplished, the patient's jaw should be wrapped in a Barton bandage, and the patient should be instructed to avoid opening the mouth widely to prevent repeat dislocation. Though some physicians obtain x-rays to confirm the relocation of the condyles and to exclude any fractures that occurred during reduction, others do not find this necessary (16,22).

Soft Tissue Injuries

Many patients with facial fractures have associated cutaneous injuries. These do not routinely need to be closed in the patient who will undergo surgical evaluation in the ED, as the opening may be used for examination or repair. Rapid suture ("whip stitching") is appropriate to achieve hemostasis in some cases, as the sutures can be easily removed by the consultant. Wound repair is important as cosmesis is of paramount importance to the patient. Laceration repair

is discussed in Chapter 21. In addition to lacerations, oral, ocular, salivary, lacrimal, otologic, or neurologic injuries may be associated with maxillofacial trauma (Fig. 23.5).

Any dental appliances present should be removed to prevent their aspiration from compromising the airway. These appliances should be saved, as they are expensive and may provide important guides to pretraumatic oral alignment.

The significant incidence of ocular injuries associated with various facial fractures necessitates meticulous ophthalmologic evaluation in all patients sustaining maxillofacial trauma. Injuries to the lacrimal system, with associated findings such as epiphora, may be present in patients with midface fractures. Lacrimal disruption is rare in blunt trauma, even in patients with significant craniofacial injury. These injuries are discussed in Chapter 25.

Clear or pink fluid leakage from the cheek suggests parotid gland laceration or Stensen duct damage. Lacerations that cross an imaginary line drawn from the tragus of the ear to the corner of the lip may traverse the parotid duct or facial nerve. Parotid lacerations do not require repair, as commonly occurring salivary fistulas resolve spontaneously in less than a month. Stensen duct may be repaired by suturing the ends together over a stent; this is most appropriately performed by a surgical consultant.

Tympanic membrane rupture can occur when there is significant force applied to the condyles that fractures the temporal bone. They generally heal spontaneously, but referral may be necessary in those with large disruptions.

CRITICAL INTERVENTIONS

- Secure the airway in patients with evidence of progressive swelling or airway obstruction using rapid sequence orotracheal intubation. Consider “awake” intubation for those patients who are likely to be difficult to intubate but who are currently maintaining their airway.
- Have equipment for “backup” cricothyrotomy readily available when managing the airway of a patient with significant maxillofacial trauma.

- Include evaluation for vision-threatening injury with the initial assessment of facial trauma, including pupillary size and shape, reactivity to light, lid lacerations, globe tension, and visual acuity.
- Perform facial CT as the initial radiologic study if mechanism or physical examination findings are concerning for facial fracture.
- Perform cranial CT scanning in patients with significant facial fractures to rule out intracranial injury, especially with loss of consciousness or neurologic abnormalities. Cervical spine CT and CT angiography for cervical vessel injury should also be considered.
- Obtain urgent neurosurgical consultation for patients with posterior table fractures of the frontal sinus.
- Obtain urgent surgical or ophthalmologic consultation for patients with orbital fractures who have paralysis of extraocular motions, ptosis, and periorbital anesthesia (superior orbital fissure syndrome) or visual loss.
- In mandibular fractures, perform a thorough examination to evaluate for open fracture.
- Administer intravenous antibiotics (penicillin or clindamycin) to patients with open facial fractures.

DISPOSITION

In the vast majority of patients with maxillofacial trauma, the emergency physician can perform the initial resuscitation and stabilization without the need for consultation with maxillofacial specialists. The role of emergent surgical consultation in patients with airway compromise or refractory facial hemorrhage has been discussed.

Involvement of the appropriate surgical specialist is now recommended at a time earlier than had been standard in the past for patients with severe facial fractures. Delays in treatment have been shown to result in suboptimal outcome in some facial injuries (13).

Patients with CSF leak must be evaluated by a neurosurgeon in addition to a facial specialist. Although prophylactic antibiotics may

be ordered by some consultants, in general they are not recommended as their use is not supported by the literature (39).

The surgical therapy for maxillofacial trauma is a rapidly evolving field. Patients with significant injuries should be transferred to referral centers if local consultants lack expertise in treating the injury in question. Before transfer, the patient who requires definitive care of maxillofacial injuries must be evaluated for other life- or limb-threatening injuries. Even in the setting of isolated maxillofacial trauma, the potential for airway deterioration may be present, and pretransfer stabilization in these instances may include intubation. The potential for airway compromise, as well as the high frequency of significant associated injuries, dictates a high level of training for personnel involved in the prehospital or interhospital transport of patients with significant maxillofacial trauma.

Common Pitfalls

- Failure to manage the airway aggressively with intubation or cricothyrotomy when indicated. Waiting too long in the presence of progressive swelling or hemorrhage may convert an urgent procedure into an emergent one.
- Failure to consider the presence of subtle or physically remote injuries. Particular attention should be paid to the neurologic and ophthalmologic examinations.
- Failure to realize that frontal bone injuries are associated with intracranial injury as well as infection.
- Failure to screen for and recognize intimate partner violence in patient presenting with facial trauma.

CHAPTER 24 Dental Injuries

Kip Benko

Complaints pertaining to the teeth are common and patients frequently present to the emergency department (ED) for initial care. Complaints range in scope from simple chipped teeth to odontogenic deep space infections or complex maxillofacial injuries. Estimates are that 3 million ED visits for dental-related complaints occurred in the United States between 1997 and 2000 (17). Recent data indicate that these numbers have continued to grow, with more than 830,000 visits in 2009 alone, an increase of 16% compared with 2006 estimates (25). The age group with the highest frequency of dental-related complaints is 18 to 35 years old; however, traumatic dental emergencies are more likely in patients 18 years old and younger (17). The frequency of dental-related visits is expected to increase over the next several years as a larger segment of the population becomes uninsured or underinsured. Although these patients can be frustrating and challenging, the emergency physician (EP) should be equipped to diagnose and treat basic traumatic dental conditions until definitive dental evaluation can be obtained.

CLINICAL PRESENTATION

Dental injuries in the younger population are often related to falls or accidents as new motor skills are developing. Frequently cited causes of injury to the permanent dentition include assaults, falls, motor vehicle collisions, and sports-related mishaps (7,22). Traumatic dental injuries presenting to the ED usually involves the permanent dentition and most commonly the anterior teeth. Dentoalveolar injuries in adults are also found in association with mandibular and

facial fractures. Patients with dental injuries usually present with pain, although bleeding and swelling may be associated with these injuries. Patients may also complain of abnormalities of occlusion or of loosened teeth.

A thorough understanding of dental anatomy allows not only proper ED diagnosis and treatment, but also a more concise and accurate discussion with dental consultants. The adult dentition consists of 32 teeth of which there are four distinct types: incisors (8), canines (4), premolars (8), and molars (12). Starting in the midline, each quadrant has central incisor, lateral incisor, canine (cuspid), two premolars (bicuspids), and three molars, the last of which is the wisdom tooth (Fig. 24.1). The adult teeth are numbered from 1 to 32 as noted in Figure 24.2, although it is more important that the EP be able to describe the tooth involved (i.e., upper left quadrant wisdom tooth) rather than remembering the actual tooth number. Teeth of primary dentition (baby teeth) are, likewise, best described by location and type. The earliest teeth to erupt in a child are the central incisors, usually at 4 to 8 months. The child usually has a full complement of primary teeth by the end of the third year of life. The primary teeth are not numbered but rather lettered as shown in Figure 24.2. The permanent teeth usually start replacing the primary teeth at approximately 5 years of age and this process begins with the incisors (Table 24.1).

TABLE 24.1
Teeth Eruption Times

Baby (Primary) Teeth		
Tooth Designation	**Name of Tooth**	**Appearance in the Mouth (mos)**
A	Central incisor	4–14
B	Lateral incisor	8–18
C	Canine tooth	14–24
D	First molar	10–20
E	Second molar	20–36
Adult (Permanent) Teeth		
Tooth Designation	**Name of Tooth**	**Appearance in the Mouth (yrs)**
1	Central incisor	5–9
2	Lateral incisor	6–10
3	Canine tooth	8.5–14
4	First premolar (bicuspid)	9–14
5	Second premolar (bicuspid)	10–15
6	First molar (6-yr molar)	5–9
7	Second molar (12-yr molar)	10–15
8	Third molar (wisdom tooth)	17–25

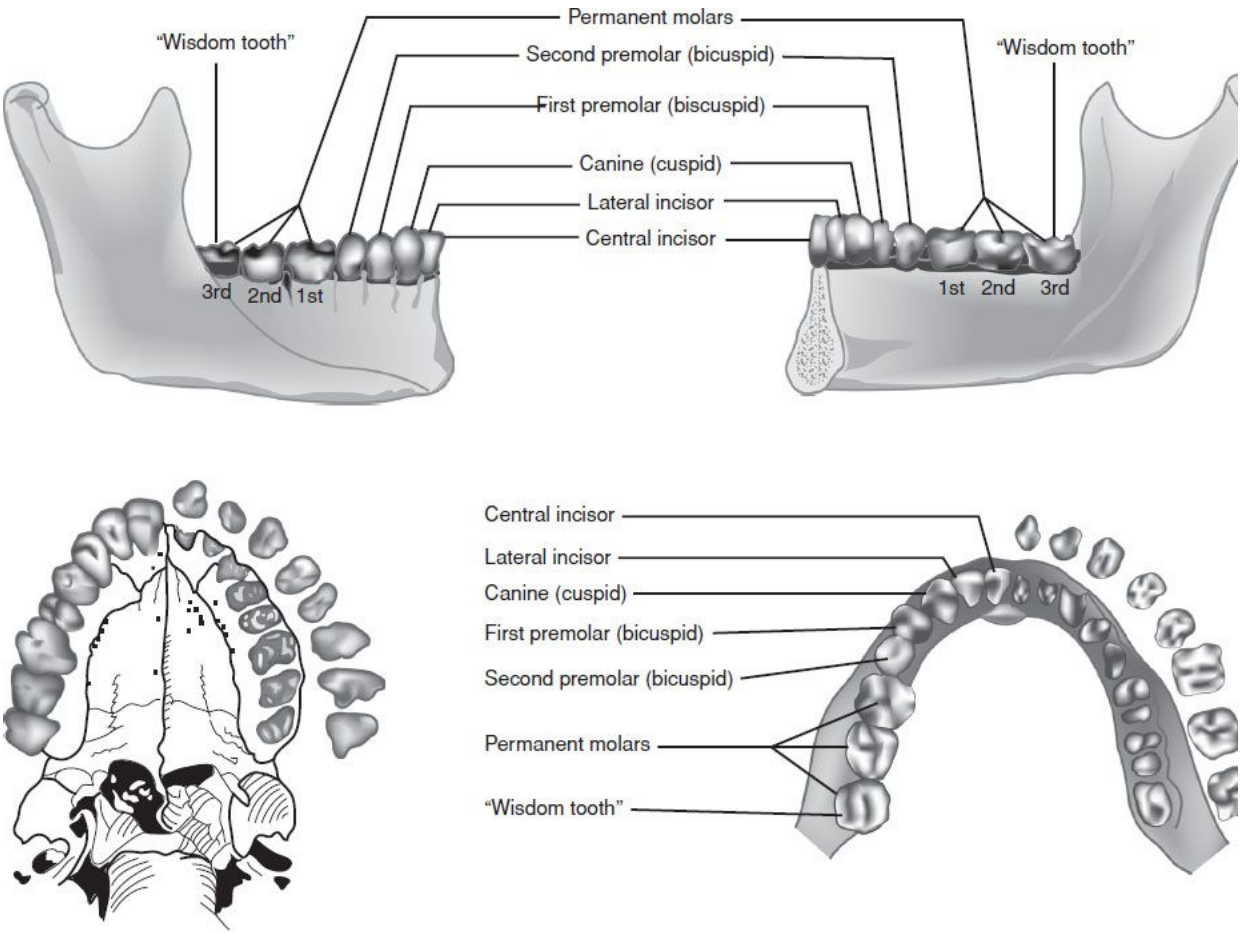

FIGURE 24.1 Classification of teeth.

A tooth consists of the central pulp, the dentin, and the enamel (Fig. 24.3). The pulp contains the neurovascular supply of the tooth that carries nutrients to the dentin, a microporous layer that consists of a system of microtubules. The dentin serves to cushion the tooth during mastication and makes up the majority of the tooth. The enamel is the visible portion of the tooth and is considered the hardest part of the body. The tooth may also be described in terms of its crown or root. The crown is that portion covered in enamel and the root anchors the tooth to the alveolar bone.

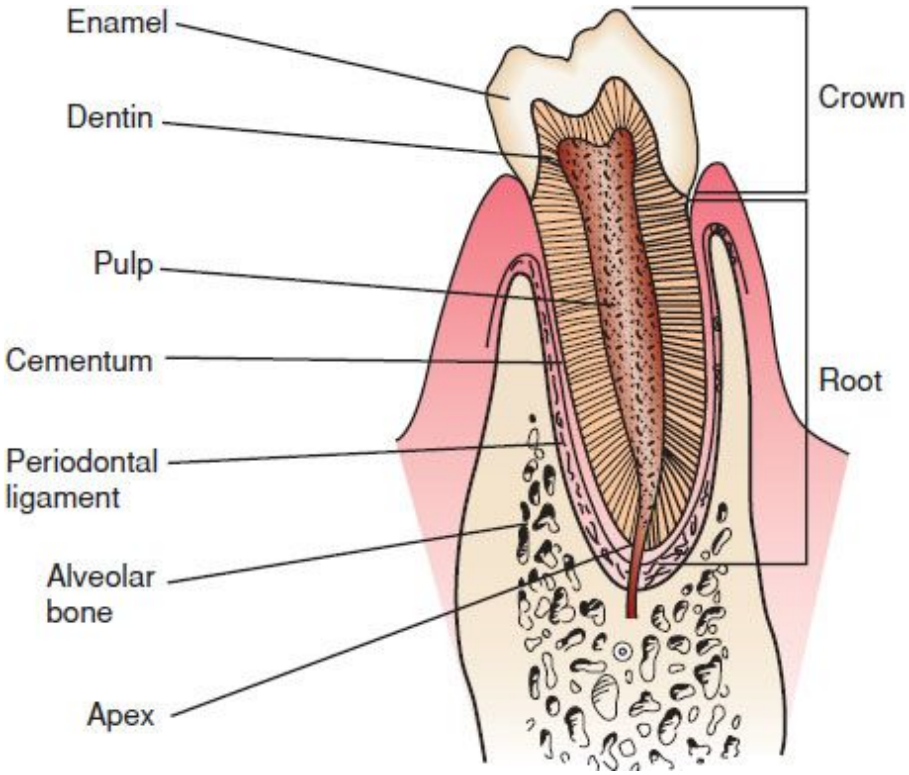

FIGURE 24.3 The dental anatomic subunits.

The following terms are used to identify the different anatomic surfaces of the tooth and are helpful when describing a specific tooth injury to a consultant.

Facial: Refers to the surface of the tooth that is seen when a person smiles. This is a general term, is applicable to all the teeth, and is sufficient to use when describing an injury, however, the following is more specific and precise.

Labial: Refers to the facial surface of the canines and incisors.

Buccal: Refers to the facial surface of the molars and premolars.

Oral: Surface that faces the tongue or the palate. This is also a general term and is applicable to all the teeth, but the following is more precise.

Lingual: Toward the tongue, the oral surface of the mandibular teeth.

Palatal: Toward the palate, the oral surface of the maxillary teeth.

Approximal /interproximal: The contacting surfaces between two adjacent teeth.

Mesial: The interproximal surface facing anteriorly or closest to the midline.

Distal: The interproximal surface facing posteriorly or away from the midline.

Occlusal: The biting or chewing surface of the premolars or molars.

Incisal: The biting or chewing surface of the incisors and canines.

Apical: Toward the root of the tooth.

Coronal: Toward the crown or the biting surface of the tooth.

The attachment apparatus, or periodontium, consists of two major subunits and is necessary for maintaining the integrity of the normal dentoalveolar subunit.

The *gingival* subunit consists of the visible junctional epithelium and the gingival tissue.

The *periodontal* subunit includes the periodontal ligament, alveolar bone, and the cementum of the root of the tooth.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of traumatic dental injuries is fairly straightforward. The primary concerns are whether the existent trauma could potentially cause airway compromise. Mandibular, maxillary, or alveolar ridge fractures may leave the tongue unsupported or the midface unstable. Each scenario may lead to difficultly when performing intubation or ventilation with a bag-valve-mask. Tongue and mucosal lacerations may cause bleeding severe enough to compromise the airway. It is also important to evaluate potential associated injuries such as traumatic brain injuries, other maxillofacial injuries, or cervical spine injuries.

Trauma to the teeth usually consists of fracture, intrusion, subluxation, (loose, nondisplaced teeth), luxation (displaced teeth), or complete avulsion. Fractures involving segments of teeth usually involve the alveolar ridge as well. The final diagnosis is primarily determined by a meticulous physical examination, accounting for each tooth, portion of the tooth, and integrity of buccal and gingival mucosa. Radiography usually serves a confirmatory role (Table 24.2).

TABLE 24.2
Differential Diagnosis of Orofacial Trauma

Dental fractures
Enamel fractures
Dentin fractures
Pulp fractures
Dental subluxation, luxation, intrusion, and avulsion
Facial fractures
Alveolar ridge fractures
Soft tissue lacerations
Traumatic ulcers
Mandible/maxilla fractures
Mucosa/tongue lacerations

ED EVALUATION

The evaluation of dental complaints in the ED consists of a focused, but meticulous, history and physical examination. Important historical information with regard to traumatic injuries includes the following:

When did the incident occur? The timing of the incident is important when evaluating avulsed permanent teeth, as the decision to reimplant the tooth is largely based on the duration that the tooth was out of the socket.

Were any teeth found at the scene? Did the patient experience any coughing or gagging after the injury? This may be suggestive of aspiration of a tooth.

Has the patient been drinking alcohol or using any other drugs, which may alter their level of consciousness (including recreational drugs)? These drugs may increase the likelihood of aspiration, especially if the gag reflex is diminished.

Was there a loss of consciousness?

Does the patient complain of pain? Do the teeth feel as if they are meeting normally? Is the pain associated with occlusion? Mandibular fractures are often worsened with jaw movement and patients will also complain that their teeth do not meet normally. Pain from temporomandibular joint (TMJ) injuries is often referred to the ear.

Pain from fractured teeth is made worse with the inspiration of air or contact with hot or cold substances. Alveolar ridge fractures are made worse with any movement of that segment.

Did the patient apply any substance to the teeth to decrease the pain? Over-the-counter anesthetics and topical analgesics can cause sterile abscesses if applied to the pulp or the dentin (12).

Does the patient have a history of dental work with regard to the traumatized tooth?

Is the tooth a primary or secondary tooth? Traumatized primary teeth are managed differently than permanent teeth.

Does the patient have a history of bleeding disorders or allergies to medicines?

A meticulous physical examination is important. Injuries to the dentition and mucosa are easily missed during a casual examination or if the examiner is distracted by more obvious physical findings. The many nooks and crannies of the mouth can easily hide fairly significant sized lacerations, tooth fragments, and other foreign bodies.

The examination should begin with observation and simply talking to the patient; muffling, drooling, and voice change may signify airway involvement. Individuals with mandible dislocations or fractures often talk with a partially open mouth without pursing their lips. External inspection should be performed next. Mandibular dislocations and fractures are associated with asymmetry, deformity, or swelling of the face. The EP should visualize the face from multiple angles to note subtle asymmetries. The opening and closing of the mouth should be smooth and full, with no limitations or hesitations. The face is palpated for crepitus, tenderness, or step-offs. The mandible and entire midface should be palpated with particular attention being paid to the maxilla, zygomas, mandibular condyles, and coronoid processes. The TMJs should be palpated throughout the entire range of motion. There should not be any pops, clicks, or complaints of pain.

The physician should palpate the neck with special attention to the area beneath the mandibular body and assess for swelling or tenderness, and examine the skin for bruising. The oral cavity should

be inspected for bleeding, swelling, or tenderness. Each tooth should be accounted for. A tongue blade can be used to visualize the entire mucobuccal fold region. Often, when the buccal mucosa is redundant or if there is swelling secondary to trauma, a two-tongue blade technique is necessary to visualize the entire oral cavity. Using a gloved hand, the EP should palpate the buccal mucosa and the floor of the mouth. Each tooth should be percussed with a tongue blade for sensitivity and palpated with fingers for mobility. Blood in the gingival crevice (where the enamel contacts the tooth) is suggestive of a traumatized tooth or a mandibular or maxillary fracture. The teeth should meet evenly when biting and the patient should be able to exert firm pressure on a tongue blade with his or her molars. The inability to crack a tongue blade bilaterally when it is twisted between the molars (tongue blade twist) is suggestive of a mandibular fracture (1).

The basic evaluation and treatment of most dental emergencies can be performed without any radiographic or laboratory evaluation. Unlike definitive care in the specialist's office, the ED treatment of tooth and alveolar ridge fractures is usually not changed by information gained from x-rays. Radiographs should be obtained if a tooth fragment is missing and thought to be aspirated or otherwise lodged in the lip or buccal mucosa. Similarly, intruded teeth are not always apparent and x-rays can help distinguish between an intruded and an avulsed tooth.

A panorex and a Towne view are probably the most useful and cost-effective views to obtain when evaluating mandibular trauma in the ED (8,12). The panorex of the mandible shows the mandible in its entirety and demonstrates fractures in all regions, including the symphysis; however, it can rarely miss overriding anterior fractures (18). An occlusal view or CT scan is indicated if this is likely. The Towne view allows slightly better visualization of the condyles and should be used if the condylar regions cannot be visualized adequately with a panorex (8). Coronal CT scanning is more precise and definitive and is often used in the preoperative evaluation, however, CT scanning is usually unnecessary in the ED evaluation. CT scanning should be obtained if multiple facial fractures are

suspected or if clinical suspicion is high and standard radiographs are negative or equivocal. If the patient is unable to sit still in the panorex machine or is immobilized, then CT scanning or standard lateral mandibular films should be obtained. Lateral mandibular films have the disadvantage of not visualizing the symphysis well and occlusal films may be required to better evaluate this part of the mandible.

Laboratory work is not necessary for the routine evaluation of dental and and maxillofacial trauma but should be considered on an individual basis. Likewise, bleeding times and coagulation profiles are unnecessary in most individuals, but should be considered if the patient is anticoagulated or the history is compatible with a bleeding disorder.

KEY TESTING

- Radiographs should be obtained if a tooth or tooth fragment is missing and thought to be either aspirated, intruded, or lost in the buccal or gingival tissue.
- An initial panoramic radiograph should be obtained if there is a suspicion of mandibular fracture
- A Towne radiograph should be obtained if there is suspicion of a mandibular condyle fracture and the initial panorex is negative or inconclusive.
- CT scanning should be considered if there is suspicion of multiple facial fractures or the panorex is negative and suspicion remains high for mandibular fracture.
- CT or lateral mandibular films can be used to evaluate mandibular injury if the patient is immobilized.
- Bleeding times and coagulation profiles should be considered if the patient exhibits ongoing bleeding and the history is suggestive of anticoagulation or a bleeding disorder.

ED MANAGEMENT

Table 24.3 lists the equipment that EDs should have for taking care of dental-related injuries. There are several key principles which

apply to the management of dental trauma in the ED.

TABLE 24.3
Dental Equipment Needed in the ED

Packing gauze
Dental roll gauze
Calcium hydroxide paste or glass ionomer cement or zinc oxide cement
Dry socket paste or eugenol
Topical anesthetic gel (20% benzocaine or 5% lidocaine)
Periodontal paste (Coe-Pak) or self-cure composite
Bupivacaine cartridges with epinephrine
EMT Toothsaver Preservation system, Save-A-Tooth or fresh milk
Zinc oxide/eugenol temporary cement (Temrex) or other dental cement
Ringed injection syringe
Stainless steel spatula and mixing pads
Oral surgery tray with arch bars and ligature wires
Tongue blades and cotton-tipped applicators
Disposable electrocautery (optional)

The EP should identify all fracture fragments as well as loose teeth and note if a mandibular fracture is open or closed. Radiographs should be taken if there is any suspicion of intrusion into the alveolar bone or surrounding mucosa. A chest x-ray (CXR) is obtained if a patient with a missing tooth does not recall the location of the tooth. Lack of pulmonary complaints cannot be counted on to rule out an aspirated tooth.

Over-the-counter topical tooth remedies and analgesics should be avoided as their use can lead to the development of sterile abscesses and soft tissue irritation (14).

It is much easier to repair the dentition if the tooth can be manipulated without causing significant discomfort. Dental block anesthesia and tooth and supraperiosteal injection should be a part of the EP's armamentarium. Dental blocks, topical and injectable anesthetics and regional oral anesthesia should be used to treat pain and to provide anesthesia for manipulation and temporary repair of the injured tooth. Narcotic and nonnarcotic alternatives, although

helpful after treatment is completed, do not usually offer the patient the comfort required to do most dental manipulations.

Tetanus vaccine should be administered if indicated.

Dental Fractures

Maxillary central incisor injury accounts for between 70% and 80% of all fractured teeth (20). The associated morbidity of fractured teeth can be considerable and includes failure to complete eruption, abscess, loss of space in the dental arch, color change of the tooth, ankylosis, abnormal exfoliation, and root resorption.

The ED management of acute tooth fractures depends upon the extent of fracture, the degree of development of the apex of the tooth, and the age of the patient. There are many systems for classifying dentoalveolar injuries and, in particular, tooth fractures. The Ellis classification system is one classification system often cited in the EM literature. An Ellis Class I fracture is only through the enamel. An Ellis Class II fracture involves the dentin as well as the enamel and an Ellis Class III, the most severe, is a fracture through the pulp, dentin, and enamel. Many dental specialists, however, do not use this nomenclature and, therefore, the most widely understood and recognized method of classification is based on description.

Crown Fractures

Crown fractures may be divided into complicated and uncomplicated categories. Uncomplicated crown fractures involve the enamel alone or the dentin in combination with the enamel.

Fractures that involve only the enamel are considered uncomplicated and are usually not sensitive to forced air, temperature extremes, or percussion and generally pose no threat to the dental pulp. They are characterized by the loss of some portion of the normal contour of the tooth edge. Immediate ED treatment is not necessary but may consist of smoothing the sharp edge of the tooth with an emery board or a rotary disk sander if the patient is very uncomfortable because of the sharp edges of the fractured tooth. The

patient should be reassured that the tooth can be restored to its pretraumatic state by a dentist using composite bonding materials. Follow-up is important, as pulp necrosis and color change occasionally do occur after these fractures (Fig. 24.4A,B) (3,7).

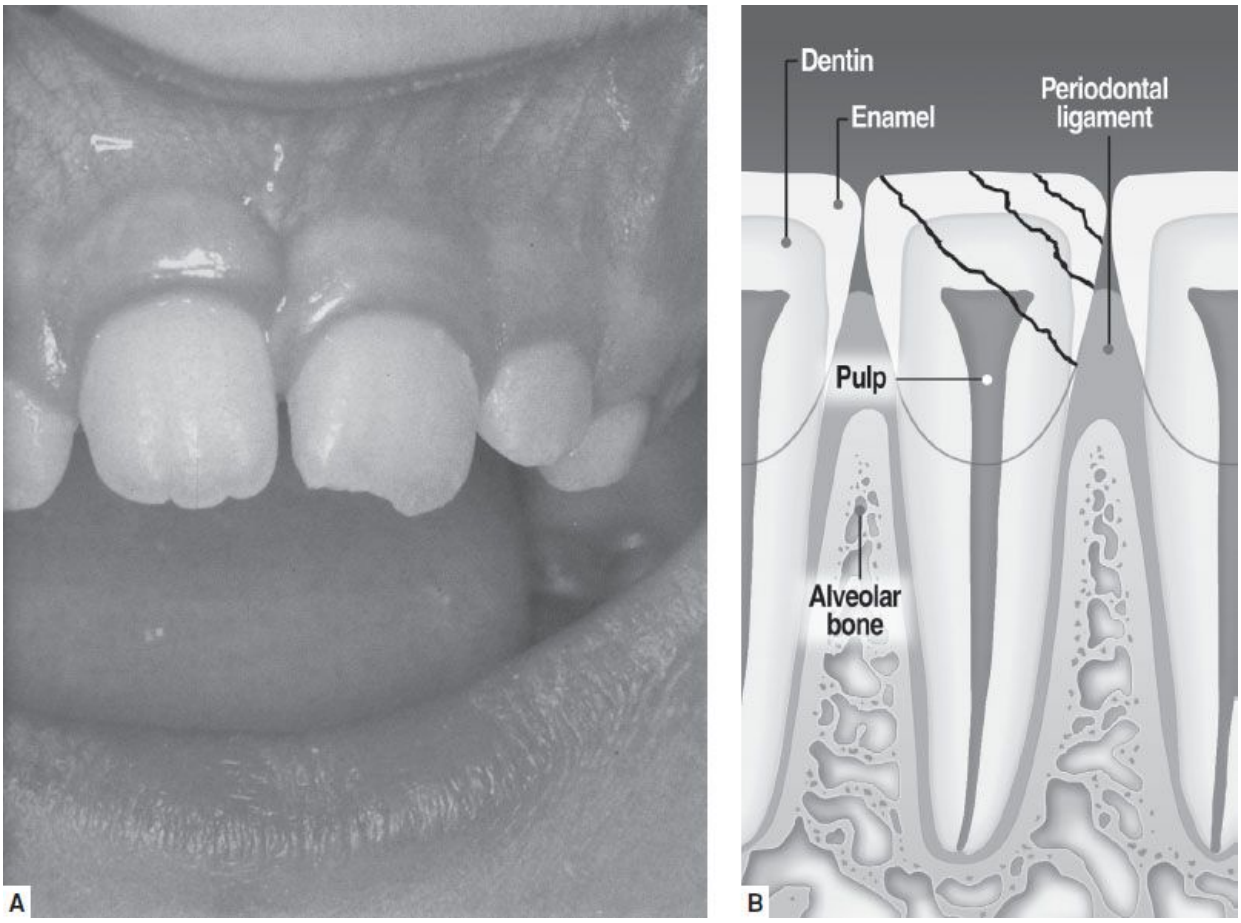

FIGURE 24.4 Fractures of the crown should be described as through the enamel, the dentin, or the pulp. Fractures through the enamel and dentin are uncomplicated, and fractures through the pulp are considered to be complicated.

Uncomplicated Fractures through the Enamel and Dentin

Fractures that extend into the dentin are at a higher risk of pulp contamination with subsequent abscess development and possible pulp necrosis. They are also more likely to have an associated periodontal ligament injury because of the force sustained in creating the injury. The overall prognosis of dentin fractures depends upon

the extent of dentin exposed and the overall injury to the Periodental Ligament (PL) (10). The risk of pulp necrosis in these patients is 1% to 7%, but this increases as treatment time extends beyond 24 hours (7). Patients often complain of sensitivity to extremes of temperature, forced air, or palpation. The physical examination reveals the yellow tint of the dentin as contrasted to the white hue of the enamel. (Fractures that are closer to the pulp cavity reveal a pink tinge to the dentin.) The dentin's porous quality allows passage of bacteria from the oral cavity to the pulp, which may result in inflammation and infection of the pulp chamber. The inflammatory response occurs usually after 24 hours, but may occur sooner if the level of injury is closer to the pulp. Younger patients less than 12 years of age have a pulp/dentin ratio larger than in the mature adult and are at increased risk of pulp contamination. They should be treated aggressively and should be seen within 24 hours (15).

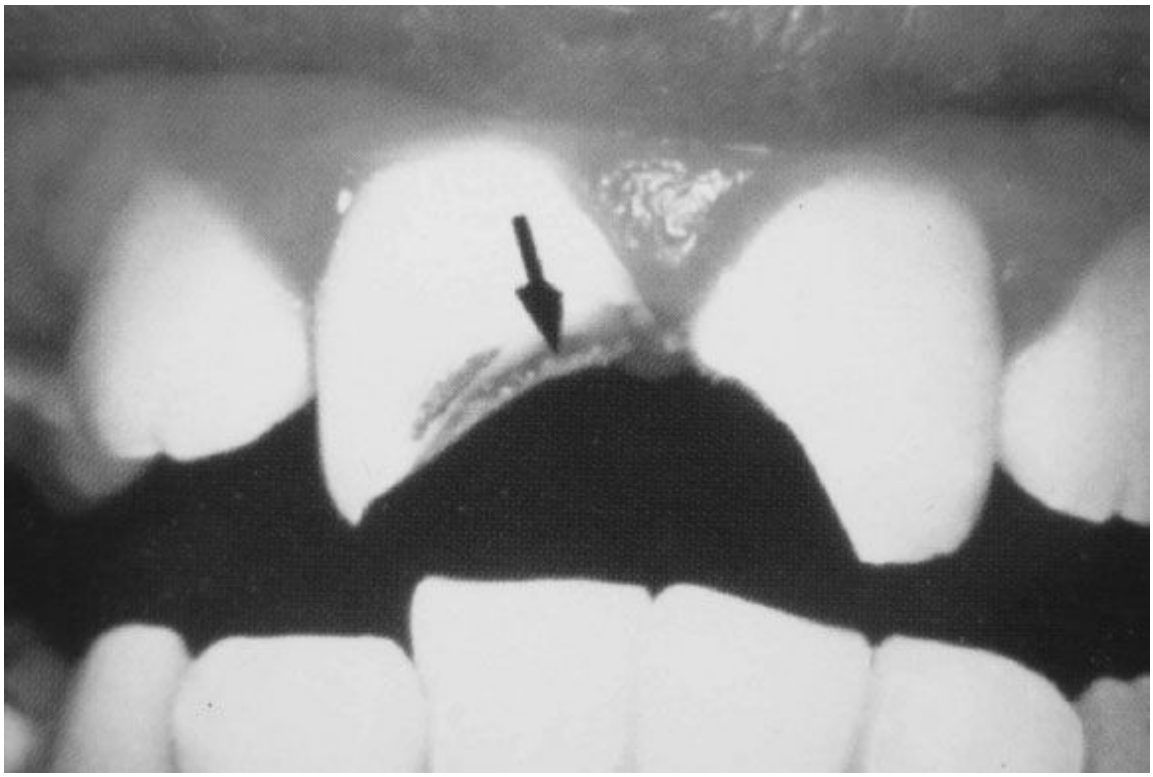
There are two goals in treating dentin fractures in the ED. The exposed dentin should be covered to prevent secondary contamination or infection, and the clinician should provide pain relief. After a fracture is covered emergently in the ED, a dentist can later rebuild it with modern composites, often directly over the appropriate dressing applied by the EP, provided the pulp is in good condition. A supraperiosteal injection performed prior to covering allows manipulation of the tooth and increased patient cooperation. Surface coverings include calcium hydroxide, dentinal sealants, bonding agents, and glass ionomer composites (2,14,18,20). Topical agents that are applied by a dentist or dental professional are often not realistic for use in the ED. Likewise, composites that are used in the dental office are often cured with a bonding light and are beyond the scope of most emergency practice. The ease of applicability of calcium hydroxide paste, the long shelf life and the fact that it can be used easily by itself make it attractive for ED use (5,20). Topical skin adhesives are among the many topical dressings often applied to teeth in the ED, however, they are not approved for intraoral use and are broken down by salivary enzymes before the patient can be seen in follow-up. Many patients sustaining a fracture through the dentin will eventually require a root canal or other definitive endodontic

treatment. The timely application of an appropriate dressing in the ED, however, may prevent contamination of the pulp and make root canal unnecessary. As with any trauma to the anterior teeth, it should be explained to the patient that disruption of the neurovascular supply is possible and that long-term complications such as pulp necrosis, color change, and root resorption may occur.

Complicated Fractures of the Crown Involving the Pulp

Complicated fractures of the crown that extend into the pulp are true dental emergencies as they result in pulp necrosis in 10% to 30% of cases, even with appropriate initial treatment (7). They are distinguished from fractures of the dentin by the pink or red color of the pulp. The fracture surface of the tooth should be wiped off with gauze and observed for frank bleeding or a pink blush, which indicates exposure of the pulp (Fig. 24.5 and eFig. 24.1). These fractures are usually exquisitely sensitive, however, occasionally there is a lack of sensitivity secondary to a concussion of the nerve supply of the tooth (2).

FIGURE 24.5 A fracture through the pulp. Acute fractures through the pulp usually bleed.



eFIGURE 24.1 A pulp fracture.

Management includes referral to a dentist, oral surgeon, or endodontist and usually a pulpectomy (complete removal of the pulp) or, in the case of primary teeth, a pulpotomy (partial removal of the pulp) is the definitive treatment (3,6). The longer the pulp is exposed, the greater the chance of contamination and abscess formation. If a dental consultant cannot see the patient immediately, then the EP should attempt to relieve the pain and cover the exposed pulp. Supraperiosteal injection (dental block) should be performed if significant pain is present and the tooth should be covered with one of the dressings described in the previous section.

There is currently no literature that addresses the issue of whether or not antibiotics should be prescribed for fractured teeth seen in the ED. Patients who present to the dentist and then undergo definitive treatment do not usually receive antibiotic prophylaxis (6,20). In the ED, patients must be treated under the following assumptions. First, it is uncertain as to whether the patient is going to be able to secure follow-up care, and second, the status of the patient's underlying

dentoalveolar health is not always known. Delayed fracture care and poor gingival health increase the risk of pulp necrosis and, potentially, periapical abscess. These factors suggest to some that tooth fractures involving the dentin or pulp should receive antibiotic prophylaxis, unless follow-up is certain and is within a reasonable time period (i.e., several days).

Luxation, Subluxation, Intrusion, and Avulsion

Subluxation refers to teeth that are mobile but not displaced and luxation refers to teeth that are displaced, either partially or completely from their sockets. Luxation injuries are further divided according to the direction of the displacement. Extrusive luxation refers to displacement of the tooth in an axial direction (eFig. 24.2). Intrusive luxation occurs when the tooth is displaced apically (toward the root) and is often accompanied by crushing or a fracture of the apex of the tooth (eFig. 24.3).

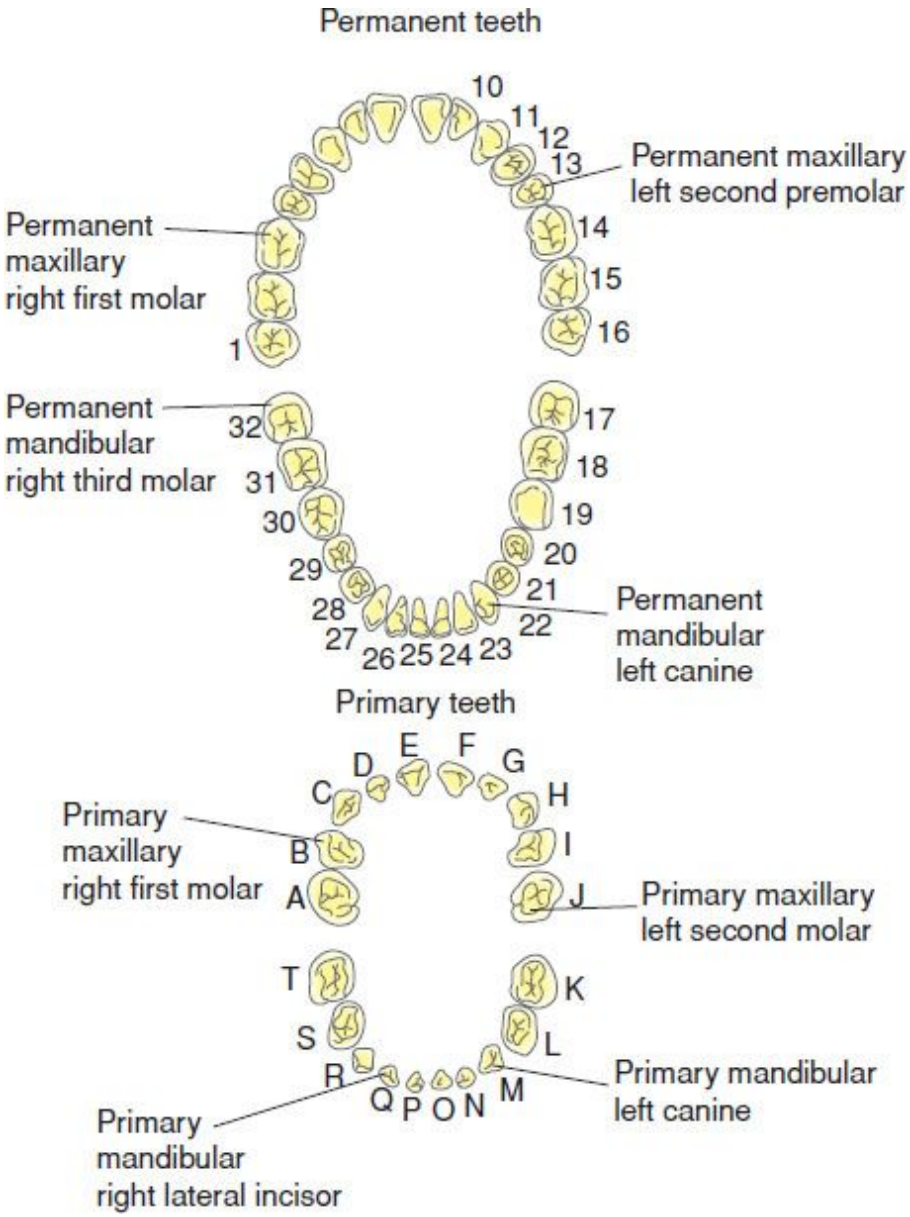


FIGURE 24.2 Identification of teeth.

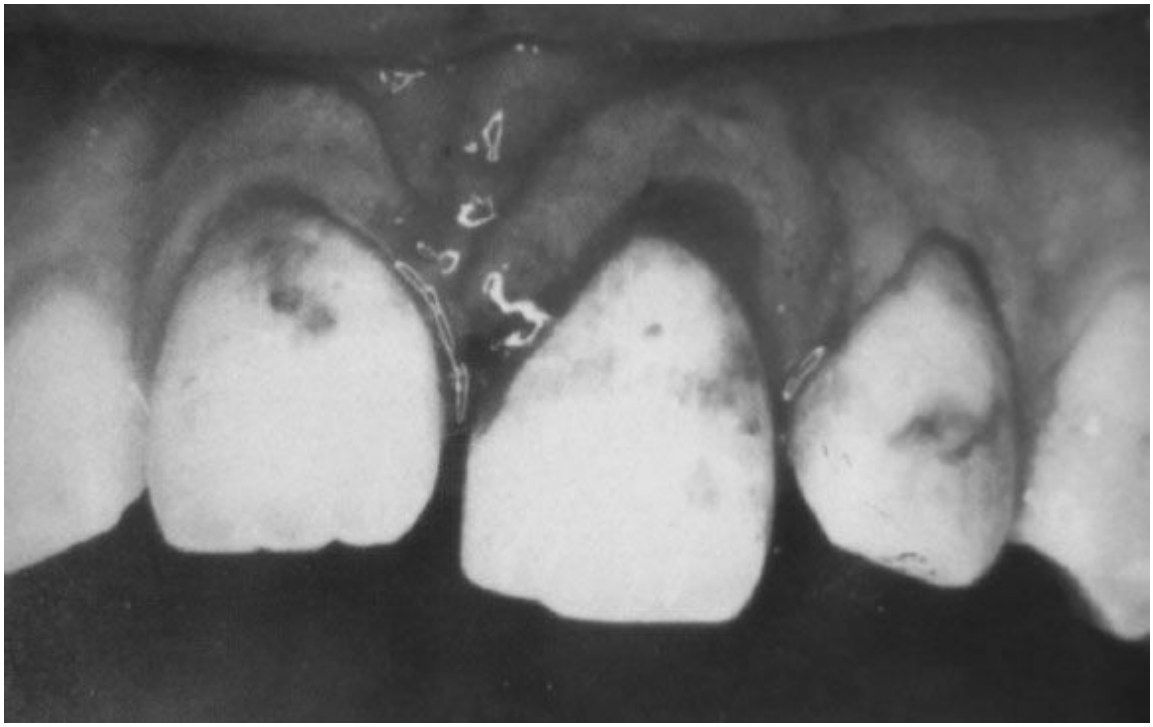
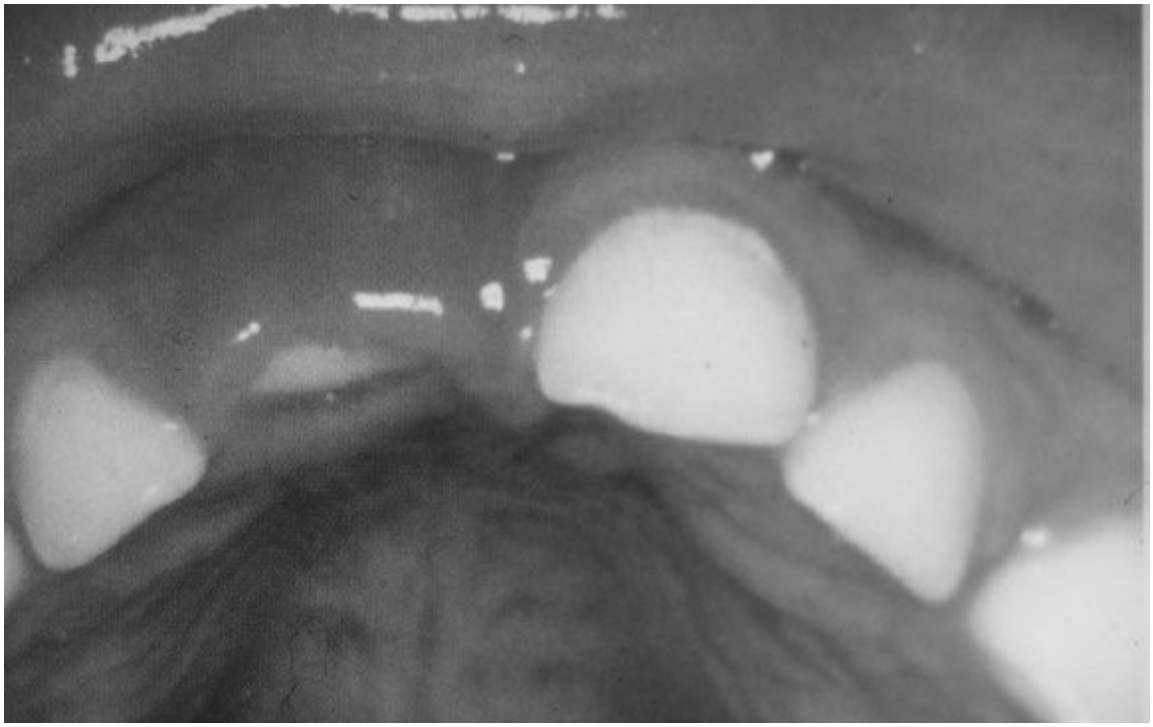


eFIGURE 24.2 Extrusive luxation. Extruded teeth are displaced coronally.



eFIGURE 24.3 Intruded teeth. Intruded teeth are displaced apically.

Lateral luxation occurs when the tooth is displaced facially, mesially, lingually, or distally. Fractures of the alveolus frequently accompany lateral luxation injuries. Complete luxation, also known as complete avulsion, occurs when the tooth is entirely lost from the socket.

Teeth that are minimally mobile and not displaced do very well with conservative treatment only. As the periodontal ligament reattaches to the alveolar bone, the tooth will tighten up in the socket without intervention and the vascular supply of the tooth will reestablish itself. Patients should be instructed to eat a soft diet for 1 to 2 weeks and follow-up with their dentist as soon as possible.

Grossly mobile teeth require stabilization in the ED. Fixation is best performed by the dental specialist with bonding materials or wire ligation. Temporizing splinting techniques suitable for use by EPs include periodontal paste and self-cure composite. A commercially available periodontal paste is Coe-Pak, a moderately sticky clay-like dressing that becomes firm after application. Self-cure composite is another splinting option in the ED. This composite does not require acid etching or a bonding light and is applied only to the enamel surface of the tooth. Both periodontal paste and self-cure composites are easy to remove by the dentist during formal restoration.

Intruded teeth have been forced apically into the alveolar bone and often result in a disruption of the attachment apparatus or fracture of the supporting alveolar bone. Intruded teeth are usually immobile and do not need stabilization in the ED, but often do require later endodontic treatment because of root necrosis. X-rays should be obtained any time there is uncertainty as to whether a tooth is intruded or avulsed. Permanent teeth need to be repositioned the majority of the time as they are often associated with alveolar bone fracture, but primary teeth are usually given a trial period to erupt on their own before any intervention is taken (10,11).

An avulsed tooth is a true dental emergency. The first goal is to find the tooth. Missing teeth may be lost, intruded, aspirated, swallowed, fractured, or embedded in the oral mucosa somewhere. Radiography should be considered to find the lost tooth or

fragments. Management in the ED is based on patient age, time since avulsion, presence of other maxillofacial trauma such as alveolar ridge fractures, and the overall health of the periodontium (4). Primary teeth are not replaced because they can fuse to the alveolar bone and potentially cause craniofacial abnormalities or infection and they may prevent normal eruption of the permanent teeth (9,11). There are a few reports of successful reimplantation of primary teeth by dentists, however, most resources do not recommend it be performed by dentists, family members, or EPs (9). Parents can be reassured that prosthetic replacements can be worn, if desired, until the permanent teeth erupt.

Time is the essential consideration when deciding to replace an avulsed tooth. The longer the tooth is out of the socket, the higher the incidence of periodontal ligament necrosis and subsequent failure of reimplantation (4). Periodontal ligament cells begin to die within 20 minutes outside of the oral cavity and cell death is usually complete within 60 minutes if the tooth is not placed in appropriate transport medium (15). Various transport media, including milk, Hanks balanced salt solution (HBSS), water, saliva, and Gatorade have all been studied. Certain cell culture media have also been developed that cause periodontal cells to proliferate and remain viable, but milk and commercially available HBSS products (known as EMT Toothsaver or Save-A-Tooth) are currently best for prehospital transport and ED storage (19). HBSS has been shown to maintain PL cell viability for 24 hours and is currently recommended by the American Association of Endodontists. If such a product is unavailable, milk should be used as the storage media until reimplantation can be performed. The pH and osmolarity of milk have been shown to maintain PL viability for up to 4 hours (26). Saline or the patient's saliva can be used at the scene if nothing else is available as both will maintain PL viability for up to 2 hours. The use of water as a transport medium should be discouraged as the low osmolarity causes PL cell disruption. Likewise, the transporting of the tooth in the oral cavity or under the tongue should be discouraged because of the risk of aspiration of the tooth as well as physical trauma which can occur to the PL from structures in the mouth.

Antibiotics are controversial in the management of avulsed and fractured teeth. Human trials have not shown any significant effect of systemic antibiotics on the outcome of avulsed teeth reimplantation, but animal study data suggests that antibiotics may decrease resorption of the tooth root and increase the likelihood to successful tooth reimplantation. Recent dental association guidelines recommend oral antibiotics be administered until conclusive data is obtained (27,28). The goal of the EP in any tooth avulsion or injury or fracture is to keep the native tooth if possible. Therefore, it is of utmost importance that the tooth be stored in an appropriate storage media until the EP can prepare the socket for reimplantation. Once reimplanted, the tooth usually loses the majority of its blood supply and undergoes pulp necrosis, but it remains a functional tooth if the PL stays intact.

Alveolar Bone Fractures

Fractures to the alveolus, which is the tooth-bearing portion of the mandible or maxilla, often occur in multitooth segments but will vary in the number of teeth involved, the amount of displacement, and the amount of mobility of the affected segment. The diagnosis is confirmed by noting a segment of mobile teeth that are misaligned. Dental bitewing x-rays confirm the diagnosis and panorex or facial films may show a fracture line apical to the roots of the involved teeth.

The treatment of alveolar ridge fractures involves rigid splinting of the affected segment, which should be performed urgently by an oral surgeon or a dentist. The urgency is dependent upon the mobility, the displacement, and the extent of the segment. This ideally should be done within 24 hours. The role of the EP is to identify the injury as well as any avulsed or fractured teeth and preserve as much of the alveolar bone and surrounding mucosa as possible. Alveolar bone that is lost, debrided, or missing is difficult for the specialist to restore properly (5).

Soft Tissue Trauma

It is imperative for the EP to carefully inspect the mucosa of the perioral region and determine the presence of any foreign bodies, lacerations, or tooth fragments. The repair of injured mucosa should generally take place after the repair of the dentition as soft tissue manipulation can result in damage to sutures already placed in the soft tissue.

The rates of infection of intraoral lacerations are extremely small, and most heal uneventfully without antibiotic coverage. One prospective study showed a trend toward decreased infections in intraoral lacerations treated with prophylactic penicillin, however, the results were not statistically significant (22). It is reasonable to use antibiotics if the wound contains a large amount of devitalized tissue or is through and through.

Buccal Mucosa Injuries

Most lacerations and abrasions of the oral mucosa heal quickly and do not require definitive repair. Large lacerations (>1.5 cm) should generally be repaired using 4-0 or 5-0 chromic sutures. Absorbable sutures should be placed so that the knots are buried. Silk is an acceptable alternative, but used much less commonly as it requires removal. It is also more reactive. Nylon should be avoided as it is sharp and irritating to the tissues.

Through and through lacerations require a meticulous physical examination to rule out foreign bodies, damage to Wharton or Stenson ducts, or damage to the facial nerve. Guidelines for closure are controversial but, in general, larger lacerations (>1 cm) should be closed (23). The mucosa is repaired as described and the skin is closed with 6-0 nylon, prolene, or rapidly absorbable suture. The mucosa is closed first so as not to damage the skin layer. It is reasonable to close only the skin layer if the mucosal laceration is very small. Large lacerations, through and through lacerations, or lacerations with large amounts of devitalized tissue should be rechecked in 2 days. Facial sutures should be removed in 4 to 5 days. Saline rinses and a soft diet should be prescribed.

Gingival Injuries

Most small injuries over the maxillary or mandibular gingiva usually heal uneventfully without intervention. If the laceration is large, gaping, if a flap is present or if there is bone exposed, the edges should be approximated with 4-0 or 5-0 absorbable suture. If difficulty arises because there is little soft tissue underneath the gingival to anchor your suture, the practitioner can wrap the suture around the teeth and use them as anchors for your suture. Periodontal paste, which is used for stabilizing loose teeth, can also be used to repair gingival lacerations without the need for sutures. When placed over nongaping gingival lacerations, it protects the mucosa and allows the laceration to heal uneventfully. The paste is removed in 7 to 10 days by a dentist.

Frenulum Injuries

Lacerations of the frenulum rarely require suturing except in complex lacerations which extend into the surrounding mucosa or gingiva. In these cases, the mucosa should be tacked down and approximated with absorbable suture. Wounds of the frenulum are very uncomfortable and analgesia should be prescribed even if suturing is not required.

Tongue Lacerations

Tongue lacerations that are <1 cm in length and whose edges are not gaping seldom require repair. Gaping lacerations require repair as the edges will epithelialize leaving a grooved or bifid appearance. Likewise, wounds that are bleeding profusely, are flap shaped, or are on the edge of the tongue should be sutured. Small avulsions heal without intervention.

Repair should be initiated with anesthesia via local infiltration or by lingual block. Absorbable sutures, 4-0 are ideal, but silk can be used as well as it is easy to work with. It has the disadvantage of having to be removed in 5 to 7 days.

CRITICAL INTERVENTIONS

- Identify all teeth and consider aspiration of fractured or avulsed teeth. Inspect all lacerations for possible foreign bodies or tooth fragments.
- Cover all fractures of the dentin or pulp, unless dental consultation is available immediately.
- Splint all moderately or severely loosened teeth.
- Place avulsed teeth in an appropriate storage medium, such as milk, EMT Toothsaver or Save-A-Tooth until reimplantation is possible.
- Do not replace primary teeth.
- When performing a dental block, aspirate before performing injecting local anesthetic.
- Obtain x-rays if there is any suspicion of intruded teeth, alveolar ridge, mandible fractures, or oral foreign bodies (such as tooth fragments).
- Repair tongue lacerations that are gaping or that involve the tongue margin.

DISPOSITION

The disposition of most dental injuries is somewhat dependent upon what treatment is provided in the ED. Any fractured tooth should receive follow-up as even small chip fractures through the enamel can result in pulp necrosis. Fractures through the dentin and pulp should both be seen as soon as possible, preferably within 24 hours, if tooth salvage is to be an option. If the dentin/pulp is covered with CaOH, the 24 hour window is lengthened somewhat, the patient will be more comfortable and abscess may be less likely. A fracture through the pulp should be seen as urgently as can be arranged. Luxated or reimplanted avulsed teeth, if stable, can also be seen in 24 to 48 hours. If a luxated tooth, reimplanted tooth, or alveolar ridge fracture remains unstable and splinting by the EP is not possible, dental or oral surgery consultation should be obtained immediately. Intruded teeth should be seen within 24 to 48 hours for evaluation of possible alveolus fracture and realignment. Mobile or open alveolar ridge fractures require immediate consultation. Any mucosal or tongue laceration which is extensive or will require

plastic surgery repair should receive appropriate consultation or be transferred to facility where repair is possible.

Common Pitfalls

- Failure to replace an avulsed tooth assuming that the patient can get an implant. It is always better to have a functional native tooth if possible.
- Replacing primary teeth. They may cause problems later on. The tooth should be left out and the patient referred to the dentist.
- Failure to consider that the patient aspirated a tooth or that it may be embedded in the oral mucosa.
- Failure to close a significant tongue laceration, which can be debilitating and creates a more difficult delayed repair.
- Failure to use proper anesthesia, such as a dental block, prior to manipulating a fractured tooth. The patient's pain makes it very difficult to complete the procedure properly. Dental blocks with long-acting anesthetics control pain very effectively (Table 24.3).

CHAPTER 25

Eye Trauma

Kevin J. Knoop and William Dennis

Eye trauma accounts for approximately 1% of annual ED visits, with more than 2 million ocular injuries yearly (1). Of these, 60,000 require admission, and lasting visual impairment results in approximately 50,000. The emergency physician (EP) has an important role in the diagnosis, management, and referral of eye injuries. Thus, the EP must be cognizant of the spectrum of ocular trauma to preserve vision and prevent disability.

CLINICAL PRESENTATION

A rapid, focused history must direct the EP early in the evaluation. Surrounding context and events as well as injury mechanism and presenting symptoms should be elicited. For example, elderly patients frequently present after falls and may have additional systemic injuries and an underlying condition that may have precipitated the fall. There are four mechanisms of ocular trauma: abrasion, blunt force, laceration or penetration with a foreign body (FB), and burn. Prognosis may be linked to mechanism, as lacerations generally have better outcomes than blunt trauma that may contuse or rupture the globe (2).

ED EVALUATION

When evaluating eye trauma, the EP should consider concomitant nonocular injuries. Rapid primary assessment of airway, breathing, circulation, and disability before conducting a systematic and comprehensive eye evaluation will address this possibility. After

determining patient stability, ocular trauma is addressed as immediate treatment is imperative in many instances. The chemically burned eye must be irrigated immediately and continuously for at least 30 minutes with 2 L of saline, lactated Ringer, or another neutral solution, until the measured pH reaches physiologic neutrality (7 to 7.4). If the pH is normal after initial irrigation, a recheck of pH every 15 minutes ensures neutral pH. Traumatic endophthalmitis usually presents as pain and inflammation out of proportion to the penetrating injury preceding the infection. It requires immediate ophthalmologic consultation for injection of intravitreal antibiotics.

Visual Acuity

Visual acuity is the single most important predictor of visual outcome and is documented as soon as possible. It is helpful if a baseline acuity can be obtained by history or medical records. The EP should test one eye at a time while covering the opposite eye, beginning with the affected eye. Corrective lenses are worn when possible; if not available, a piece of paper with multiple pinholes (pinhole acuity) can be used. Contact lenses should not be placed in an injured eye. The EP should test routine distant visual acuity at 20 ft from a Snellen chart. Emergent assessment of visual function includes an assessment of light perception, hand motion, finger counting, ability to read print (the distance should be noted), and formal near vision (14 in from a Rosenbaum card). Children require some special consideration. From age 6 months to 3 years, fixing on a moving light source corresponds to 20/40 vision. From age 3 years to 6 years, Allen pictures are used or the “E” chart for those who cannot read. Formal visual acuity should never delay important therapeutic interventions such as eye irrigation (3).

Lids and Other Periorbital Structures

The lids and periorbital structures should be examined for injury (Fig. 25.1). When there is any suspicion of an open globe secondary to blunt or penetrating trauma, no pressure or object is applied to

the globe thereafter for any part of the examination. An exception is bedside ultrasonography (no pressure applied) performed by an experienced examiner in selected patients. The EP should inspect for swelling, ecchymosis, proptosis, enophthalmos, ptosis, lacerations, and FB. If the eye is swollen shut, ultrasonography or lid retraction is used to assess the globe and underlying structures. Ptosis suggests contusion or laceration of the levator palpebrae, Horner syndrome, or third nerve palsy. Upper lid lacerations should be explored for penetration of the tarsal plate, the muscle, or the entire structure (through and through). All three indicate significant force and raise concern for globe injury. Any visible surface FBs should be removed. Penetrating FBs should be left for an ophthalmic surgeon to address. The EP should palpate the orbital rim and soft tissues and the zygomatic arch area, noting point tenderness, step-offs, and subcutaneous emphysema.

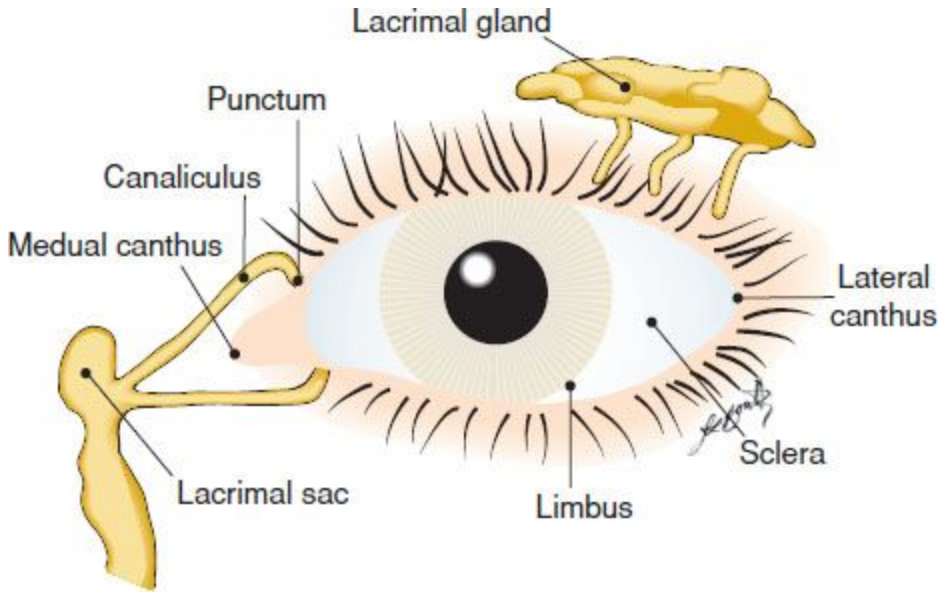

FIGURE 25.1 Periorbital structures.

Anterior Segment

The anterior segment of the eye includes the sclera, conjunctiva, cornea, anterior chamber, iris, and lens (Fig. 25.2). A topical anesthetic is used to examine this part of the eye, generally two drops are adequate, but may be augmented with one to two

additional drops. The EP should inspect for globe laceration, FBs, subconjunctival hemorrhage, chemosis, limbal edema, lid laceration, and contact lenses (these should be removed). Nonadherent FBs should be evacuated as soon as they are identified. The EP should perform a slit-lamp examination to evaluate each anterior chamber component separately: globe, lid margins, cornea, anterior chamber, iris, and lens. A cobalt light and fluorescein dye will highlight abrasions on the cornea and are necessary to perform Seidel test for leaking aqueous.

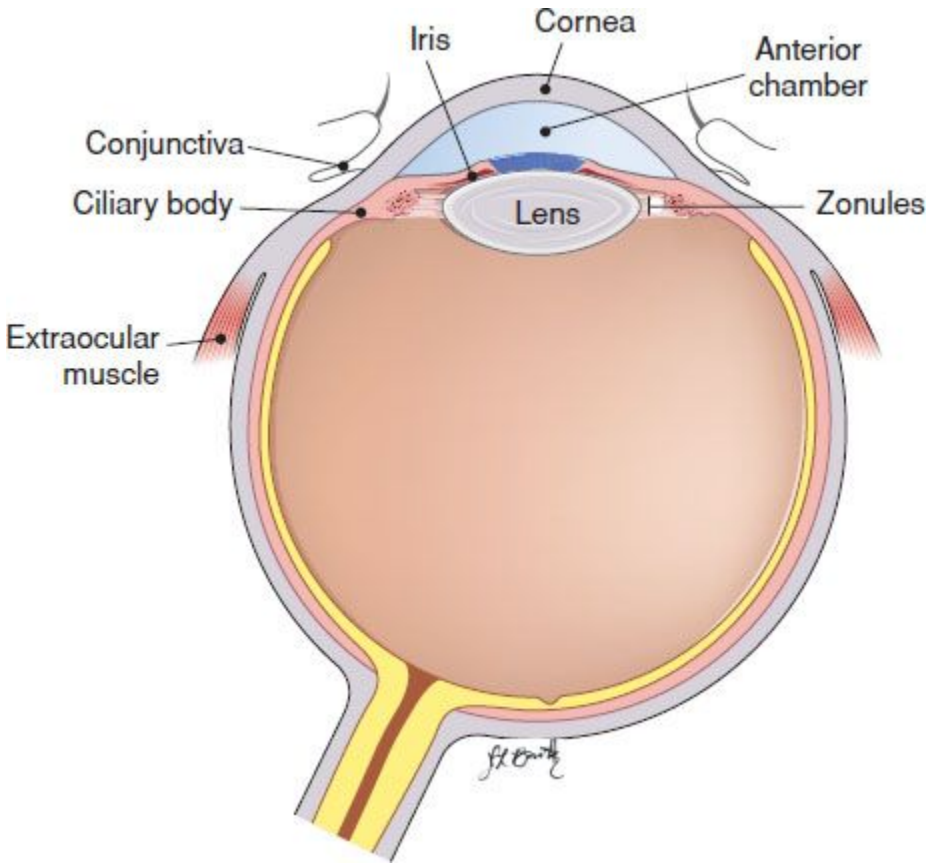

FIGURE 25.2 Cross section of the eye.

Pupils

Pupils provide information via their size, shape, and reaction. The EP should inspect for anisocoria and pupillary distortion. *Anisocoria* is defined as a disparity in size >0.3 to 1 mm. If pupils react briskly and the degree of anisocoria is unchanged with and without bright

light, the anisocoria is physiologic. A distorted pupil suggests globe rupture, iridectomy, or synechiae. In a ruptured globe, the pupil is tear shaped, with the apex of the teardrop pointing toward the rupture. A relative afferent pupillary defect (RAPD) suggests one or more of the following: efferent third nerve damage, glaucoma, iris incarceration, massive internal derangement of the eye (trauma to the eye so severe that light pathways are disrupted), optic chiasm or tract damage, optic nerve damage, retinal detachment, traumatic mydriasis, or vitreous hemorrhage. To test for RAPD, the EP should observe pupil symmetry and size of the unaffected eye while swinging a bright light from eye to eye. When the light strikes the unaffected eye, the pupil constricts. When the light strikes the affected eye, the pupil of the unaffected eye paradoxically dilates.

Extraocular Muscles

Extraocular muscles are tested in the six cardinal positions of gaze. Lateral rectus is innervated by cranial nerve (CN) VI, superior oblique by CN IV (LR6 SO4), and the remainder by CN III. Keys, a light, or toys should be used with infants. Binocular diplopia is seen with an abscess, cellulitis, CN palsy, hematoma compressing the globe or anterior chamber (retro-orbital hematoma or a large external eyelid hematoma), orbital edema, orbital floor or wall fracture with muscle entrapment, or retrobulbar hemorrhage. Monocular diplopia is seen in conditions that distort structures through which light must pass (corneal irregularity, dislocated lens [natural or implant], iridodialysis, or retinal detachment).

Posterior Segment

The posterior segment consists of the optic nerve, retina, and vitreous. Direct ophthalmoscopic examination yields limited but important information. Pupillary dilation is not necessary. Absence of the red reflex or inability to visualize the fundus suggests cataract, hyphema, lens rupture, retinal detachment, or vitreous hemorrhage. Visual field testing by confrontation is sufficient in the ED. Optic nerve function is assessed by testing for RAPD. If the

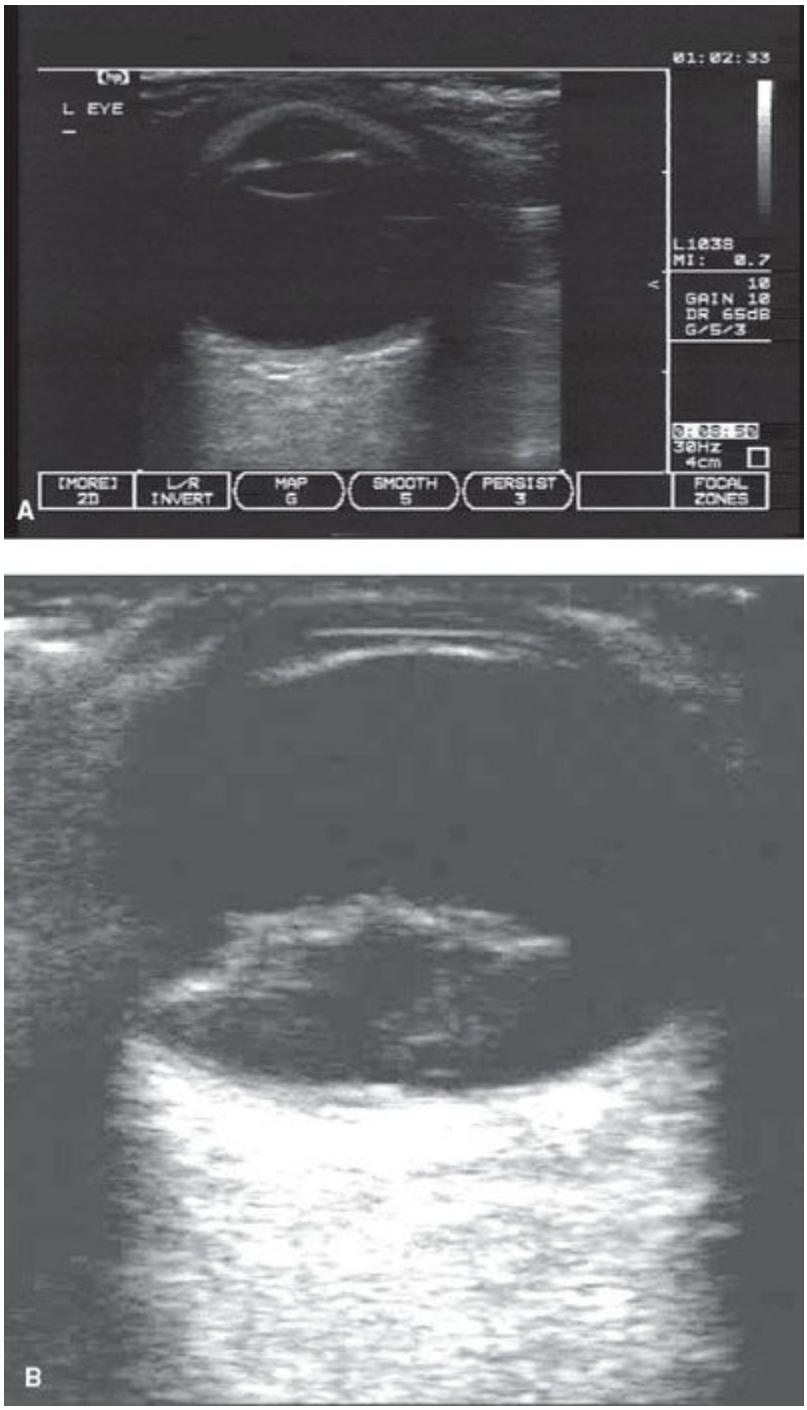
pupils are nonreactive or irregular, red desaturation testing is a suitable substitute. To test red desaturation, the EP should ask the patient to view a bright red object with each eye separately and compare the two images. If the optic nerve is damaged in one eye, the image coming from that eye will appear gray or washed out in comparison to the unaffected eye.

Intraocular Pressure

The intraocular pressure (IOP) may be elevated (>22 mm Hg) in several conditions, including acute glaucoma, globe rupture, hyphema, lens dislocation or swelling, suprachoroidal hemorrhage, and retrobulbar hemorrhage. Normal pressure ranges from 10 to 20 mm Hg (4). IOP measurement is contraindicated if a globe penetration is suspected. When the pressure is <5 mm Hg, penetration of the globe is likely.

Imaging of the Eye

Spiral computed tomographic (CT) scan with axial and coronal cuts is the preferred study when there is suspected injury to the orbit or globe. Plain x-ray has been replaced by CT as the primary radiologic diagnostic tool, as x-ray is unreliable for detecting small (0.2 to 1.5 mm) and nonmetallic FBs (60% false-negative rate), nor is it precise in determining the location of an FB. CT can also identify choroidal detachment, endophthalmitis, fracture, extraocular hemorrhage or hematoma (<3 days old), lens luxation or subluxation, globe rupture, orbital cellulitis, subperiosteal hematoma, vitreous hemorrhage (<3 days old), and retinal detachment. Bedside ultrasound performed by EPs with training and experience has been shown to be highly accurate and useful in diagnosing ocular pathology including FBs (as small as 0.2 mm), retinal detachment, lens dislocation, and vitreous hemorrhage (eFig. 25.1) (5).



eFIGURE 25.1 Emergency bedside ultrasonography of the eye is obtained with minimal pressure on the eye. A: A normal eye is shown with lid, anterior chamber, iris, lens capsule, and vitreous clearly seen. B: A retinal detachment is seen as a hyperechoic area anterior to the retina.

KEY TESTING

Physical examination

- Visual acuity
- Lids and periorbital structures
- Anterior segment
- Pupils
- Extraocular muscles
- Posterior segment
- IOP

Imaging

- CT for detecting FBs and orbital injuries
- Ultrasound for detecting retinal detachment, lens dislocation, and vitreous hemorrhage

ED MANAGEMENT

Subconjunctival Hemorrhage

Typically, an isolated subconjunctival hemorrhage is flat and involves a small portion of the bulbar conjunctiva without any break in the membrane. The history may reveal a related Valsalva maneuver or rubbing of the eye but often does not explain the event. There may not be a history of anticoagulant use, blood dyscrasia, or recurrent subconjunctival hemorrhage. No treatment is necessary as the condition is not threatening to the orbit or globe and will resolve over approximately 14 days. Bulging circumferential bloody chemosis after trauma should alert the EP to the possibility of a ruptured globe.

Simple Eyelid Lacerations and Periorbital Contusion

Eyelid laceration or periorbital contusion mandates a thorough evaluation to rule out involvement of the globe or associated structures. Periorbital contusion is generally managed with ice packs. Concurrent intracranial injury must be ruled out based on history and examination. Instructions for head injury and visual changes are given. Resolution of a simple contusion can take 2 to 3

weeks, whereas hemorrhage into the levator palpebrae may produce ptosis that can last for months. A *simple* eyelid laceration involves neither underlying structures nor the lid margin and can be repaired by the EP. Contaminated wounds must be irrigated without force against the underlying globe. No tissue should be debrided, owing to the excellent blood supply of the eyelid and desire for cosmetic and functional integrity. Wound closure is accomplished with single interrupted sutures of 6-0 or 7-0 nonabsorbable material, which are removed in 5 days. For contaminated wounds, parenteral antibiotics to cover *Staphylococcus* and *Streptococcus* are administered in the ED and oral antibiotics prescribed for 7 to 10 days. Unless trauma was minimal, the patient requires referral to an ophthalmologist for follow-up evaluation.

Complex Eyelid Lacerations and Other Penetrating Trauma

At the first evidence of globe penetration, the EP should document visual acuity, shield the eye, and consult an ophthalmologist. Any protruding penetrating objects are left in place and protected from manipulation until an ophthalmologic surgeon assumes management of the injury. Penetrating wounds near the eye are assumed to have penetrated the globe until proven otherwise.

Isolated lacerations of the conjunctiva are benign; however, laceration of the sclera or full thickness of the cornea is regarded as a penetrating injury. When the cornea is injured, the iris plugs the wound and distorts the pupil into a teardrop shape, with the apex of the drop pointing toward the wound (Fig. 25.3). When there is doubt regarding globe penetration, Seidel test is performed. Fluorescein is instilled onto the eye and observed for a fluid stream leaking from the globe under cobalt light. Parenteral antibiotics should be administered prophylactically to help prevent endophthalmitis. All penetrating eye wounds require an emergent ophthalmologic consultation.

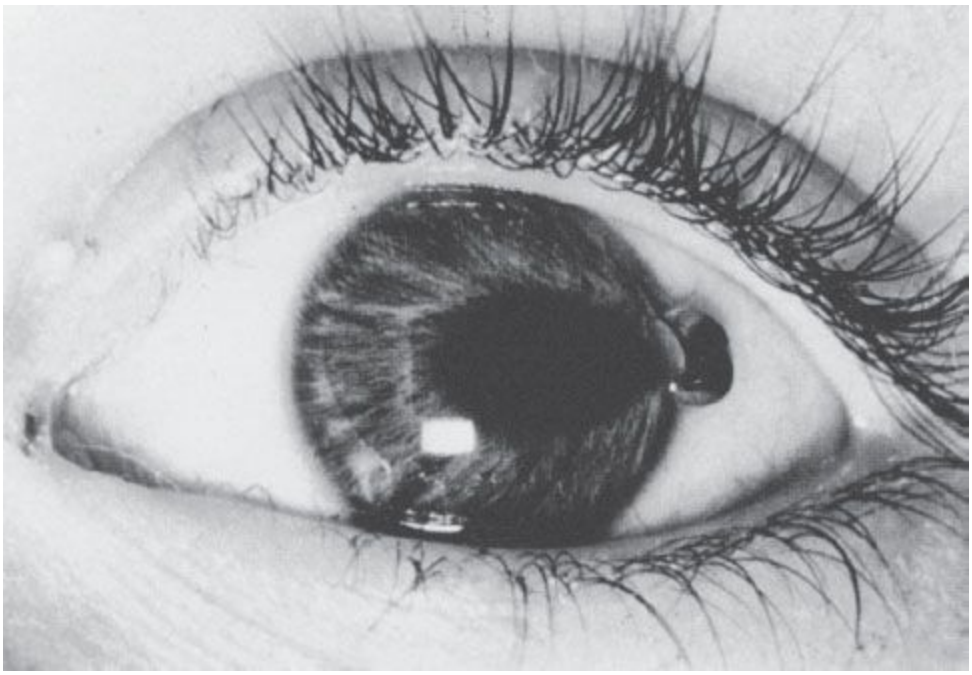


FIGURE 25.3 Penetrating corneal foreign body with entrapment of the iris, forming a teardrop pupil.

Complex eyelid lacerations should be repaired by an ophthalmologic surgeon. These wounds are characterized by exposed orbital fat, globe penetration, muscle laceration, nasolacrimal system damage, tarsal plate laceration, or through-and-through laceration. With any periorbital wound, it is imperative that the lids be retracted to rule out globe penetration. Injury to the *nasolacrimal duct system* is considered when wounds are in close proximity to the anatomic location in the medial eyelids, extending laterally 5 to 7 mm from the medial canthus. Medial to the canthus, the system runs vertically into the nose. A parenteral antibiotic to cover *Staphylococcus* and *Streptococcus* should be administered prophylactically. Wounds should be covered with a sterile saline dressing to keep the tissues moist until the ophthalmologist arrives.

Blowout Fractures and Other Facial Fractures

When a ball, fist, or other object larger than the orbital rim strikes the eye, a blowout or other facial fracture may result. Suggestive complaints and findings are diplopia, enophthalmos, epistaxis,

inferior displacement of the globe, ipsilateral numbness of the cheek and the upper lip, point tenderness of the orbital rim or maxilla, palpable step-off, periorbital ecchymosis, swelling, or even subcutaneous emphysema when sinuses are affected. Plain films have been used for diagnosis but can be falsely negative (≥60%) or falsely positive (≥46%) (6). A spiral CT scan with coronal cuts is preferred for diagnosis. Most blowout fractures involve the inferior or medial walls of the orbit. Involvement of the roof of the orbit signals that considerably more force was sustained and suggests violation of the cranial vault with associated injury to the brain.

Facial injuries such as Le Fort, tripod, and nasal fractures may have an associated eye injury. At the minimum, for an apparently uninvolved eye, the EP should document visual acuity, extraocular movement, the absence of any obvious trauma, and absence of visual symptoms. See Chapter 23 for further discussion of facial trauma.

Management consists of oromaxillofacial and ophthalmologic referral, antibiotics (to cover *Staphylococcus* and *Streptococcus*) for 10 to 14 days, ice packs, nasal decongestant spray, and avoidance of blowing the nose. Surgical repair may be delayed for up to 14 days. The vast majority of blowout fractures will resolve without surgical intervention (7). Urgent ophthalmology referral is indicated for injuries with entrapment or obvious injury to the globe or anterior chamber. Close ophthalmology follow-up is indicated for all others so that occult injuries can be identified.

Burns

Chemical, electrical, infrared, thermal, and ultraviolet (UV) burns may affect the eye. Chemical burns are irrigated immediately with saline for at least 30 minutes. “Time is sight,” and irrigation at the scene is often inadequate. Triage and registration should not further delay immediate and thorough irrigation upon ED presentation. Copious irrigation should continue uninterrupted for at least 20 minutes in the ED. The local poison control center should be contacted for assistance in characterization of the chemical in

question, its pH, and its potential to cause ocular damage. After irrigation is completed (defined as normal serial pH testing of the affected eye for at least 10 minutes after irrigation has stopped), the EP should then examine the eye. *Alkali burns* are particularly devastating. They destroy tissue via *liquefaction necrosis* and are classified by four grades of involvement:

1. Corneal epithelial damage similar to a corneal abrasion with a good prognosis.
2. Cornea hazy but the details of the iris are seen and up to one-third of the limbus is ischemic (whitened). The prognosis is still good.
3. Corneal epithelium is destroyed, and the details of the iris are blurred; one-third to one-half of the limbus is ischemic. The prognosis is guarded.
4. Cornea is opaque, and the details of the iris and pupil are obscured; more than half of the limbus is ischemic. The prognosis is poor.

Acid burns are classified with the same severity grades; however, they tend to produce less extensive damage, as strong acids precipitate proteins via *coagulation necrosis,* which may form a barrier to further spread.

For severe chemical burns, all foreign matter should be removed prior to irrigation by sweeping the fornices with a moistened cotton-tipped applicator. *Calcium hydroxide* tends to cake and may be easier to remove if the applicator is moistened with 10% ethylenediaminetetraacetic acid (EDTA). Minimal irritation and lack of symptoms after irrigation require no further follow-up. Moderate irritation with persistent symptoms requires instillation of antibiotic ointment and referral to an ophthalmologist in 24 hours. Any injury producing more than moderate irritation and having associated significant changes in vision mandates immediate consultation with an ophthalmologist.

Electrical burns are rare; however, the injury may be indirect. Nine percent of patients experiencing electrical injuries involving the head develop cataracts 6 to 12 months after the injury. *Infrared radiation* can produce keratitis, macular damage, or “glassblower’s

cataract" (a heat injury that damages the anterior lens capsule of unprotected glassblowers) after prolonged exposure to heat. *Thermal burns* are rare, as the light of a heat flash reaches the eye faster, producing the upward rotation reflex of the globe (Bell phenomenon), which protects the cornea from damage. Thermal corneal injury occurs when hot objects, such as lighted matches, spitting grease, or car radiator steam, are propelled into the eye. These burns rarely involve more than the corneal epithelium and heal in a few days. Treatment involves the application of cold compresses for up to 2 hours. For partial-thickness burns of the lids and surrounding skin, ophthalmic antibiotic ointment is applied. Minor burns of the cornea are managed similarly to a corneal abrasion. For more severe burns, an ophthalmologist is consulted immediately. *UV radiation* from the sun, tanning salons, or a welder's arc produces acute, diffuse, superficial punctate keratitis of the corneal epithelium about 6 to 12 hours after exposure. The amount of UV radiation is enhanced by reflection off of water, rocks, or snow and at altitudes above 8,000 ft (2,438 m). Prolonged exposure may damage the retina, particularly the fovea, and visual changes may manifest up to 1 to 2 days later (8). Management is similar to that of a corneal abrasion. A nonsteroidal anti-inflammatory medication and narcotic-containing analgesic are prescribed. Ophthalmologic follow-up for all burns of the eye is essential unless the injury is minimal.

Corneal and Conjunctival Injuries

The corneal epithelium is 4 to 6 cells thick, and abrasions generally heal in 12 to 36 hours, sometimes longer, depending on the injury. Full-thickness injuries require prompt surgical repair. Further examination is deferred. Evidence of full-thickness injuries may include a positive Seidel test, an irregular pupil with or without iris prolapse, shallow anterior chamber, cataract, hyphema, or microhyphema. Infection is a risk with any wound, and a retained FB heightens that risk. Consider tetanus prophylaxis for susceptible wounds. Iron-containing FBs will leave a rust ring deposit after

being in place for a couple of hours. Rust rings extrude to the surface over 48 hours, where they are easily removed with an ophthalmic burr.

Corneal abrasions usually present as an FB sensation. Often, there is a history of something striking the eye. Exposure to high-speed particles raises the suspicion for a penetrating eye injury. In addition to an FB sensation, symptoms include blepharospasm, blurred vision, eye pain, halos around lights, photophobia, red eye, and tearing. Visual acuity is mildly decreased. The eye is hyperemic, eyelids mildly swollen, and an anterior chamber reaction (cells or flare) is sometimes noted. Abrasions are highlighted by fluorescein and are best seen on slit-lamp examination. A handheld cobalt light in a darkened room may be used for minor abrasions but will miss more subtle findings such as anterior chamber reaction or corneal microperforation. Soft contact lenses should be removed prior to fluorescein instillation. The EP should evert the upper lid to examine for FBs. Low-mass, low-speed particles largely produce insignificant trauma without anterior chamber reaction; therefore, the IOP does not need to be measured. When larger objects, such as a finger, fist, or ball, strike the eye, the IOP should be measured. After instilling anesthetic ophthalmic drops, removal of an FB is accomplished by either gentle irrigation, a saline-moistened cotton-tipped applicator (brush off), an ophthalmic burr, or a 25-gauge needle held tangential to the corneal surface (pick off). Rust ring removal is accomplished with an ophthalmic burr. The EP should consider instilling a short-acting cycloplegic (one to two drops) to reduce ciliary muscle spasm and synechiae formation secondary to inflammation. Patching is not shown to improve healing rates or reduce pain and thus are generally not used (9). Despite a lack of supporting evidence, ophthalmic antibiotics are often prescribed. Analgesics include a nonsteroidal anti- inflammatory medication (daily dosing for 3 days) and a narcotic as needed. Patients who wear contact lenses or those with large or centrally located abrasions are followed up closely by an ophthalmologist, usually at 1-day interval, until healed. EPs can follow up these corneal

abrasions, but referral to an ophthalmologist the next day is advisable.

Contact lens usage can lead to a corneal symptom complex similar to corneal abrasions. Contact lens–related corneal abrasions, due to overwear or improper fit, result from hypoxic injury, toxic deposits under the lens, or trauma related to insertion or removal of the lens. Infectious keratitis with gram-negative bacterial organisms, particularly *Pseudomonas,* and protozoa, specifically *Acanthamoeba,* may occur as well. Chemical irritation may result from preservatives such as thimerosal and chlorhexidine and inadequate rinsing of lenses after enzyme use. *Tight lens syndrome* occurs within 2 days of placement of the offending lens. The lens appears "sucked-on," leaving a conjunctival imprint after lens removal. Other complications of contact lens use include corneal ulceration, superficial punctate keratitis, anterior uveitis, and infrequently, hypopyon. Treatment begins with removal of the contact lens; fluorescein will permanently stain the lens. An antipseudomonal ophthalmic antibiotic preparation should be prescribed. A cycloplegic should be used if needed. The patient should follow up with an ophthalmologist within 24 hours. (See Chapter 57.)

Conjunctival and *subconjunctival* injuries are minor when the underlying sclera remains intact because the conjunctiva does not provide any structural support to the eye. Visual acuity is usually unaffected. There may be an associated corneal injury, exhibiting the usual corneal symptoms. All conjunctival wounds, with or without an associated FB, must be examined under magnification for scleral penetration. The EP should anesthetize the eye and tease the wound with a cotton-tipped applicator, observing for exposed white scleral tissue. Seidel test can provide additional information. If there is any doubt regarding penetration of the sclera, the injury is managed as though there has been violation of the globe, and an ophthalmologist is consulted immediately. The EP should remove FBs from the fornices by handheld irrigation or forniceal sweeping with a saline-moistened cotton-tipped applicator after anesthetizing the eye. Although commonly practiced, there is no evidence to

support empiric antibiotic treatment. The patient should be referred to an ophthalmologist for next day follow-up.

Other Anterior Segment Injuries

Blunt and penetrating forces inflame, contuse, lacerate, rupture, stretch, and tear the tissues of the anterior segment of the eye, resulting in various injuries such as hyphema, glaucoma, lens displacement, and cataracts. When these conditions are suspected, an ophthalmologist should be consulted immediately.

Traumatic iritis occurs in up to 18% of eye trauma (10). Synonyms for this condition are *anterior chamber reaction, anterior uveitis, uveitis,* and *iridocyclitis.* Inflammation in the anterior segment of the eye results in symptoms of blurred vision, impaired visual acuity, pain, photophobia, hyperemia, and tearing; symptoms vary from mild to severe. The pain of ciliary spasm is exacerbated by light shining in either eye (photophobia) or with accommodation, which increases ciliary muscle contraction (11). When light strikes the unaffected eye, the consensual response exacerbates the pain (consensual photophobia). Protein and white blood cells are visible by slit lamp in the anterior chamber. The limbus is injected. In severe reactions, there may be hypopyon (a layer of white blood cells seen in the anterior chamber). The IOP may be increased or decreased. Treatment includes a short-acting cycloplegic, a nonsteroidal anti-inflammatory medication (for 3 days), and a narcotic analgesic. The patient should be referred for ophthalmologic follow-up within 36 hours.

Hyphema may be microscopic (cells visualized only by slit lamp) or gross (characterized by the percentage of the anterior chamber that is filled) (Fig. 25.4). If blood fills the chamber entirely, it is commonly called an “eight-ball” hyphema. Symptoms include pain, red eye, and blurred vision. Treatment begins by shielding the eye and elevating the head to 30 degrees. Medications, other than those for pain and nausea, are administered only at the direction of an ophthalmologist. Rebleeding occurs in approximately 30% of cases. Outpatient management may be appropriate for some

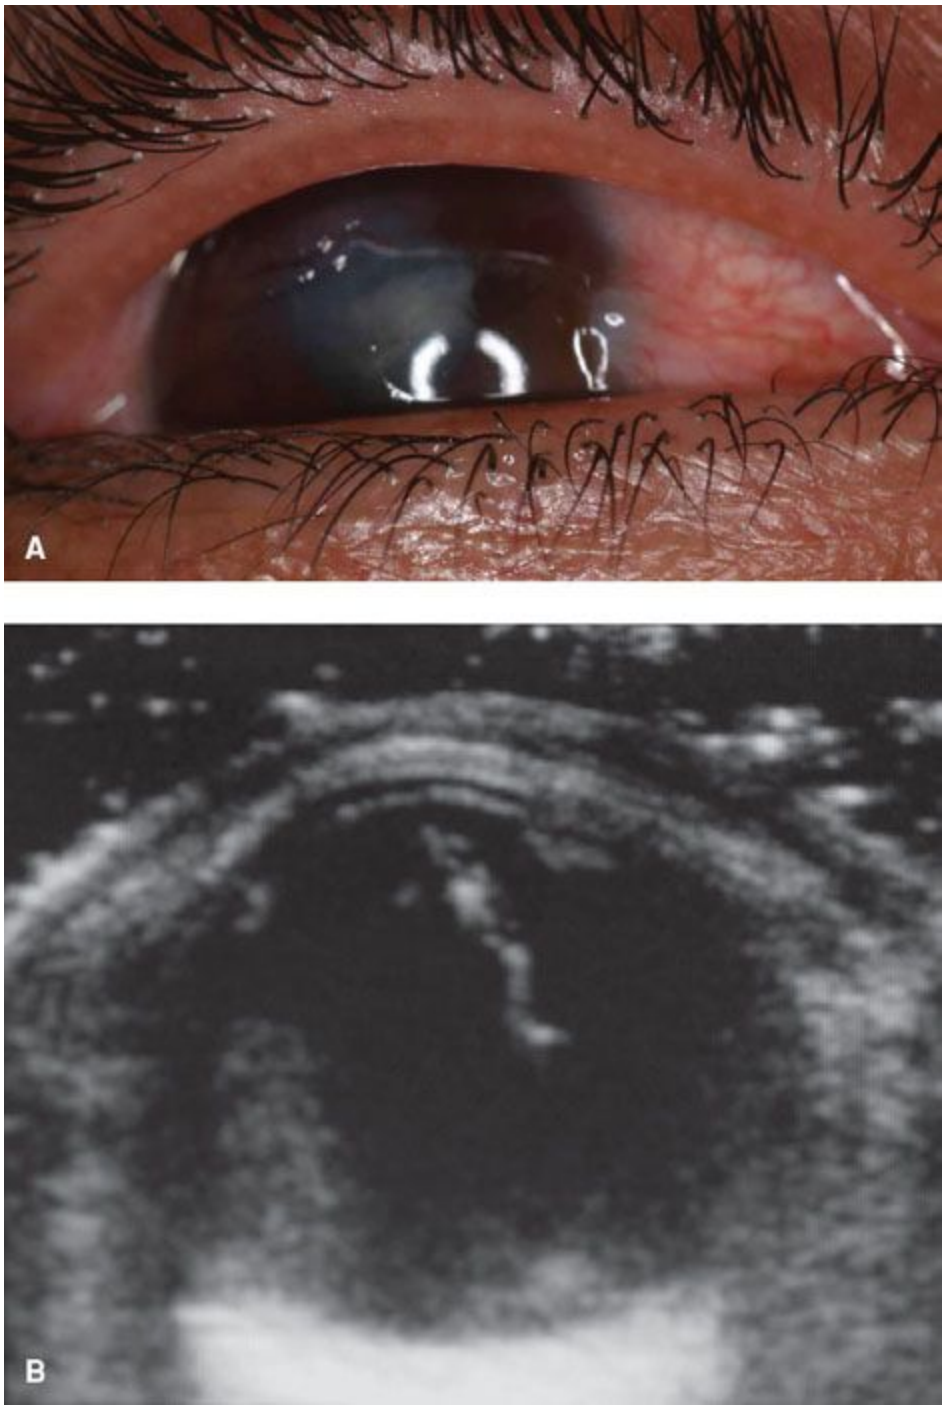
microhyphemas and in compliant patients with good follow-up and no risk factors for complications (e.g., sickle cell disease or bleeding diathesis). Which patients to hospitalize is controversial and should be discussed with an ophthalmologist. Many ophthalmologists manage uncomplicated small hyphemas (<25% of the anterior chamber) without hospital admission. When there is a history of sickle cell disease or trait and IOP is >25 mm Hg, the anterior chamber may need to be washed out (12).

FIGURE 25.4 Traumatic hyphema (20%) with blood layering in the anterior chamber, subsequent to blunt trauma.

Traumatic glaucoma occurs when the trabecular meshwork is disrupted or obstructed by blood or inflammatory debris. Glaucoma may develop acutely over hours or may be delayed for months to years. Medications employed acutely include topical β-blockers, acetazolamide, mannitol and, occasionally, miotics. Lens displacement varies in degree, as do associated symptoms, including myopia, monocular diplopia and, most commonly, blurred vision. Signs include decreased visual acuity, anterior chamber asymmetry, a displaced lens, quivering of the iris (iridodonesis) or the lens

(phacodonesis) after rapid eye movement, visibility of the lens edge, and the presence of vitreous in the anterior chamber.

Traumatic cataracts can occur secondary to blunt trauma (*contusion cataracts*) or penetrating trauma, irrespective of direct injury to the lens capsule, though violation of the lens capsule tends to accelerate the process. Symptoms include blurred vision, glare from lights (particularly headlights), and reduced color vision. Signs include decreased visual acuity, an indistinct retina, lens opacity, and a reduced red reflex (eFig. 25.2). In acute trauma, the eye is shielded as soon as any of these conditions are identified or suspected. Outpatient ophthalmology follow-up is indicated for all patients at risk for traumatic cataract.



eFIGURE 25.2 A: Traumatic cataract (white pupil) after penetrating injury. B: Ultrasound shows a collapsed anterior chamber and foreign body track through the lens and vitreous.

In *traumatic iridodialysis,* the iris is pulled away from the ciliary body along a portion of the circumference (eFig. 25.3). A secondary

"pupil" is formed, causing diplopia. There may be an associated hyphema or dislocated lens. The EP should refer patients with isolated injuries to an ophthalmologist for outpatient follow-up.

eFIGURE 25.3 The iris has been pulled away from the ciliary body (traumatic iridodialysis).

Intraocular Foreign Bodies

Eighty percent of all intraocular FBs enter the eye through the cornea. An obvious penetrating FB of the eye is easy to diagnose. However, there are also more subtle presentations suspected in certain circumstances, including a history of hammering metal on metal (grinding usually does not lead to penetration), a child with eye pain and a history of something sharp near the eye, and a history of head trauma with the eye(s) swollen shut. Metal splinters produced by hammering metal on metal and glass splinters produced by shattering glass can penetrate the eye painlessly (13). Plain films can be helpful but do not differentiate intraocular from extraocular FBs. Some FBs are not intraocular but are intraorbital. In

this circumstance, damage to the globe must be ruled out. The imaging study of choice for detecting intraocular FBs is spiral CT. Intraocular FBs that remain in the eye can produce varying degrees of inflammatory reaction. Copper, iron, steel, vegetable matter, and wood produce severe reactions. Aluminum, nickel, mercury, and zinc produce mild reactions. Carbon, coal, glass, gold, lead, plaster, plastic, platinum, porcelain, rubber, silver, and stone are inert. Iron, nickel, and steel are magnetic. Inflammatory reactions put the eye at risk for endophthalmitis.

Globe Luxation or Subluxation

Luxation of the globe is rare (eFig. 25.4). Visual acuity in the involved eye may vary from being mildly reduced to no light perception. Immediate globe reduction is mandated to relieve symptoms and to minimize visual impairment. If an ophthalmologist cannot be present within 20 minutes to reduce the globe, the EP should attempt reduction by applying gentle pressure to the globe while retracting the eyelids. Attempts at reduction are contraindicated when there is obvious globe rupture. Admission is mandatory for further ophthalmologic management.

eFIGURE 25.4 Globe luxation occurred in this patient from lid traction during contact lens insertion.

Globe Rupture from Blunt Trauma

The globe is ruptured in up to 3.5% of patients with blunt eye trauma (14). Ruptures typically occur at the weakest areas of the globe—the equator (an imaginary line equally dividing the globe into anterior and posterior halves), the limbus, and muscle insertions. Another site of rupture is the globe portion opposite the point of impact. The conjunctiva often remains intact after rupture, and bleeding occurring beneath the conjunctiva produces circumferential bloody chemosis (Fig. 25.5). When severe eye hemorrhage (hemorrhagic chemosis, hyphema, vitreous hemorrhage) or severe periocular hemorrhage has occurred, the presence of one of the following four signs predicts rupture with a sensitivity of 100% and a specificity of 98.5%: (a) a visual acuity that demonstrates light perception or less, (b) an anterior chamber

that is abnormally deep or shallow, (c) an IOP ≥ 5 mm Hg, or (d) an opacity that prevents fundus visualization (15).

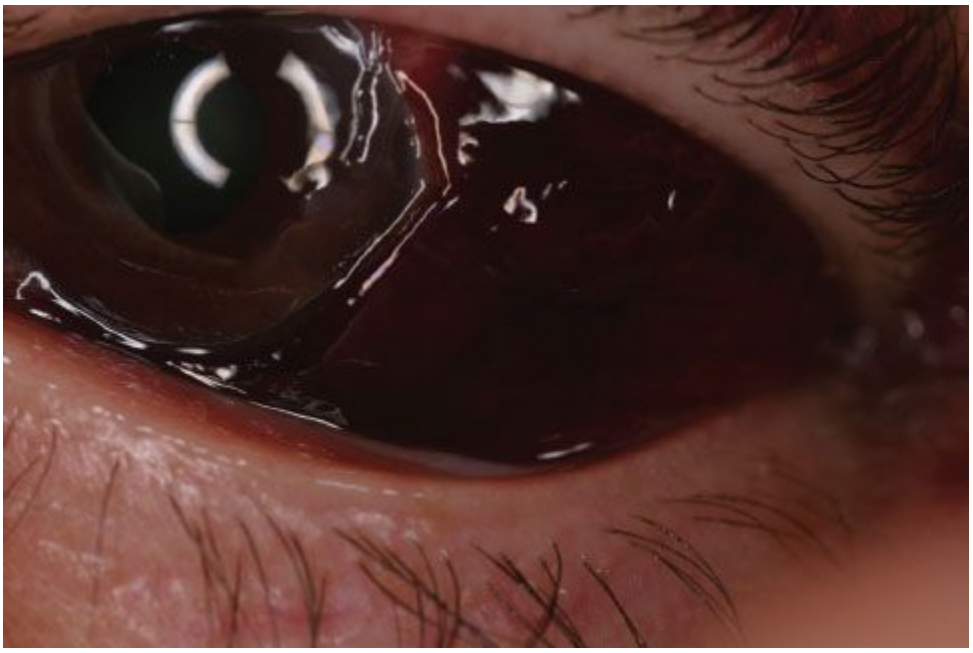


FIGURE 25.5 Large subconjunctival hemorrhage with bloody chemosis associated with blunt trauma.

As soon as a ruptured globe is suspected, the EP should shield the globe using a Fox shield, paper cup, Styrofoam cup, or similar device and consult an ophthalmologist (Fig. 25.6). Parenteral antibiotics (gentamicin plus vancomycin or clindamycin) are administered prophylactically to help prevent endophthalmitis. Bed rest with the head of the bed elevated and antiemetics are indicated to lessen the occurrence of stresses that might increase IOP. When intubation is necessary, the use of succinylcholine should be avoided, if possible, because it raises extraocular muscle tone and will increase IOP. However, the clinical significance of the increase in IOP has been questioned (16).

FIGURE 25.6 Teardrop pupil seen in this patient represents an open globe, and is easily mistaken for a superficial injury.

Posterior Segment Injuries

The posterior segment consists of the choroid, optic nerve, retina, and vitreous. Any indication of injury mandates an immediate ophthalmologic consultation. The choroid, retina, and vitreous may be detached, hemorrhagic, ruptured, or torn. The optic nerve may be injured along its course by direct or indirect mechanisms.

Symptoms are often lacking, or they are nonspecific. They include blurred vision, curtain of darkness, flashes of light, floaters, pain, and red eye. Important signs are blurring of fundus detail, decreased acuity, and RAPD. Anatomic findings are not necessarily apparent on direct fundoscopy performed in the ED, even with dilatation. They are best identified by an ophthalmologist using dilated indirect fundoscopy. EP performed ultrasonography may be helpful in identifying posterior segment injuries at the bedside (17).

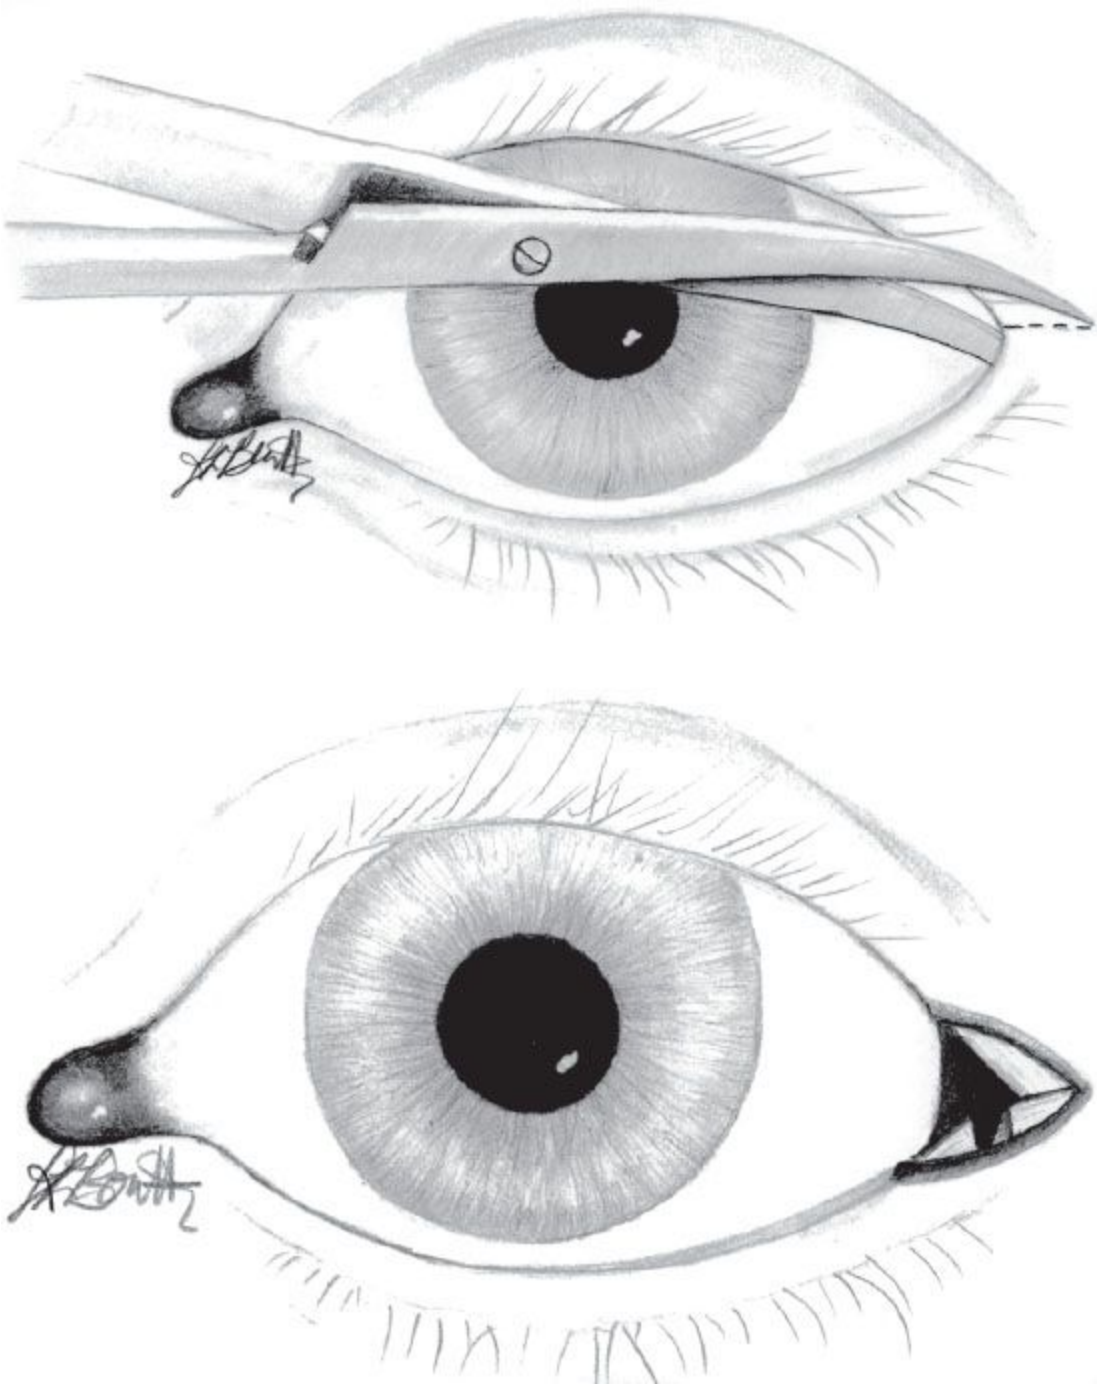
Retrobulbar Hematoma

Retrobulbar hematoma (*orbital compartment syndrome*) is a very rare condition. It is associated with intraoperative retrobulbar injections

and occurs postoperatively. It is less often associated with trauma (eFig. 25.5). Signs and symptoms include severe eye pain, nausea, vomiting, decreasing vision, diplopia, RAPD, decreased ocular motility, hemorrhagic chemosis, proptosis, and resistance to retropulsion of the globe. The retina can withstand total ischemia for only about 90 minutes before damage may be permanent, so rapid treatment without any delays is required. Initiating conservative management (head elevation, ice packs, acetazolamide, mannitol, timolol) while preparations are underway (including consultation) is appropriate, as long as the definitive treatment is not delayed.

eFIGURE 25.5 Retrobulbar hemorrhage demonstrating dramatic proptosis and subconjunctival hemorrhage after a fist strike in a man on warfarin.

Definitive treatment is decompression of the eye by lateral canthotomy and cantholysis to maximize the chance of preserving vision. After local injection with an anesthetic agent, this is performed by crushing the lateral canthus with a small hemostat to reduce bleeding, then incising 1 cm into the tissue with scissors, taking care to avoid injury to the globe. The inferior arm of the lateral canthal tendon is cut to release the globe (eFig. 25.6). An ophthalmologist should be consulted as soon as this condition is suspected.



eFIGURE 25.6 Lateral canthotomy and cantholysis. The inferior arm of the lateral canthal tendon has been incised to release the globe. (Adapted from Cullom RD Jr, Chang B (eds). The Wills Eye Manual. Philadelphia, PA: Lippincott–Raven Publishers; 1994.)

Complications of Eye Trauma

Eye trauma and eye surgery predispose to *endophthalmitis* (25% and 62% of cases, respectively). It develops in 8% to 13% of patients with eye trauma when there is a retained FB. The percentage rises to 26% if the FB is organic material from a rural setting. The onset is sudden and begins from hours to 2 months after the injury. *Bacillus cereus* infection has been reported to develop within 24 hours, streptococci within 2 days, and Staphylococcus epidermidis within 4 days (18). Treatment is intravitreal injection of vancomycin and amikacin by an ophthalmologist. Delay in treatment of even a few hours, particularly with *Bacillus* species, can lead to the loss of an eye. There is an association between *B. cereus* infections, metallic intraocular FBs, and injuries related to soil. Symptoms include blurred vision, fever, a red eye, and severe pain. Signs are anterior chamber reaction, markedly decreased acuity, cells and opacities in the vitreous, conjunctival hyperemia, decreased red reflex, hypopyon, increased IOP, and proptosis. The EP should consider endophthalmitis in any patient presenting with these signs and symptoms and a history of previous eye trauma. Early diagnosis is imperative for the best outcome.

Sympathetic ophthalmia is an immune-mediated inflammatory condition that occurs in the uninjured eye days to years after severe trauma to the opposite eye. After a penetrating or rupturing injury, antigens in the injured eye are exposed, and an immune response is mounted against the uninjured eye. The incidence is 0.2% after penetrating eye trauma and 0.01% after routine eye surgery. Sixty-five percent of cases begin between 2 and 8 weeks after the insult and 90% within 1 year. The signs and symptoms in the sympathetic eye begin as a mild anterior uveitis, which progresses over time to anterior and posterior uveitis. Enucleation of a severely traumatized eye, with no hope for useful vision, appears to eliminate the risk of sympathetic ophthalmia.

CRITICAL INTERVENTIONS

- Document the best-corrected visual acuity. Failure to improve with pinhole suggests a posterior segment injury.

- In patients with chemical burns, continue eye irrigation in the ED until pH is normal and the injury has been assessed.
- Obtain a history of contact lens use (corneal ulcer) or striking metal on metal (globe perforation) in patients with suspected corneal abrasion.
- Protect the eye when globe penetration is suspected; confirm with Seidel test.
- Perform a lateral canthotomy or obtain immediate ophthalmology consultation in patients with retrobulbar hematoma.

DISPOSITION

Disposition of patients with ophthalmologic trauma is arranged on a case-by-case basis. Immediate consultation in the ED or transfer to an appropriate center when an ophthalmologist is not available should take place for patients with globe penetration (or suspicion thereof), complex eyelid lacerations, penetrating FBs, orbital fracture with entrapment, ocular burns, anterior chamber injuries, hypopyon, hyphema (>25% of anterior chamber, associated with increased IOP or blood disorders), globe luxation, orbital compartment syndrome, and traumatic endophthalmitis. All but the most trivial of ocular injuries should be discussed with an ophthalmologist and appropriate outpatient follow-up and care arranged; even apparent trivial injuries may harbor significant occult injury.

Common Pitfalls

- Failure to test visual acuity.
- Using nitrazine paper (measures pH only up to 7.4) to assess alkaline injuries.
- Inadequate visualization of the eye on examination; a slit lamp should be used for best magnification.
- Failure to evert the upper lid to diagnose FB.

CHAPTER 26
Blunt Neck Trauma

Edward Ullman

The majority of blunt neck trauma occurs in conjunction with significant injuries to the head, cervical spine, and face (1). The most commonly reported injury is the "padded dash syndrome." This occurs when the unrestrained driver decelerates against the steering wheel or dashboard. There have been case reports of isolated neck trauma due to a "clothesline" mechanism in motorcycle, jet ski, snowmobile, and all-terrain vehicle users (2,3). Strangulation occurs from hanging, ligature suffocation, and manual manipulation. Other etiologies include blunt impact secondary to a punch, kick, strike by a baseball bat or other object.

CLINICAL PRESENTATION

There is a wide range of presentations in patients with blunt neck trauma; patients may be asymptomatic, have minimal symptoms, or present in extremis. Therefore, it is critical to recognize that a lack of obvious soft tissue trauma does not rule out a significant injury (2).

Airway injuries can present with hoarseness, stridor, subcutaneous emphysema, hemoptysis, or respiratory distress (4). Laryngotracheal injuries include vocal cord damage or disruption, dislocation of the arytenoid cartilage, tracheal transection, and fractures of the thyroid or cricoid cartilage or hyoid bone (Fig. 26.1) (5). Patients with any alteration in voice should be assumed to have a laryngeal injury. Development of a soft tissue hematoma or edema can externally compress the airway and cause respiratory

compromise. Therefore, continuous airway reassessment is required in patients with blunt neck trauma. Palpation of the thyroid and cricoid cartilages will often reveal tenderness and crepitus as an indication of injury, especially in men, as these landmarks are prominent. If there is loss of definition or deviation of these structures, the likelihood of underlying injury is high.

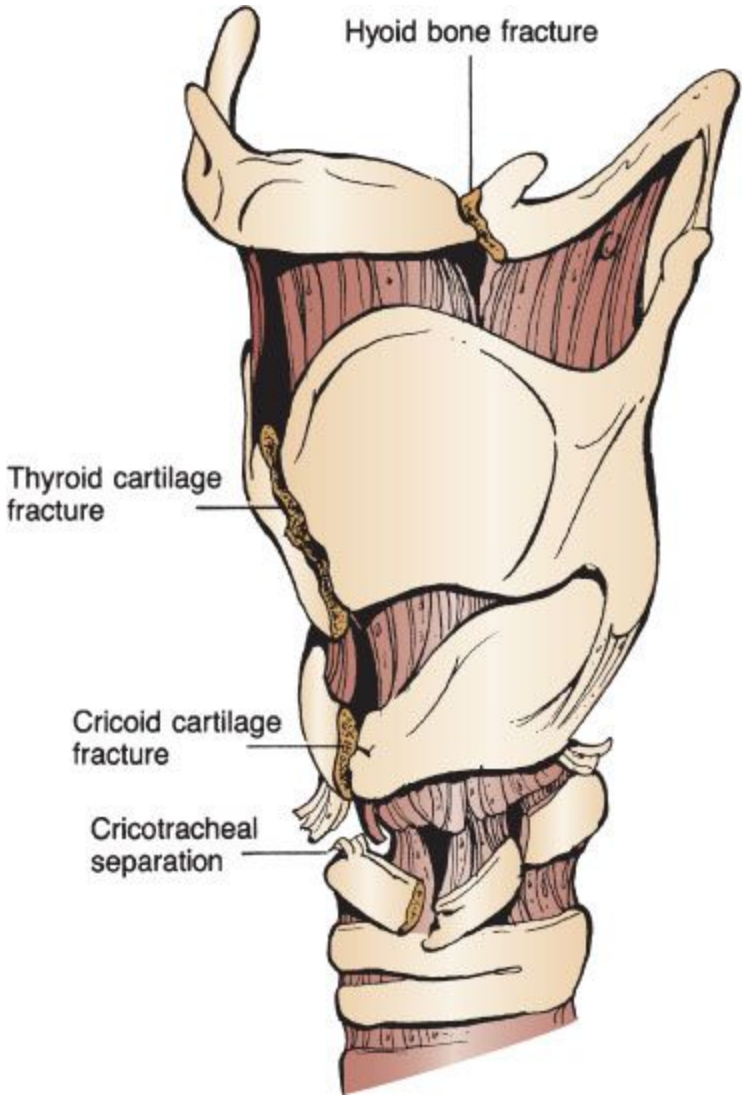

FIGURE 26.1 Types of laryngeal injuries: hyoid bone fracture, thyroid cartilage fracture, cricoid cartilage fracture, cricotracheal separation.

The incidence of vascular injury in blunt trauma patients is 0.08% to 1% (6). As a result, blunt vascular injuries to the carotid or

vertebral arteries are often diagnosed after admission (7). The majority of these injuries occur at the carotid bifurcation or higher and involve multiple vessels (8). Carotid injuries include intimal tears, hematoma, thrombosis, and pseudoaneurysms. Injuries that cause hyperextension and rotation can stretch the carotid artery and compromise the vessel. Acute flexion injuries may crush the carotid artery between the mandible and the cervical spine, leading to thrombosis or intimal damage. An intraoral blow to the soft palate can cause carotid thrombosis, especially in the pediatric population. This usually occurs when a child has an object in his or her mouth and falls, forcing the object into the soft palate. Carotid injuries can present with isolated ipsilateral cerebral findings that include contralateral hemiplegia, sensory loss, and aphasia (9). The presence of a bruit can indicate partial disruption of the carotid by either intimal dissection or thrombus formation. Patients may also present with Horner syndrome (ipsilateral miosis, ptosis, and anhidrosis) owing to disruption of the thoracic sympathetic chain that encircles the carotid artery.

The incidence of vertebral artery injury has increased (10). However, vertebral artery involvement remains difficult to diagnose. Many patients remain asymptomatic owing to an extensive collateral circulation (11). Those who have some deficit complain of vague symptoms such as dizziness, visual disturbances, nausea, and vertigo. Furthermore, because the vertebral artery connects to the basilar artery, an embolic event from trauma could affect either the ipsilateral or contralateral posterior circulation. This can leave the patient with a variety of neurologic deficits without an apparent vascular source.

Several studies recommend evaluation for vascular pathology if any of the following injuries are noted upon trauma evaluation: Horner syndrome; cervical spine fracture that involves the transverse foramen or a facet joint dislocation; Le Fort 2 or 3 fracture; and neurologic deficit not explained by a cervical spine fracture or abnormal head computed tomograph (CT) (12).

DIFFERENTIAL DIAGNOSIS

The existence of other associated injuries and the lack of external neck findings make vascular injuries difficult to diagnose. Neurologic deficits are often delayed; only 10% of those with vascular injury have initial findings. The diagnosis should be suspected in patients with neurologic deficits not explained by head CT and in hemiparetic patients without alteration in mental status. In a series of 66 patients, 34% of those with neck vascular injuries had incongruent neurologic findings (6). The emergency physician should consider this diagnosis in patients with basilar skull fractures and marked external cervical trauma, as associated vascular injuries are often present. The diagnosis should also be considered in patients with anterior neck soft tissue injury such as abrasions, edema, or hematoma.

There are only 10 reported cases of isolated gastrointestinal injury in blunt neck trauma (13). The majority of these injuries occur in conjunction with laryngotracheal injury. Gastrointestinal injury should be considered in patients with pain on swallowing or subcutaneous emphysema; the latter group has a higher incidence of airway compromise.

ED EVALUATION

Because of the difficulty in diagnosing vascular, airway, and gastrointestinal injuries in blunt neck trauma, a systematic evaluation is critical. Table 26.1 lists signs that should raise the suspicion of a vascular injury. In the patient without signs of vascular injury the Denver Modification of Screening Criteria should be used to identify patients at high risk for injury who likely need imaging (14) (Table 26.2). These criteria have been used by the Eastern Association for the Surgery of Trauma (15).

TABLE 26.1
Signs and Symptoms of Vascular Injury

Glasgow coma scale less than 8
Petrous bone fracture
Diffuse axonal injury
Cervical spine fracture: C1–C3 and fracture through the foramen transversarium
Cervical spine fracture with subluxation or rotation
Le Fort 2 or 3 fracture

In the patient with acute findings (Table 26.1), there is an increasing body of literature that supports the use of multidetector CTA as a screening modality (16,17). While there is earlier data that raises concern in using CTA, that data used 4-slice CTA compared to current 64-slice MDCT CTA (18). Although there is conflicting data, many trauma centers are using CTA for initial evaluation of vascular injuries. Benefits include that it is readily available, noninvasive, and can image other involved anatomy. In those patients with a negative CTA but high concern for vascular injury, angiogram is recommended (16). Magnetic resonance angiography has a reported sensitivity as high as 95% (8). However, difficulty in obtaining this modality in an acute trauma setting limits its usefulness in the ED.

Previously, standard of care for vascular evaluation of blunt cerebrovascular injury was four-vessel digital subtraction angiography. It has a reported sensitivity that approaches 99%. However, there are risks involved with its use. There is a reported 0.5% risk of stroke (19) with another 0.5% risk of hemorrhage and hematoma. Furthermore, it is difficult to obtain off-hours, is invasive, resource demanding, and more expensive.

In the asymptomatic patient or those who have sustained a low-risk event (minor trauma without evidence of acute findings), color-flow Doppler ultrasonography (US) may identify arterial dissection. It has been shown to have sensitivities as high as 92% to 100% in detecting *penetrating* injuries. However, given that the "miss rate" for US in detecting carotid injury is reported to be as high as 8% in the literature, when evaluated retrospectively (9), it is difficult to recommend US as the sole diagnostic modality.

Evaluation of the airway is crucial in patients with blunt neck trauma. Fiberoptic visualization of the endolarynx allows for identification of function and pathology. Plain films have limited values but may indicate evidence of subglottic narrowing of the air column, prevertebral soft tissue swelling, fractured calcified larynx, or the presence of subcutaneous air. CT is effective for identification of cartilage disruption and defines anatomical relationships (20).

Although isolated esophageal injuries after blunt neck trauma are rare, those patients with signs of gastrointestinal injury (Table 26.3) require additional examination. Gastrografin swallow is often the initial study of choice owing to less pleural irritation if extravasation occurs. Barium provides a more sensitive study but has an increased risk of pulmonary complications. Recently, several studies have shown endoscopy as an adequate modality to evaluate for perforation (21).

TABLE 26.3
Signs and Symptoms of Gastrointestinal Injury

Pain on swallowing
Subcutaneous air
Blood in saliva

KEY TESTING

- CT cervical spine in the initial trauma evaluation
- CT angiography for the initial evaluation when there is a concern for vascular injury

- Digital subtraction angiography is reserved for patients with a high concern for vascular injury and a negative CTA

ED MANAGEMENT

Blunt trauma can create difficult airway situations. Evidence of air hunger, stridor, or sonorous respirations should be addressed immediately. The emergency physician should prepare all airway management equipment upon recognition of possible airway compromise. If time permits, anesthesiology or otolaryngology should be alerted owing to the potential for a difficult airway. The current literature indicates that orotracheal intubation is the first-line airway management technique for all blunt neck trauma patients requiring airway control (2). Surgical or needle cricothyrotomy is relatively contraindicated in the presence of bruising, hematoma over the cricothyroid membrane or suspected laryngotracheal injury. In these cases, emergency tracheotomy is recommended to avoid the risk of converting a partial cricotracheal disruption into a complete one. The development of subcutaneous emphysema and a large air leak after intubation and initiation of positive-pressure ventilation indicates a tracheal injury distal to the cuff of the endotracheal tube. This situation requires immediate tracheotomy and, in some cases, median sternotomy to regain control of the distal tracheal segment. Nasotracheal intubation is relatively contraindicated given the high rate of failure and the possibility of worsening an already difficult airway by extending the laryngeal injury.

In patients with marked laryngeal injuries, bleeding and edema can obscure landmarks (22). In those with complete laryngeal transection, use of neuromuscular blockade can make endotracheal intubation nearly impossible. Upon paralysis, the muscles that provide internal stabilization become relaxed, which may result in the endotracheal tube creating a false lumen in the soft tissues of the neck (23). Given this concern, oral-awake intubation is an alternative to rapid sequence intubation, especially in the presence of an anterior neck hematoma. Owing to the increased incidence of

cervical injury in blunt neck trauma patients, careful in-line stabilization should be performed with any airway management technique.

Fiberoptic laryngoscopy has replaced direct laryngoscopy as the standard method of evaluating upper airway injuries. It is useful in assessing airway patency, vocal cord mobility, and the presence of endolaryngeal lacerations or hematoma without causing movement of the cervical spine. Fiberoptic bronchoscopy permits additional visualization of the subglottic airway and may be used to facilitate endotracheal intubation.

It is rare for patients with blunt neck trauma to have life-threatening hemorrhage. However, concern for expanding neck hematoma should always be addressed. This requires aggressive, early airway management as well as otolaryngology or general surgery consultation. In the case of suspected gastrointestinal injury, broad-spectrum antibiotics with anaerobic coverage should be administered.

As the majority of vascular injuries result in luminal narrowing and thrombosis, anticoagulation is the recommended therapy; it results in improved neurologic outcomes in patients with blunt neck trauma (24). As the majority of blunt cervical vascular injuries are high in the internal carotid artery, surgical repair is difficult. Furthermore, in one study, the majority of injuries were “long dissections” not amenable to surgery (12). There is growing evidence that endovascular repair of pseudoaneurysms produces favorable results. This may prove to be a rational approach in patients with cervical vascular injuries (25).

CRITICAL INTERVENTIONS

- Perform early orotracheal intubation in blunt neck trauma patients with evidence of airway compromise.
- Perform CTA in patients who are at high risk for vascular injuries.
- In patients with suspected blunt laryngeal injury, order a neck CT to elucidate the injury pattern.

- Administer broad-spectrum antibiotics to patients with esophageal injuries to help prevent abscess formation.

DISPOSITION

Patients with evidence of blunt neck trauma that involves the airway, vascular, or gastrointestinal systems should be admitted or carefully observed. For these patients, early consultation with an otolaryngologist or general surgeon should be obtained. If the patient is asymptomatic and has a negative workup, discharge is recommended. Comprehensive instructions are critical for patient education in discharged patients. Symptomatic patients should be admitted or transferred to a trauma center where an otolaryngologist and general surgeon are available. It is critical to secure the airway in those symptomatic patients who are transferred, given the potential for respiratory compromise.

Common Pitfalls

- Failure to secure the airway early and failure to prepare for a difficult airway that may require specialty intervention.
- Failure to recognize potential vascular injury in the patient with neurologic deficits and a normal head CT.
- Failure to recognize that vascular injuries frequently have a delayed presentation.

CHAPTER 27

Penetrating Neck Trauma

Julie Mayglothling

Penetrating wounds of the neck present a therapeutic and diagnostic challenge to the emergency physician. Mortality among patients who suffer penetrating neck injuries in the civilian population approaches 6%. Fatality rates for major vascular injuries may reach 50% (1). Successful management of a penetrating neck wound demands an understanding of the regional anatomy and those structures vulnerable to injury, familiarity with the options for proper airway management, and appreciation of the evolving concepts in the diagnosis and treatment of significant injuries. Even the most benign-appearing wound may belie serious pathology, and extreme vigilance is essential to avert catastrophic airway, vascular, neurologic, and gastrointestinal complications.

A number of anatomic factors predispose structures within the neck to serious injury in the setting of penetrating trauma. Vital components of the respiratory, vascular, neurologic, and gastrointestinal systems course through the neck. Dense musculature and the structural integrity of the cervical spine afford some protection to these structures posteriorly, but the lack of similar shielding anteriorly exposes them to significant injury. Moreover, the majority of the vital structures of the neck are contained within dense, tightly confined fascial compartments, rendering them vulnerable to distortion and compression when bleeding occurs within the deep tissues (Fig. 27.1). For these reasons, penetrating wounds to the neck are best approached conceptually with regard to the site of external penetration, the depth of the wound, and the potential pathway of injury within the deeper compartments.

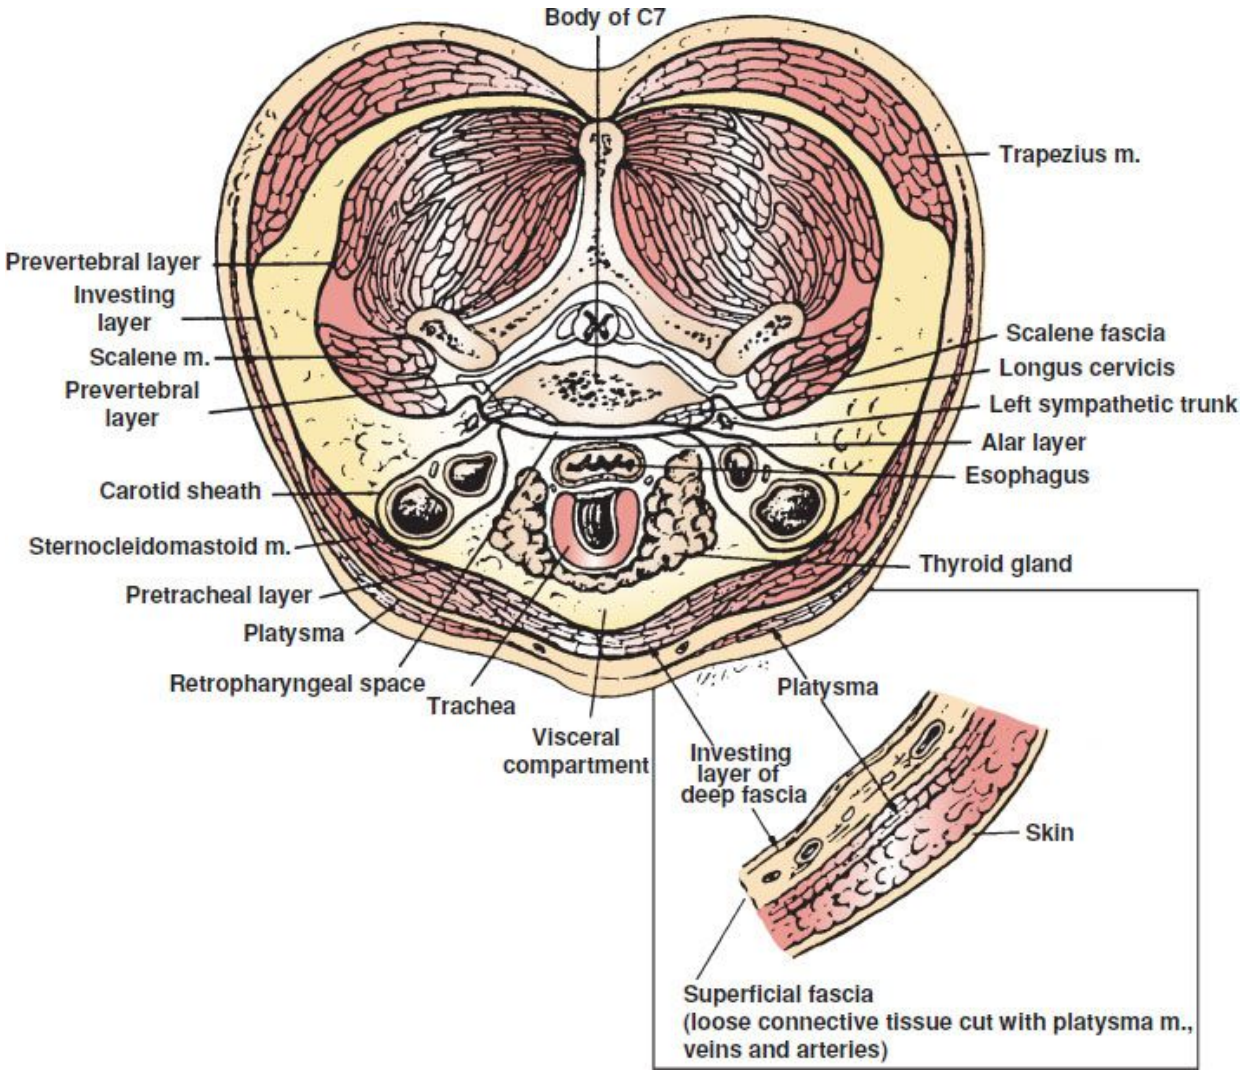

FIGURE 27.1 Cross-sectional anatomy of the neck. (From Gray SW, Skandalakis JE, McClusky DA. *Atlas of Surgical Anatomy*. Baltimore, MD: Williams & Wilkins; 1985, with permission.)

Most sources concur in dividing the external neck anatomically into *posterior* and *anterior* triangles. The *posterior triangle* connotes an area bordered by the posterior aspect of the sternocleidomastoid muscle anteriorly, the anterior edge of the trapezius muscle posteriorly, and the clavicle inferiorly (Fig. 27.2). The defining sides of the *anterior triangle* consist of the mandible superiorly, the anatomic midline anteriorly, and the anterior aspect of the sternocleidomastoid posteriorly. The anterior triangle is further subdivided into three zones, with penetrating injury to each zone

and its underlying structures carrying distinct and important implications for diagnostic evaluation and clinical management (Fig. 27.3).

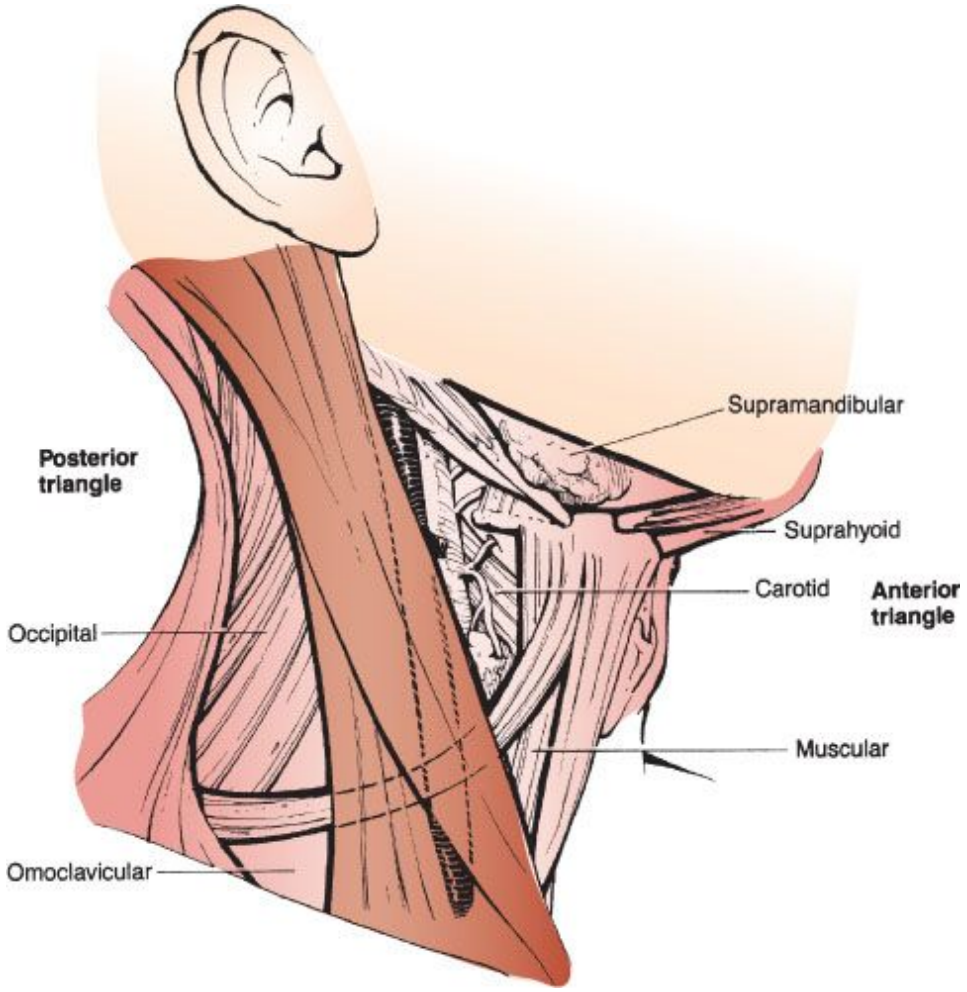

FIGURE 27.2 Anatomy of the neck: anterior and posterior triangles.

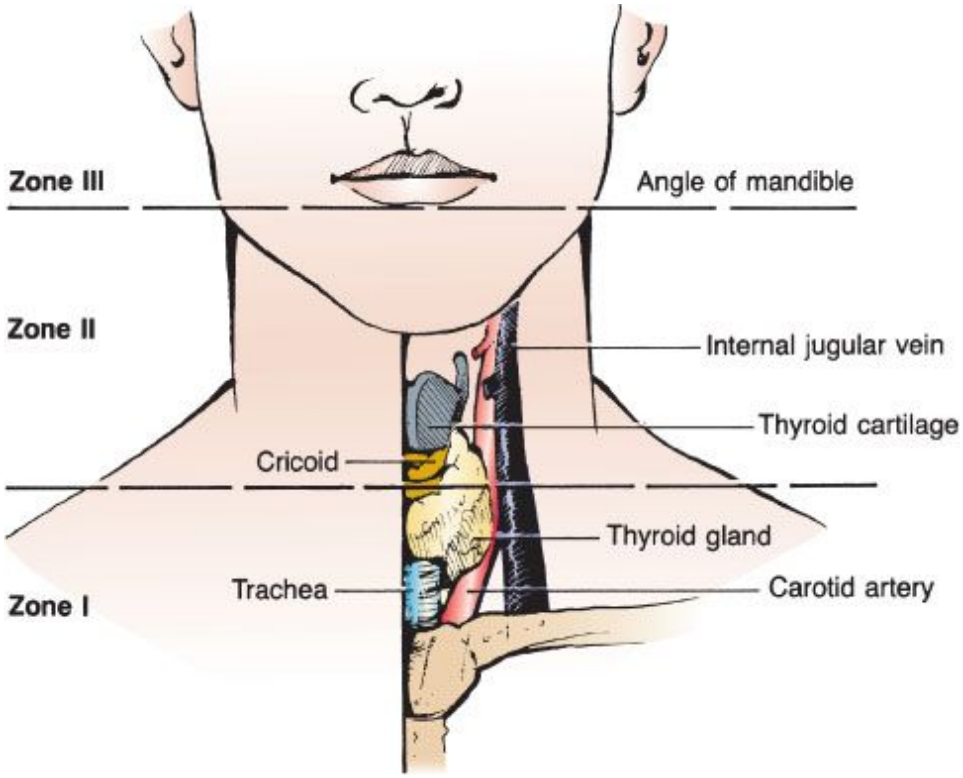

FIGURE 27.3 Anatomy of the neck: zones I, II, and III.

Zone I defines the region between the clavicles and the inferior rim of the cricoid cartilage. Vital structures susceptible to injury after penetrating trauma to zone I include the proximal common carotid, vertebral, and subclavian arteries, the thoracic outlet, the apex of the lung, the trachea, the esophagus, the thoracic duct, and the thyroid. Mortality rates for penetrating wounds to zone I are the highest of the three zones because of the inherent inability to achieve rapid proximal control of vascular injuries and the overall difficulty in gaining exposure to injuries within the thoracic cavity (2).

Zone II spans the distance from the superior edge of the cricoid to the angle of the mandible. Injuries to zone II threaten the carotid and vertebral arteries, the jugular veins, the vagus and recurrent laryngeal nerves, the cervical spinal cord, the trachea and larynx, and the esophagus. As the most exposed anatomic region of the neck, zone II injuries are the most common penetrating wounds in most series (3).

Zone III extends superiorly from the angle of the mandible to the base of the skull. Vulnerable structures in this region include the distal carotid and vertebral arteries, the salivary and parotid glands, the pharynx, the spinal cord, and cranial nerves IX to XII. As with zone I, management of zone III wounds may be problematic because of the difficulty in gaining surgical access to injured structures and control of bleeding vessels.

Within the anterior neck, the superficial fascia lies immediately beneath the skin and envelopes the platysma, a thin sheet of muscle that extends upward from the upper thorax over the clavicles to cover the entirety of the anterior triangle as well as the anteroinferior portion of the posterior triangle. As it extends cephalad, the platysma crosses the mandible to merge with the musculature of the face. This superficial structure has historically been an important landmark in gauging the potential severity of a wound—violation of the platysma by a penetrating mechanism signifies injury to vital underlying structures until proven otherwise.

CLINICAL PRESENTATION

Penetrating neck trauma is most commonly the result of a violent attack. This is reflected in the fact that the majority of victims are young adult males, and that most victims have ingested alcohol or other abusive substances immediately prior to the trauma (4). Other mechanisms of injury include unintentional impalements and bites from animals such as dogs. In most societies, stabbings outnumber gunshot and other wounds as the most common cause of penetrating neck trauma. In the United States, however, gunshot wounds account for an increasing proportion of injuries, particularly among the pediatric and young adult population (3).

Low-energy penetrations occur through such injuries as stabbings with knives or other cutting instruments, impalements, or wounds inflicted by air guns, low-caliber handguns, or shotguns at long range. High-energy mechanisms include discharges from rifles and shotguns at close range as well as shrapnel from explosive devices.

Stab wounds to the neck are typically unilateral and more frequently involve the left side because of the higher likelihood of

right hand dominance in a facing attacker. As the most exposed portion of the anterior neck, zone II is the area injured most frequently, accounting for 50% to 80% of stab wounds to the neck (1). Information relating to an assault, such as the size of the instrument and the angle of the attack, may yield some insight into the potential depth and tract of a wound. Nevertheless, the external appearance of a stab injury to the neck correlates poorly with its underlying severity, and even the most superficial-appearing injury should be approached as potentially life threatening.

Because of the higher kinetic energy imparted to the tissues by an offending missile, approximately 50% of gunshot wounds to the neck results in injury to vital structures (1). As with stab wounds, the depth and pathway of injury of a gunshot wound to the neck can be difficult to predict based upon its external appearance, particularly when it is secondary to a low-velocity projectile. When the wound traverses the anatomic midline of the neck, however, the likelihood of significant injury doubles (5).

DIFFERENTIAL DIAGNOSIS

Penetrating trauma to the neck demands consideration of potential injury to vital respiratory, vascular, neurologic, and gastrointestinal structures (Table 27.1). This differential diagnosis should guide the clinician through an initial evaluation that is rapid yet thorough. Moreover, subtle signs of significant injury may not be appreciable initially and can evolve rapidly. Frequent reevaluation of the patient for developing clinical signs and symptoms is therefore essential to avoiding a disastrous outcome.

TABLE 27.1
Signs and Symptoms of Specific System Injuries

Vascular	Aerodigestive	Neurologic
Hematoma	Respiratory distress	Altered sensorium
Persistent hemorrhage	Stridor	Hemiplegia/quadriplegia
Neurologic deficit	Cyanosis	Respiratory paralysis
Pulse deficit	Hemoptysis	Brown-Séquard syndrome
Horner syndrome (carotid injury)	Tracheal deviation	Extremity paresis or sensory loss
Hypovolemic shock	Subcutaneous emphysema	Horner syndrome (stellate ganglion)
Vascular bruit or thrill	Pneumothorax	Hoarseness (recurrent laryngeal nerve)
Altered sensorium	Sucking wound	Cranial nerve deficit (VII, XI, and XII)
Harsh, machinery-like precordial murmur (venous air embolism)	Dysphonia, aphonia, hoarseness	
	Dysphagia	
	Odynophagia	

Respiratory Injuries

Structures of the respiratory tract that are vulnerable to penetrating neck wounds include the oropharynx, larynx, trachea, and lung apices. Assessment for airway and respiratory compromise takes the highest priority during the initial and subsequent evaluations, and obvious signs of injury include dyspnea, cyanosis, and stridor. Air bubbling at the wound site, subcutaneous emphysema, pneumomediastinum, hemoptysis, voice change, tenderness over the larynx, and unilaterally diminished breath sounds are other important indications of respiratory injury.

Vascular Injuries

Vascular injuries are present in approximately one-fourth of patients and are the leading cause of mortality in the setting of penetrating neck trauma (1). Death results most often from exsanguination secondary to arterial injury, venous injury, or both. Unequivocal or "hard" signs of a major vascular insult include the following:

- Shock either with or without active hemorrhage

- An expanding or pulsatile hematoma
- Carotid bruit or thrill
- Absent radial or ulnar pulses
- Any focal neurologic deficit consistent with hemispheric stroke

Other indications of vascular injury may include diminished pulses in the temporal or facial arteries, decreased breath sounds as a consequence of hemothorax, bleeding within the oropharynx, and signs of venous air embolism such as hemodynamic collapse unresponsive to standard resuscitative measures or the presence of a loud, machinery-like murmur over the precordium.

Gastrointestinal Injuries

Violation of the pharynx and esophagus is frequently unrecognized during the initial evaluation of the patient with a penetrating neck injury, yet the consequences of such an injury can be devastating. Extravasation of saliva, gastric acid, digestive enzymes, and bacteria through a penetrating wound can ignite an aggressive necrotizing inflammatory reaction within the neck and mediastinum. Mortality and morbidity increase sharply when there is a delay in diagnosis and treatment in this setting (6). Pertinent signs and symptoms include dysphagia, odynophagia, hematemesis, and air within the soft tissues as manifested by subcutaneous emphysema or radiographic free air within the retropharyngeal space or mediastinum.

Nervous System Injuries

A number of neurologic injuries can manifest as distinct clinical syndromes after penetrating neck trauma. Gunshot wounds and, occasionally, stabbings that enter the spinal canal from a posterior orientation can partially or completely transect the spinal cord. Complete transection of the cord above the level of C5 may cause acute respiratory failure because of paralysis of the diaphragm. Transection at a lower point will cause paraplegia and loss of upper extremity function according to the level of injury. Hemisection of the spinal cord, or the Brown-Séquard syndrome, yields ipsilateral

hemiplegia, loss of tactile and proprioceptive sensation, contralateral loss of pain, and temperature sensation. Injury to the cervical sympathetic ganglia can present with the ipsilateral ptosis and myosis of Horner syndrome. Damage to the recurrent laryngeal nerve as it courses in the groove between the trachea and the esophagus impairs vocal cord movement, resulting in dysphonia or hoarseness. Cranial nerve transection may result in ipsilateral drooping of the corner of the mouth (CN VII), inability to shrug the shoulders (CN XI), or tongue deviation (CN XII). Injury to a nerve root as it travels from the vertebral foramen to the brachial plexus causes sensory and motor deficits in the corresponding upper extremity.

Cervical Spine Considerations

There is controversy as to whether cervical spine immobilization should be routinely performed in victims of gunshot wounds to the neck. Although such injury is unlikely to result from a stab wound, high-energy projectiles such as bullets can cause injuries that destabilize the cervical spine. The reported incidence of cervical spine injury as a result of gunshot wound ranges from 2.7% to 22% (7). Victims of gunshot wounds to the cervical spine may suffer neurologic deficit either from direct injury to the spinal cord by a transecting bullet or as a consequence of the concussive force imparted to the cord by a projectile passing in close proximity. Victims of gunshot wounds to the neck who do not manifest a neurologic deficit, on the other hand, are very unlikely to have an unstable cervical spine.

A retrospective review of over 45,000 patients using the National Trauma Data Bank (NTDB) found that 0.08% of patients with penetrating trauma would have potential benefit from cervical spine immobilization (7). However, the small potential benefit of routine cervical spine immobilization for penetrating wounds to the neck must be weighed against its dangers. Stabilization devices deprive the clinician of direct visualization and easy palpation of the neck, thus increasing the likelihood that signs of life-threatening complications of injury might be missed. Moreover, cervical spine immobilization may make visualization of the vocal cords more

difficult, further complicating an already challenging intubation. The NTDB review found that prehospital spine immobilization is associated with higher mortality in penetrating trauma and recommends against its use. For these reasons, the Prehospital Trauma Life Support (PHTLS) course and textbook, recommend that spine immobilization is not indicated in patients with penetrating trauma to the head, neck, or torso without neurologic deficit or complaint (8). Thus, the most recent recommendations promote selective spine immobilization in penetrating trauma only for patients with altered mental status, cervical spine tenderness or an abnormal sensory or motor examination.

ED EVALUATION

Attention to airway patency and protection is the central focus of the initial evaluation of any patient with penetrating neck trauma. Vigilance for signs of actual or impending airway compromise begins with the initial patient contact in the prehospital setting and must continue throughout the victim's ED evaluation.

Although several acceptable options for establishing definitive airway control in this clinical setting exist, each possesses inherent challenges and the risk of failure or complication. The emergency physician must therefore be familiar with and capable of quickly implementing an array of airway management techniques when confronted with the victim of a penetrating neck wound. At the same time, rapid and thorough assessment of the patient's circulatory status, the need for emergent operative intervention, and the potential for injury to the major structures of the neck is essential.

In the prehospital setting, all patients with penetrating neck trauma should be considered to have a life-threatening injury. If circumstances allow, prehospital personnel can gather pertinent information such as the circumstances related to the trauma, the character and size of the weapon responsible for the injury, the position of the attacker relative to the patient, and an estimation of the amount of blood lost at the scene.

Immediate airway management in the field is indicated for any patient with acute respiratory distress, stridor, or cardiopulmonary

arrest. If transport to an appropriate trauma center will be rapid, attempts at intubation may otherwise be deferred until arrival in the emergency department (ED). High-flow oxygen should be provided, but ventilation via bag valve mask should be avoided if possible because of its potential to force air through a tracheolaryngeal wound and into the surrounding tissues, distorting neck anatomy and further compromising the airway. Direct pressure should be applied to sites of hemorrhage, and at least one large-bore IV catheter should be placed at a site contralateral to any potential vascular injury.

Upon arrival to the ED, the primary survey must be quickly and thoroughly repeated. Indications for emergent airway stabilization include acute respiratory distress or persistent stridor, copious blood or secretions threatening the airway, extensive subcutaneous emphysema, visible expanding hematoma or tracheal shift, and altered mental status. When such frank signs of airway compromise are absent, however, the emergency physician must remain vigilant for subtle indications of airway compromise such as voice change or odynophagia. Early airway management is warranted, as deterioration can be rapid and catastrophic.

Due to potential damage to surrounding structures causing edema and distortion of airway anatomy, airway management in the patient with a penetrating neck injury should be managed as a difficult airway. Many institutions have difficult airway algorithms or carts which should be available for these situations. A number of options exist for appropriate airway management after penetrating neck trauma. Intubation over a fiberoptic bronchoscope in the awake patient may allow for effective visualization of the vocal cords and passage of an endotracheal tube despite the presence of airway distortion or excessive blood and secretions. It may also identify specific laryngotracheal injuries. Its disadvantages include the need for specialized equipment and expertise and the potential to induce gagging and coughing.

In most EDs, rapid sequence intubation (RSI) using a neuromuscular paralytic agent is the primary modality of airway management in trauma (9). Some authors recommend using caution with RSI in this setting, however, arguing that a decrease in muscle

tone following paralysis holds the potential to worsen airway distortion and thus invite airway disaster. Appropriate caution and, more importantly, preparation for an alternative means of airway management in the event of failure are therefore essential before attempting RSI after penetrating neck trauma. The increased use of videolaryngoscopy may be particularly useful in situations where visualization of the glottis is difficult, as it has been shown to improve first pass success rates and decreased complications compared to direct laryngoscopy (10). To date, there are no studies specifically evaluating the use of videolaryngoscopy in patients with penetrating neck trauma. Similar to fiberoptic bronchoscopy, significant bleeding or copious secretions may limit visualization using such adjuncts.

The establishment of a surgical airway is the most commonly used rescue technique for airway management after failed RSI among patients with penetrating neck injuries (11). Cricothyroidotomy should be performed with a vertical incision to allow for extension of the incision if the cricothyroid membrane is not easily identified initially. Significant hematoma overlying the cricothyroid membrane is a contraindication to cricothyroidotomy because of the potential to convert a partial cricotracheal separation into a complete disruption. Emergent tracheostomy is warranted in this setting.

When the patient is stable, the wound itself should be inspected *but never probed* to determine if it has violated the platysma. Wounds that do not penetrate the platysma may be irrigated and closed. Otherwise, a thorough secondary assessment for the signs and symptoms of significant vascular, respiratory, neurologic, and gastrointestinal injury described previously should proceed to determine further appropriate evaluation and management in the ED.

All patients with penetrating trauma to the neck should receive an upright or supine (if cervical spine precautions are being maintained) chest radiograph. Potentially life-threatening injuries such as pneumothorax or hemothorax can be rapidly diagnosed with chest radiograph. In addition, subcutaneous air that may not be appreciated on physical examination may be visualized on plain

radiograph and may signify injury to the aerodigestive system. Although it may be difficult to distinguish air from an esophageal or tracheobronchial injury from air tracking through a penetrating wound, any positive finding should prompt strong consideration of and further evaluation for these injuries.

The evaluation and management of all penetrating injuries to the neck has changed with the increasing availability of computed tomography (CT), particularly multidetector CT angiography (CTA). The technology is available in most centers around the clock, and it provides rapid information about the vascular, aerodigestive, soft tissue, and bony cervical spine with high resolution (12). In addition, CT, even one performed without contrast, can provide information regarding the trajectory of the penetrating missile and potential injuries from its path (13). Wounds concerning for vascular injuries that were previously evaluated with arteriography, are now evaluated with CTA with equal sensitivity (1,11). All patients who do not have indications for emergent surgical management, and in whom further testing is warranted, should undergo CTA as a first diagnostic modality.

Duplex ultrasonography, or color flow Doppler imaging, is a modality used for diagnosis of arterial injuries and has been demonstrated to have sensitivities of 85% to 92% and specificity of 100% (14). Specifically in zone I and zone III injuries, duplex ultrasonography may be limited due to bony artifact. However, in situations where CTA may be equivocal due to metallic fragments causing difficulty in visualization of the vessels, ultrasonography may be helpful.

Arteriography used to be the gold standard and used frequently for evaluation of vascular injuries in penetrating trauma. However, given the use and sensitivity of CTA, arteriography has been used mostly as a confirmatory test in equivocal CTA's or as a therapeutic modality for those patients necessitating embolization or thrombolytic therapy for vascular injuries (1,15).

Evaluation of the digestive system is imperative in patients with a missile trajectory that is adjacent to the oropharynx or esophagus. Most frequently, patients are found to have an injury on CTA that

either crosses the mediastinum or comes dangerously close to the digestive structures, and requires further testing with either contrast esophagography (usually with either barium or a high osmolality contrast agent such as Gastrografin or Hypaque) or esophagoscopy (endoscopy). Both modalities have been found to have adequate sensitivity and specificity to be used alone and both do not need to be performed (1,16,17).

Diagnostic laryngoscopy and bronchoscopy are used to evaluate injuries of the larynx and trachea. Most airway system injuries can be initially diagnosed by either physical examination or CT, and endoscopic studies are performed for further evaluation or management of these injuries. CT scans without concern for airway injuries do not need routine evaluation with laryngoscopy or bronchoscopy.

KEY TESTING

- Chest radiography
- Multidetector CTA
  - First diagnostic modality for patients who do not have indications for emergent surgical management
- Duplex ultrasonography, or color flow Doppler imaging
- Either contrast esophagography (usually with either barium or a high osmolality contrast agent such as Gastrografin or Hypaque) or esophagoscopy (endoscopy) for evaluation of the digestive system
- Diagnostic laryngoscopy and bronchoscopy are used to evaluate injuries of the larynx and trachea

ED MANAGEMENT

Historically, surgeons advocated mandatory operative exploration of all penetrating neck wounds because of the high mortality and morbidity associated with delays to diagnosis and treatment observed during the First World War. For much of the 20th century, this practice was extended to wounds suffered by the civilian populace as well. As effective adjunctive diagnostic modalities have

emerged, selective operative management for victims of penetrating neck trauma based on clinical assessment and supplementary diagnostic imaging has become standard (1).

Thorough clinical examination is essential for differentiating those patients in need of operative intervention from those who may be observed and further evaluated without immediate surgery. The “hard signs” of vascular injury mentioned above, (active or pulsatile hemorrhage, shock unresponsive to volume resuscitation, expanding hematoma, presence of a bruit or thrill, diminished distal pulses, and a focal neurologic deficit) are clear indications that immediate operative management is required. In addition, air bubbling from a wound, hematemesis, odynophagia, subcutaneous emphysema, or blood in the saliva or aspirate can be signs of injury to the aerodigestive system and also warrant immediate surgical exploration.

Those patients who do not present with signs mandating immediate surgery may be divided into two groups: those who are asymptomatic and those with findings or symptoms concerning for vascular, neurologic, or aerodigestive injury. The specific zone of injury determines the approach to further evaluation and management for patients in either group.

Patients with zone I injury who do not proceed emergently to surgery should undergo further diagnostic evaluation regardless of whether they manifest any of the vascular, neurologic, or aerodigestive symptoms described previously. Asymptomatic patients may harbor occult injury to the structures of the lower neck and upper thorax that may not become apparent until catastrophic decompensation occurs. CT with angiography should be obtained in these patients to evaluate for significant injury. For any trajectory that traverses the mediastinum or passes in the vicinity of the aerodigestive system, evaluation with esophagoscopy or esophagography should then be performed. If the trajectory of the injury is unable to be determined by CT, evaluation of the esophagus should still occur, given the high morbidity associated with missed injury.

Zone II injuries have received the most scrutiny and rigorous study in the past decade. The Eastern Association for the Surgery of Trauma reviewed the literature on penetrating zone II injuries and published Practice Management Guidelines (PMG) in 2008, looking specifically at the management of Zone II injuries (1). A synopsis of their evidence-based recommendations is as follows.

1. Selective operative management for patients without hard signs of injury is recommended to minimize unnecessary operations.
2. High resolution CTA is the initial diagnostic study of choice when available. Arteriography is no longer necessary to rule out an arterial injury.
3. CT of the neck (even without CTA) can be used to rule out a significant vascular injury if it demonstrates that the trajectory of the penetrating object is remote from vital structures.
4. Either contrast esophagography or esophagoscopy can be used to rule out an esophageal perforation.

One question addressed by the PMG that is more controversial is whether the sensitivity of physical examination is high enough to rule out both vascular and aerodigestive injuries. Based on several studies that suggest that physical examination is $>95\%$ sensitive for detecting significant injuries, the EAST PMG gave a level III recommendation that asymptomatic patients with zone II injuries and a normal physical examination do not need imaging studies or operative exploration and may be safely observed for serial physical examinations. However, given the potential morbidity of missed injury, the ease of obtaining CT, and the time commitment needed for serial physical examinations, most clinicians have a low threshold for obtaining imaging studies.

Zone III injuries are evaluated and treated similarly to penetrating head trauma. Patients who are stable but manifest signs of vascular or neurologic injury should receive further diagnostic imaging, most commonly CTA of the neck and head, to evaluate the extent of injury and assist in determining the optimal method of surgical repair. Similar to zone II, although the safety and cost effectiveness of observation in asymptomatic patients with zone III injuries has been reported (3), the increasing use and ease of CT has made most

practitioners evaluate these patients radiographically, regardless of the presence or absence of symptoms. In patients with hard signs of vascular injury, arteriography may be an alternative to operative management. Because of the difficulty of obtaining surgical access, injuries diagnosed by arteriography may be amenable to embolization, thrombolytic therapy or even observation (15).

CRITICAL INTERVENTIONS

- Perform early airway management for patients with acute respiratory distress, stridor, copious blood or secretions, extensive subcutaneous emphysema, expanding hematoma, tracheal shift, or altered mental status.
- Apply direct pressure to active bleeding sites.
- If direct pressure fails to control hemorrhage, insert and inflate a Foley catheter balloon within the wound to tamponade bleeding.
- Evaluate all patients with penetrating neck wounds for vascular, esophageal, and airway injuries.

DISPOSITION

Patients with wounds that do not violate the platysma should receive standard wound care, after which they may be discharged safely. All patients with injuries deep to the platysma must receive emergent surgical consultation and should undergo systematic evaluation as described previously. Even the most benign-appearing wound that violates the platysma in an asymptomatic patient must either be investigated radiographically or be observed for 12 to 24 hours. Patients with negative imaging can safely be discharged from the ED.

Common Pitfalls

- Failure to appreciate the potential severity of a small or “trivial” penetrating neck wound.
- Failure to appreciate subtle signs and symptoms of impending airway compromise.
- Delaying definitive airway management until airway distortion or respiratory compromise have rendered intubation exponentially

more difficult.
- Failure to anticipate difficulties in airway management and implement effective alternative strategies.
- Failure to complete a thorough physical examination to detect subtle vascular, aerodigestive, and neurologic injuries.
- Failure to obtain studies evaluating esophageal or tracheal injury when the trajectory of the penetrating missile is in close proximity to the mediastinum.

CHAPTER 28

Cervical Spine Fractures

William R. Mower and Jerome R. Hoffman

Each year, U.S. emergency physicians evaluate nearly 1 million patients for cervical spine injury (CSI). Two to three percent of these patients actually have spine injuries, including nearly 11,000 who suffer catastrophic injury and permanent paralysis. Lifetime medical care exceeds $3 million per injury victim, and the cost of annual nationwide care for these patients exceeds $2 billion (1). Medical costs reflect only a portion of the burden produced by catastrophic cervical spine injuries. Affected patients also encounter severe limitations on activity and mobility, loss of income, productivity, and independence and increased rates of medical illness, depression, and suicide (1–3).

CLINICAL PRESENTATION

CSI most frequently occurs after blunt trauma and is often accompanied by other significant injuries, particularly head injury. CSI may be severe and life threatening and may require immediate attention (1). Conversely, unstable CSI can present with subtle clinical findings. Though truly occult injury rarely if ever occurs, patients may be unaware of a serious neck injury if they are intoxicated, have another painful injury that distracts their attention, or have an altered level of alertness that impairs their ability to appreciate the spine injury (4). Though CSI should be suspected in the setting of new-onset neurologic impairment, a normal neurologic examination does not preclude a serious and potentially unstable spine injury (4).

Classification Based on Mechanism

The specific injuries associated with a given force reflect compressive, tensile, and rotatory stresses generated by the force. In general, compressive forces produce failure (fracture) in osseous elements, whereas distractive or tensile forces can result in failure of either ligament or bone, depending on the strength of the involved bone and the rate of loading (ligamentous failure is more likely at high rates of loading) (5). For example, forced flexion generates compressive stress along the anterior spine and posterior tensile or distractive stresses. The anterior compression can produce mechanical failure of the vertebral body resulting in wedge compression and flexion teardrop fractures, whereas the posterior tensile forces can cause stretching and tearing of the posterior ligament complex, as seen in anterior subluxation, or failure across the spinous process, as found in clay shoveler's fractures. Severe flexion forces may destroy the entire posterior ligament complex, obliterate all middle and anterior support, and produce bilateral interfacetal dislocation (6).

Hyperextension and lateral flexion also produce forced curvature of the spine, generating compressive stresses along the concave side of the curvature and tensile stresses along the convexity. Alternatively, pure vertical compression generates only compressive stresses, whereas some combined actions (rotation coupled with hyperflexion or hyperextension) produce relatively complex force distributions. Each of these mechanisms generates specific stress patterns and is associated with a particular family of injuries (5,6).

It is not possible to classify all CSIs in terms of specific applied forces. Injuries involving the occipital articulation and atlantoaxial complex, such as occipitoatlantal and atlantoaxial dissociation, as well as fracture of the dens, appear to have multiple etiologies (5,6). These injuries indicate the application of significant forces capable of producing other spine injuries and should prompt a careful search for additional lesions.

Classification Based on Stability

Functionally, the spine is considered stable if it is able to support physiologic loads without developing displacement or structural changes that cause irritation of the spinal cord or nerve roots or incapacitating deformity or pain (5). Although this definition is relatively straightforward, determining the stability after specific spine injuries can be extremely difficult. Consequently, general principles have been developed to aid in assessing stability (5).

The two-column concept of the spine is particularly useful in understanding pathophysiology and assessing stability of injuries to the lower cervical spine (base of the second cervical vertebra through first thoracic vertebra) produced predominantly by flexion or extension. This construct divides the spine into anterior and posterior columns based on anatomic elements. The anterior column consists of the posterior longitudinal ligament and all anatomic elements anterior to it, including the vertebral body, annulus fibrosus, intertransverse ligaments, and anterior longitudinal ligament. The posterior column consists of all elements posterior to the posterior longitudinal ligament, including the facet and capsular ligaments, the lamina and ligamentum flavum, and the spinous process and interspinous and supraspinous ligaments (5). Biomechanical studies demonstrate that clinical stability is preserved if all of the elements from one column and any single element from the other column remain intact (i.e., all of the anterior elements plus one posterior element or all of the posterior elements plus one anterior element) (7,8).

The two-column concept is not useful in assessing stability for injuries involving the occipital articulation and atlantoaxial complex, and it is of limited utility in assessing injuries associated with lateral flexion (5,6). With a very limited number of exceptions (fractures to the posterior arch of atlas, small avulsion fractures of the anterior arch, and type I dens fractures), consultation with an experienced spine specialist is recommended to determine the stability of these injuries.

Table 28.1 summarizes the injury mechanism and clinical stability associated with common cervical spine injuries. This table presents a conservative interpretation of clinical stability in that many of the

injuries described as unstable may actually have stable variants, but the detailed considerations required for a definitive assessment are beyond the scope of this text. Consultation with an experienced spine specialist is recommended in cases of uncertainty. Table 28.2 describes the specific injuries that characterize common cervical spine fractures.

TABLE 28.1
Injury Mechanism and Clinical Stability of Common Isolated Cervical Spine Injuries

Forced Flexion

Spinous process fracture (Clay shoveler's fracture) (S)
Anterior subluxation (D)
Wedge compression fracture (D)
Bilateral interfacetal dislocation (U)
Flexion teardrop fracture (U)

Extension

Avulsion of anterior arch of the atlas (S)
Fracture of posterior arch of atlas (S)
Laminar fracture (S)
Traumatic spondylolisthesis (hangman's fracture)
  Nondisplaced: type I (S)
  Displaced: types II and III (U)
Extension teardrop fracture (U)
Hyperextension dislocation (U)
Hyperextension fracture dislocation (U)

Vertical Compression

Jefferson burst fracture (U)
Vertebral body burst fractures (U)

Hyperflexion and Rotation

Unilateral interfacetal dislocation (U)
Unilateral interfacetal fracture dislocation (U)

Hyperextension and Rotation

Pillar fracture (S)
Unilateral pedicolaminar fracture separation (S)
Bilateral pedicolaminar fracture dislocation (U)

Lateral Flexion

Unilateral occipital condyle fracture (U)
Unilateral fracture of the C1 lateral mass (U)
Uncinate process fracture (U)
Transverse process fracture (U)

Injuries Due to Multiple or Poorly Understood Mechanisms

Torticollis (atlantoaxial rotatory displacement or fixation) (S)
Dens fractures
  Type I (S)
  Type II or high (U)
  Type III or low (U)
  Os odontoideum (U)
Occipitoatlantal subluxation or dislocation (U)
Occipitoatlantal dissociation (U)
Atlantoaxial rotatory dissociation (subluxation or dislocation) (U)
Atlantoaxial dissociation (U)
Occipital condyle fractures (U)

S, stable injury; D, initially stable, but delayed instability possible; U, unstable or potentially unstable injury, consider consultation with experienced spine specialist.
Modified from Harris JH Jr, Mirvis SE. *The Radiology of Acute Cervical Spine Trauma.* 3rd ed.

TABLE 28.2
Pathophysiologic Lesions Associated with Common Cervical Spine Injuries

Injury	Pathophysiology
Occipitoatlantal dislocation	Separation or disruption of the craniovertebral junction
Burst fracture of the atlas (Jefferson burst fracture)	Fracture of the anterior and posterior arches of the atlas (C1) that may be accompanied by disruption of the transverse atlantal ligament. Unilateral and bilateral variants exist
Dens fractures (odontoid fractures)	Fractures of the axis (C2) involving the dens
	Subclassification is based on fracture location with respect to the dens and has important implications to stability and treatment
Type I	Fracture of the superolateral odontoid process
Type II	Fracture at the base of the dens
Type III	Fracture of the axis body caudal to the junction with the dens
Traumatic spondylolisthesis (hangman's fracture)	Bilateral fractures of the pars interarticularis of the axis (C2). Subclassification is based on displacement of the posterior ring of the axis and disruption of the C2–C3 disk space and reflects important mechanistic and therapeutic implications
Type I	Minimal (hairline) displacement of fracture fragments with preservation of the disk space
Type II	Displacement between anterior and posterior fragments with abnormal disk space
Type III	Displacement between anterior and posterior fragments with bilateral interfacetal dislocation of C2 and C3
Vertebral body burst fractures	Compressive fracture of the vertebral body producing circumferential dispersion of bone fragments
Flexion teardrop fracture	Fracture of the anteroinferior corner of the vertebral body, with associated disruption of the anterior and posterior longitudinal ligaments and intervertebral disk
Extension teardrop fracture	Avulsion fracture of the anteroinferior corner of the vertebral body of the axis (C2)
Wedge compression fracture	Impaction and angulation of the superior endplate and anterior cortical margin of the vertebral body
	Frequently accompanied by injuries to the posterior ligament complex
Bilateral interfacetal dislocation	Disruption of the posterior ligament complex, posterior longitudinal ligament, and intervertebral disk, with bilateral anterior dislocation of the articular masses
Unilateral interfacetal dislocation	Unilateral rotation and dislocation of the articular mass (perched or locked facet); usually accompanied by disruption of the articular capsule and posterior ligament complex but may also involve disruption of the contralateral articular capsule
Hyperextension dislocation	Disruption of both anterior and posterior longitudinal ligaments and disruption or detachment of the intervertebral disk frequently reduces

DIFFERENTIAL DIAGNOSIS

Neck pain and tenderness are common findings among trauma patients, but significant CSI is rare. Most patients have minor strains and contusions that require no specific therapy. As such, it is not necessary to identify specific soft tissue injuries in most cases but rather to exclude serious injuries that could result in permanent dysfunction or catastrophic disability.

Injury to the spine and spinal cord should be suspected in any trauma patient presenting with a new-onset neurologic deficit. At the same time, it is important to recognize that these same deficits can be due to a variety of other etiologies outside the cervical spine, such as vascular injury, intracranial injury, lower spine injury, or injury to one or more peripheral nerves (4,6). Respiratory distress in blunt trauma patients may also be due to a variety of causes, including upper CSI. The neck contains a remarkable number of vital structures, including the spinal cord, carotid and vertebral arteries, jugular veins, trachea, and esophagus. All are susceptible to injury and may produce pain indistinguishable from that produced by CSI. It is important to note that trauma patients frequently have multiple injuries, and identifying a specific injury does not preclude the presence of other injuries. Spine injuries in particular provide evidence of significant axial forces and should prompt clinicians to evaluate affected patients for secondary CSIs as well as injuries to other axial elements, including the lower spine.

ED EVALUATION

Once vital functions have been ensured, blunt patients should undergo a meticulous examination to detect other injuries and ascertain baseline function. Patients should be assessed for mental status changes that may limit the reliability of clinical evaluations. Careful attention should be placed on assessing the face and calvarium. Many of the force vectors that cause CSIs originate in the head, and meticulous evaluation may disclose such injuries as well as provide information relating to potential spine injuries. The neck

and spine should be examined to detect areas of pain and swelling. A detailed neurologic examination is essential and should include an assessment of reflexes and pathologic findings associated with spine injury (bulbocavernosus reflex, priapism, decreased rectal tone). Sensory innervation follows dermatomal distributions and is particularly helpful in localizing lesions in patients with cord injuries (Table 28.3). Similarly, deficits in motor function are associated with specific nerve root levels and may also prove informative in determining injury levels (Table 28.3). Any patient with suspected spine injury should also undergo a careful evaluation of the remaining axial anatomy.

TABLE 28.3
Sensory and Motor Examination

Spinal Cord Level	Sensory Distribution	Functional Ability
C4	Neck	Spontaneous breathing
C5	Shoulder and arm	Shrug shoulders
C6	Thumb	Elbow flexion
C7	Third digit	Elbow extension
C8	Fifth digit	Flexion of fingers

Because CSI can be permanent and devastating, all trauma patients should be evaluated for potential CSI. Radiographic imaging provides the definitive means of assessment but is unnecessary in many cases. Clinical assessments based on decision guides such as the NEXUS low-risk criteria (4) and Canadian C-spine rule (CCR) (9) allow clinicians to identify patients who are at very low risk of CSI and can be safely spared the expense and radiation exposure associated with imaging. Although these instruments reliably detect injury (high sensitivity) and preclude injury in patients deemed “low risk” (high negative predictive value), they exhibit poor positive predictive value, and the majority of “non–low-risk” patients do not have a CSI.

The NEXUS criteria are based on five historical and physical examination findings. Patients are at low risk and may safely be

spared radiographic imaging provided they exhibit *all* of the following criteria: (a) no posterior midline cervical spine tenderness, (b) no evidence of intoxication, (c) normal level of alertness, (d) no focal neurologic impairment, and (e) no distracting painful injuries. The criteria are subject to interpretation by individual physicians. Although they are not precisely defined, each criterion is further clarified as follows (10).

- Midline posterior bony cervical spine tenderness is present if the patient complains of pain on palpation of the posterior midline neck from the nuchal ridge to the prominence of the first thoracic vertebra or if the patient has pain with direct palpation of any cervical spinous process.
- Patients should be considered intoxicated if they have either of the following: (a) a recent history by the patient or an observer of intoxication or intoxicating ingestion or (b) evidence of intoxication on physical examination such as odor of alcohol, slurred speech, ataxia, dysmetria or other cerebellar findings, or any behavior consistent with intoxication. Patients may also be considered to be intoxicated if tests of bodily secretions are positive for drugs (including but not limited to alcohol) that affect level of alertness.
- An altered level of alertness can include any of the following: (a) Glasgow Coma Scale (GCS) score of 14 or less; (b) disorientation to person, place, time, or events; (c) inability to remember three objects at 5 minutes; (d) delayed or inappropriate response to external stimuli; or (e) other evidence of cognitive impairment or altered alertness.
- Any focal neurologic complaint (by history) or finding (on motor or sensory examination).
- No precise definition for distracting painful injury is possible. This includes any condition thought by the clinician to be producing pain sufficient to distract the patient from a second (neck) injury. Examples may include, but are not limited to (a) any long-bone fracture, (b) a visceral injury requiring surgical consultation, (c) a large laceration, degloving injury, or crush injury, (d) large burns, or (e) any other injury producing acute

functional impairment. Physicians may also classify any injury as distracting if it is thought to have the potential to impair the patient's ability to appreciate other injuries; conversely, no injury should be considered distracting in a given patient simply because it is frequently so among a group of patients. Thus, not all fractures are distracting; it is as always a matter of judgment for the clinician to decide whether a given injury is likely to impair a given patient's ability to appreciate other (e.g., cervical spine) injuries.

The CCR excludes patients from risk classification if they (a) are younger than 16 years, (b) have a GCS score <15, (c) have grossly abnormal vital signs, (d) were injured more than 48 hours previously, (e) have penetrating trauma, (f) present with acute paralysis, (g) have known vertebral disease (ankylosing spondylitis, rheumatoid arthritis, spinal stenosis, or previous cervical surgery), as determined by the examining physician, (h) are returning for reassessment of the same injury, or (i) are pregnant (9).

According to the CCR, among patients suitable for risk classification, imaging is mandatory for those aged 65 years or greater, those with a dangerous mechanism of injury (fall from a height of 3 ft or greater, or 5 stairs; axial load to the head such as from diving; motor vehicle collision involving speed of 100 km/h or greater; motor vehicle accidents involving rollover, ejection, or a recreational vehicle; or a bicycle collision). Patients who do not meet these high-risk criteria require further risk assessment based on range of neck motion. Prior to assessing range of motion, clinicians must first determine whether a patient can safely undergo rotational assessment. Patients for whom rotational assessment can be safely completed include (a) those with a rear-end motor vehicle collision (excluding those pushed into traffic, those hit by a large vehicle such as a bus or truck, and those hit by high-speed vehicles); (b) those in a sitting position in the ED; (c) patients who were ambulatory at any time; (d) patients whose neck pain was delayed in onset (neck pain not immediately following event); or (e) those who have no midline cervical spine tenderness. Imaging should be obtained on patients who cannot safely undergo assessment of range

of motion, as well as all patients who are unable to actively rotate neck 45 degrees to the right and left (9).

Patients who fail to meet low-risk classification based on clinical assessment, should undergo imaging that is individualized according to the patient's clinical presentation and potential for CSI. Plain radiographs frequently fail to identify important cervical spine injuries, and are not highly sensitive for CSI—including for some clinically important injuries—so they should not even be considered in patients with at least a moderate prior probability of injury. These include the elderly (in whom it is often difficult to evaluate plain films because of the common presence of concomitant osteoarthritis), those in whom any movement is impossible or contraindicated, those already scheduled for computed tomography (CT) scanning for some other reason, and those with a truly high prior probability of injury (11). On the other hand, in a reasonably young patient who requires imaging merely because of failure to meet low-risk criteria, but in whom the prior probability of CSI is truly low, and it is likely that clearly interpretable plain films can be accomplished, an adequate three-view series has an extraordinarily high-negative predictive value if it can be read as clearly negative (12).

Noncontrast CT provides the most definitive means of evaluating the bony cervical spine and is the current standard for evaluating the cervical anatomy of most blunt trauma patients, including most adults and older pediatric patients (12,13). Such an imaging is highly sensitive in detecting the presence of CSI as well as the specific form of injury (12). CT imaging may miss fractures of the dens as well as injuries in the plane of the scanner such as dislocations and subluxations, particularly if imaging is completed using early-generation scanners (14). The cross-table lateral radiograph provides a reliable means for detecting these potential missed injuries and, consequently, still plays a role in the initial evaluation of blunt trauma patients undergoing radiographic imaging when reconstructions are inadequate (6,13).

Radiation exposure is an important concern on younger children, and x-ray imaging that includes an anteroposterior (AP), lateral, and

open-mouth odontoid still plays an important role in screening this population for injury (13). Plain radiography requires correct exposure and positioning; injury cannot be reliably excluded if images are incomplete or inadequate. Abnormal radiographs should also cause concern, even though no specific injury is evident. Misalignment of spine elements and changes in soft tissue contours may indicate the presence of serious injuries. The interpretation of plain radiographs can be difficult and requires comprehensive knowledge of the subtle findings that may indicate significant injury as well as a detailed understanding of the normal variants that may simulate injury patterns (6). The inexpert interpretation of inadequate cervical spine radiographs is a recipe for disaster. Noncontrast CT imaging is indicated for children with demonstrated cervical spine injuries, and for those who cannot be safely cleared on the basis of x-ray imaging (13).

Imaging, whether CT or x-ray, must be of high quality, with complete visualization of the spine and soft tissues from the base of the skull to the top of the first thoracic vertebra. High technical quality is essential, with proper patient positioning, removal of foreign bodies, and avoidance of motion artifact (6).

Magnetic resonance imaging (MRI) offers an effective and discriminating means for assessing the soft tissues of the cervical spine. Bony injuries are frequently missed on MRI; hence, it is not an adequate substitute for CT or x-ray imaging. MRI is most useful in assessing injuries to the cord, intervertebral disks, and paracervical tissues, including supporting ligaments. Use of this modality should be limited to patients with posttraumatic myelopathy or radiculopathy, patients with pain disproportionate to their physical and radiographic findings, and those with demonstrated occipitoatlantal subluxation, and to assess the acuity of anterior subluxations. MRI and MR angiography may also be valuable in assessing the vertebral arteries, particularly in patients who have pedicolaminar fracture separations (6,13).

Flexion–extension radiographs have been advocated in the acute evaluation of suspected anterior subluxation when plain films are nondiagnostic. However, this type of imaging is known to miss

acute anterior subluxations, presumably because of reflex cervical spasm, and has not been shown to enhance the early detection of this initially stable injury (15,16). Consequently, the value of flexion–extension imaging is questionable in the emergency setting and may provide false security to patients with missed injuries. A better approach to the diagnosis and management of patients with suspected anterior subluxation would be to employ MRI to evaluate patients with typical imaging findings or those with neurologic symptoms such as radiculopathy. The remaining patients appear to be best evaluated by delayed flexion–extension imaging once their spasm has resolved (13,15,17).

Motion fluoroscopy has been used to assess spine stability in selected patients, particularly those who cannot cooperate with flexion–extension imaging. Use of this modality, particularly passive fluoroscopy, is controversial because of its potential to produce permanent cord injury. Currently, there are no emergent indications for the use of this imaging (13,18).

KEY TESTING

- Use clinical judgment to initially assess whether a blunt trauma patient is truly at risk of a CSI.
- Apply a decision instrument to determine whether radiologic imaging is indicated.
- High-quality x-ray imaging provides appropriate radiologic evaluation for children and lower-risk young adults.
- CT imaging should be used in assessing high-risk individuals, and older patients.
- MR imaging is inappropriate for most patients. It is inadequate for assessing bone integrity and should be used selectively in assessing vascular and soft tissue structures.

ED MANAGEMENT

The primary goal of the emergent treatment of spine injury is to prevent further injury and disability. Although CSI can be devastating, initial management must focus on ensuring other vital

functions, including adequate airway, breathing, and circulation. Trauma patients should always be presumed to have an unstable spine injury until proven otherwise, and their entire spine should be protected until an appropriate evaluation can be completed.

Special care must be exercised in managing patients who require mechanical ventilation. Although all methods of securing an adequate airway, including surgical approaches, can produce movement of the cervical spine, this should not result in neurologic deterioration if performed appropriately and, of course, ventilatory support should not be delayed because of concerns related to spine injury. Inadequate ventilation not only places other organ systems at risk but increases the potential for ischemic and hypoxic injury to the spine.

The airway should be secured using familiar techniques that are least likely to require repeated attempts. Most patients can be orotracheally intubated, whereas those with extensive neck and facial injuries may require a surgical airway. If time, resources, and skilled practitioners are present, fiberoptic bronchoscopy offers an alternative means of intubation that may confer theoretical advantage, but has yet to be shown to improve neurologic outcomes (19). Adequate preparation and equipment are essential, as is a careful technique. An assistant who can help stabilize the spine and ensure anatomic alignment may prove particularly helpful. Axial traction may produce harmful distractive forces and is contraindicated (19).

Protecting the spine from additional mechanical injury is essential. Cervical spine “precautions” should be used to maintain an anatomically neutral position. Immobilization may include the use of various collars, backboards, and supplemental devices such as braces and sandbags. However, the use of these devices should be directed toward the primary goal of maintaining appropriate spine alignment. Ill-fitting collars and poor patient positioning may actually produce further injury, despite the fact that the spine is immobilized. Backboards and cervical collars can be removed as soon as the spine has been cleared in patients who are uninjured or

as soon as alternative measures have been initiated to provide support for patients with spine injuries.

Specific treatments for spinal cord injuries are currently limited. Meticulous supportive care, including optimization of ventilatory and circulatory support, is essential and plays a substantial role in the preservation of neurologic function. Injury to the spinal cord may produce loss of sympathetic and vasomotor tone and subsequent neurogenic shock. Intravenous crystalloids should be administered as initial treatment, and patients should be carefully assessed for other sources of hypotension, particularly other traumatic injuries. Vasopressors may be required to attain adequate perfusion pressures, but these agents should be used carefully, with an appreciation of their ability to temporarily mask the hypovolemia produced by coexisting injuries. Neurogenic shock may also be complicated by bradycardia, which may require specific pharmacologic treatment if accompanied by circulatory embarrassment.

Corticosteroids and G_{M1} gangliosides have been advocated in the treatment of acute cord injuries, but there is insufficient evidence to support the use of either agent. They are recommended as options in the treatment of spinal cord injuries but have no demonstrated benefit. Treatment with methylprednisolone in particular appears to be more likely to produce harmful side effects as opposed to clinical benefit (20).

CRITICAL INTERVENTIONS

- Suspect CSI in all trauma patients. Though CSI frequently occurs in the setting of multisystem trauma, presentation can be subtle. Geriatric patients are particularly at risk of injury after relatively minor trauma such as ground-level falls (21).
- Support the airway, ensure ventilation, and treat other life-threatening injuries. Assume cervical spine injuries are present in all blunt trauma patients until they are sufficiently stable to permit a thorough evaluation.

- Maintain normal cervical anatomy (cervical immobilization). Provide physical support for the spine to prevent further injury.
- Perform an adequate diagnostic evaluation. Obtain complete and adequate radiographic imaging in any cases in which injury cannot reliably be excluded on the basis of clinical evaluation. Ensure that the images are interpreted by clinicians familiar with the subtle radiographic findings associated with many cervical spine injuries.

DISPOSITION

Patients who have a minor spine injury, including those with a cervical strain, or an isolated stable fracture that does not require further specific intervention, may be discharged with analgesia and instructions to avoid uncomfortable or painful activities. A soft cervical collar is frequently dispensed to such patients but has little proven benefit (19,22).

An experienced spine specialist should be involved in the care of all patients with evidence of neurologic injury, those with a clinically unstable or potentially unstable spine injury, a fracture that is displaced or otherwise interferes with normal function, and those whose injury status is uncertain. Rigorous protection from additional injury is indicated in all cases involving an unstable fracture or a neurologic deficit. Consultation with a spine specialist should be initiated as soon as the patient's condition permits.

Common Pitfalls

- Failure to suspect injury, particularly in patients without localized tenderness or neurologic deficits, and among intoxicated patients, those with altered levels of alertness, and those with other painful or distracting injuries.
- Performing an inadequate physical examination. Clinical clearance is impossible in patients who cannot cooperate with a detailed examination (intoxicated patients and those with altered mentation or other painful distracting injuries). Detailed and

complete neurologic examination is essential with careful attention to dermatomal function and pathologic reflexes.

- Performing inadequate radiographic evaluation. Imaging must be of high technical quality with complete visualization of the spine from the base of the skull to the cervicothoracic junction. Images must be free of foreign bodies and motion artifacts.

CHAPTER 29

Thoracolumbar Spine Fractures

Amy Kaji and Robert S. Hockberger

Thoracolumbar spine (TLS) injuries are relatively uncommon in the United States; however, of all blunt trauma patients presenting to the emergency department (ED), the rate of TLS injury is up to 15% (1). Although there are only approximately 40 cases per million population in the United States, spinal cord injury (SCI) predominantly afflicts productive young adults. Between 1973 and 1979, the average age at injury was 28.7 years, but as the median age of the general population has increased, the average age of injury has also increased (2). Since 2005, the average age at injury is 41. Over 80% of SCI occur among males, and the total annual cost to society from medical expenses and lost productivity is estimated to be over $5 billion. Statistics from the National Spinal Cord Injury Database (NSCID) reveal that motor vehicle–related collisions account for 39.2% of all SCI, followed in frequency by falls, and intentional acts of violence, such as gun shot wounds (2). At its peak, violence caused 24.8% of SCI between 1990 and 1999, but since 2005, it accounts for only 14.6% of SCI. Sports-related injuries have also decreased over time.

The human spine consists of 33 bony vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal. In the adult, the spinal cord ends at the level of the L1 vertebrae and then continues as the cauda equina. Due to its highly exposed location above the torso and its inherent flexibility, the cervical spine is the most commonly injured part of the spinal column (see Chapter 28). In contrast, the

thoracic spine is rigidly fixed. The thoracic ribs articulate with the respective transverse processes and sternum, and a great amount of force is necessary to damage the thoracic spine. The middle of the thoracic spine is a vascular watershed area; thus, a vascular insult may lead to spinal cord ischemia. The second most commonly injured spine region is the thoracolumbar junction. The transition zone from thoracic to lumbar vertebrae is vulnerable to injury because of the juxtaposition of a rigidly fixed thoracic spine against a flexible lumbar spine. The spinal column also changes from a kyphotic curve to a lordotic curve at this level, and of all TLS injuries, 90% of the fractures occur in the region between T11 and L4. Allowing for more flexion and extension, the thoracolumbar junction facet joints are oriented differently when compared to other vertebral levels, and this is thought to concentrate greater forces at this level. Since the spinal canal is relatively wide at this level, however, thoracolumbar junction injuries rarely result in complete cord lesions and more commonly result in incomplete cord lesions (3).

CLINICAL PRESENTATION

Classification

White and Panjabi first described the concept of spinal instability, which they defined as the inability of the spine to maintain the anatomical relationships between vertebrae necessary to prevent neurologic injury or compromise (4). Since then, numerous classification schemes for TLS injuries have been reported. Utilizing results from a retrospective review of over 400 TLS injuries, Denis delineated a means to assess stability of vertebral fractures in which he divided the spinal column into three columns: anterior, middle, and posterior. The anterior column includes the anterior longitudinal ligament, the annulus fibrosus, and the anterior half of the vertebral body; the middle column comprises the posterior longitudinal ligament, the posterior annulus fibrous, and the posterior half of the vertebral body; whereas the posterior column includes the supraspinous and interspinous ligaments, as well as the facet joint

capsule (Fig. 29.1) (4). According to this scheme, the stability of the spine is based upon the integrity of two of the three spinal columns, although Denis stipulated that the stability of the middle column determined the integrity of the spine. Denis used his three-column theory to distinguish major and minor TLS fractures. Spinal instability can also be inferred from plain radiographs as a loss of 50% vertebral height or an angulation at the thoracolumbar junction of greater than 20 degrees (5). The spine is also considered to be unstable in the presence of a neurologic deficit, since the spinal column has failed to protect the cord. In general, a stable fracture pattern in a neurologically intact patient may be treated nonoperatively.

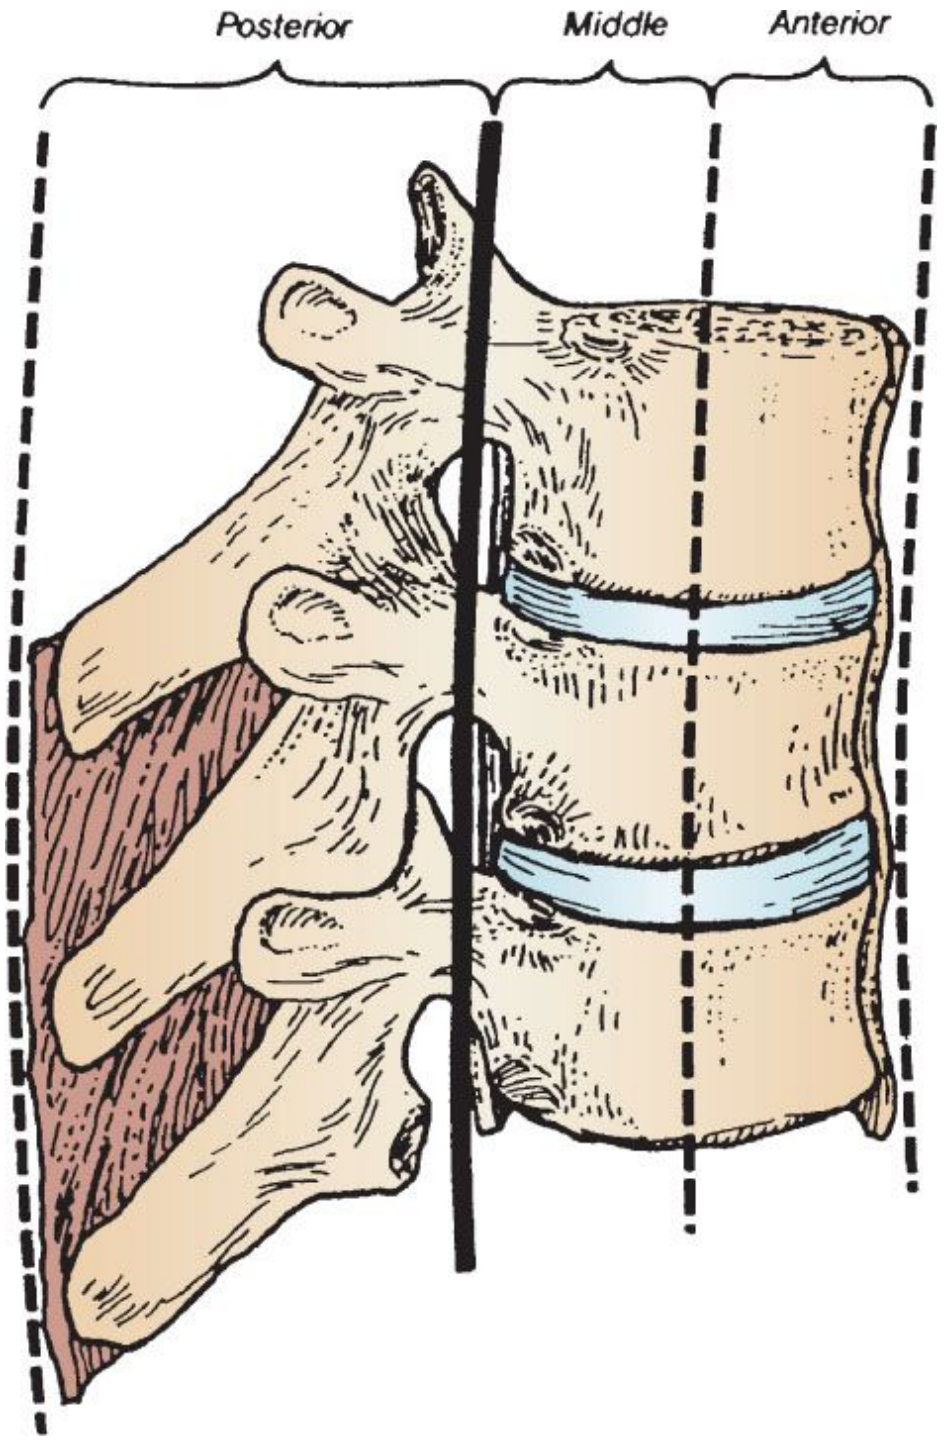

FIGURE 29.1 The three-column concept used to classify thoracic and lumbar spine fractures. (From Galli RL, Spaite DW, Simon RR. Fractures, dislocations, and major ligamentous injuries. In: Galli RL, Spaite DW, Simon RR, eds. *Emergency Orthopedics: The Spine.* Norwalk. Appleton and Lange; 1989, with permission.)

McAfee subsequently classified TLS injuries into five different patterns: wedge compression fractures, chance fractures, stable and unstable burst fractures, flexion–distraction injuries, and translational injuries. All of these fractures result from one or more of the three mechanisms of injury: axial compression, axial distraction, and translation (6). McAfee distinguished stable and unstable burst fractures based upon the integrity of the posterior ligament complex (6). A combination of Dennis' division of major and minor fracture patterns and McAfee's fracture–dislocation scheme is currently widely accepted and utilized (Table 29.1).

TABLE 29.1
Thoracolumbar Spine Injury Classification

Acute TLS Injury	
Major fracture/dislocation	Minor fracture
Wedge compression fracture: Isolated anterior column fracture	Transverse process fracture
Chance fractures: Horizontal vertebral avulsion injury with center of rotation anterior to vertebral body	Spinous process fracture
Stable burst fractures: anterior and middle column compression failure with posterior column intact	Pars interarticularis fracture
Unstable burst fractures: Compressive failure of anterior and middle columns with disruption of the posterior column	
Flexion–distraction injuries: Compressive failure of anterior column with tensile failure of the posterior column	
Translational injuries: Disruption of the spinal canal in the transverse plane, usually due to a shear mechanism	

More recently, the Spine Trauma Study Group collaborated to create the Thoracolumbar Injury Classification and Severity Score (TLICS), which identifies three major injury characteristics to describe TLS injuries: injury morphology, posterior ligamentous complex integrity, and neurologic status (Table 29.2) (7). The injury morphology is categorized as one of the following four injury

patterns: compression, burst, translational/rotational, or a distraction pattern (these are detailed further later in the chapter). The integrity of the posterior ligament complex, which consists of the supraspinous ligament, interspinous ligament, and facet joint capsules, can be assessed from plain radiographs, CT scans, and MRI. The neurologic status is graded in increasing order of severity as: neurologically intact, nerve root injury, complete SCI and incomplete SCI or cauda equina. Each characteristic is assigned a score and then summed to yield the TLICS. A score ≥ 5 suggests the need for operative treatment due to significant instability, whereas a score ≥ 3 suggests nonoperative treatment. A score of 4 may be treated either operatively or nonoperatively. The TLICS has yielded $>90\%$ agreement in the management of thoracolumbar trauma (8,9).

TABLE 29.2
Thoracolumbar Injury Classification and Severity Score Scale

Category	Points

Incomplete	3
Complete	2
Cauda equina	3
Posterior Ligamentous Complex	
Intact	0
Injury suspected/indeterminate	2
Injured	3

Wedge Compression Fractures

Wedge compression fractures account for 50% to 70% of all TLS fractures and usually result from compressive failure of the anterior column after an axial load is applied in flexion. Simple wedge fractures are defined as demonstrating less than 10% compression, and there is generally no neurologic impairment since the middle column remains intact. Simple wedge fractures are stable, since pure flexion injuries do not disrupt the posterior ligament complex, and an additional rotational force is necessary to cause an unstable fracture pattern. However, if there is severe compression (>50%), kyphosis greater than 20 degrees, multilevel compression fractures, or a rotational component to the injury, then the posterior ligamentous complex may fail and progress to involve the middle column, resulting in spinal instability (6).

Wedge compression fractures generally result from falls, motor vehicle collisions, and occasionally generalized tonic–clonic seizures. Bilateral calcaneal fractures should alert the emergency physician to the possibility of a TLS fracture due to axial compression from a vertical plunge (4). Associated injuries are common, and fractures frequently coexist at other spinal levels. It is important to image patients older than 75 who complain of back pain, even after apparently minor injury, since 25% of this age group sustains osteoporotic compression fractures. In conscious patients who have no major distracting injury, there is invariably pain or tenderness at the site. While neurologic deficits are rare, wedge compression fractures are associated with a high incidence of intestinal ileus (3).

Best seen on lateral radiographs, simple wedge compression fractures demonstrate anterior compression of the vertebral body without any disruption of the posterior cortex (Fig. 29.2). The AP radiograph may demonstrate a subtle increase in the interspinous distance if there is a kyphotic deformity. Of note is that there is no vertebral subluxation, and thus, acute neurologic injury almost never occurs with a simple, single wedge compression fracture. It is important to ascertain that the posterior elements remain intact, since the integrity of the posterior cortex is the key feature that distinguishes the wedge compression fracture from an unstable burst fracture. However, standard radiographs may not be adequate to

evaluate the integrity of the posterior vertebral cortex. In an analysis of 67 thoracolumbar radiographs reviewed by two radiologists and two orthopedists, 20% of the CT-confirmed burst fractures were initially misdiagnosed as wedge fractures (10). Thus, CT scan should be considered when plain radiographs demonstrate what appears to be a wedge compression fracture with any possible involvement of the posterior cortex, since plain radiographs are not accurate in determining involvement of the posterior wall of the vertebral body. Once an injury is identified, CT is better at delineating the bony structures and helps to demonstrate the integrity of the middle column, the degree of canal compromise, as well as subluxations and fractures of facets and lamina.

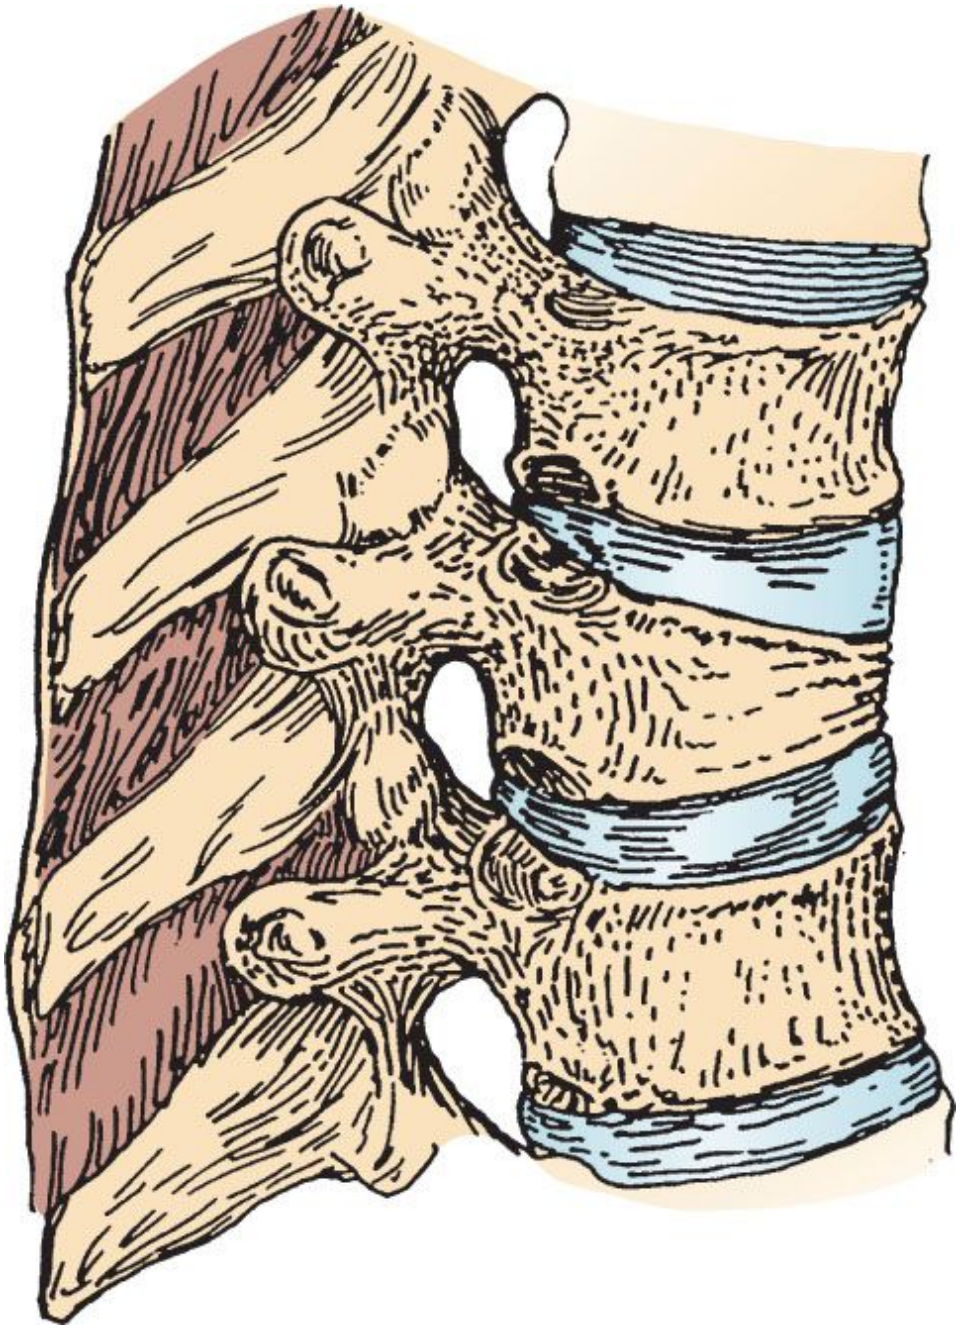

FIGURE 29.2 An anterior wedge fracture due to flexion in the thoracic region (ribs removed for visualization). (From Fractures, dislocations, and major ligamentous injuries. In: Galli RL, Spaite DW, Simon RR, eds. *Emergency Orthopaedics the Spine.* Appleton and Lange; 1989, with permission.)

Chance Fractures

Chance fractures account for only 5% of all TLS fractures and result primarily from a mechanism of distraction although there may be a minor component of flexion. The axis of flexion is anterior to the nucleus pulposus and the anterior longitudinal ligament. If the distraction forces are great enough, both the middle and posterior columns may be disrupted.

Chance fractures are usually seen in victims of automobile or airplane accidents who are wearing lap seat belts (3). Examination may reveal ecchymosis of the lower abdomen and tenderness at the fracture site, but the absence of these signs does not preclude the diagnosis. Although neurologic deficits occur in less than 5%, Chance fractures are commonly associated with intra-abdominal injuries, such as intestinal perforations, hematomas, and contusions.

Chance fractures are best seen on a lateral radiograph, which demonstrates a horizontal disruption through the spinous process, laminae, transverse process, pedicles, and the vertebral body (4). The height of the vertebral body is increased, and the distance between the spinous processes above and below the injury may appear to be widened (Fig. 29.3). The AP view may demonstrate an increased interspinous distance and a schism in the transverse processes. Routine axial CT scans of the spine frequently miss these fractures, since the image cuts are parallel to the level of the injury. Thus, sagittal reconstruction of CT images is recommended if a Chance fracture is suspected (4).

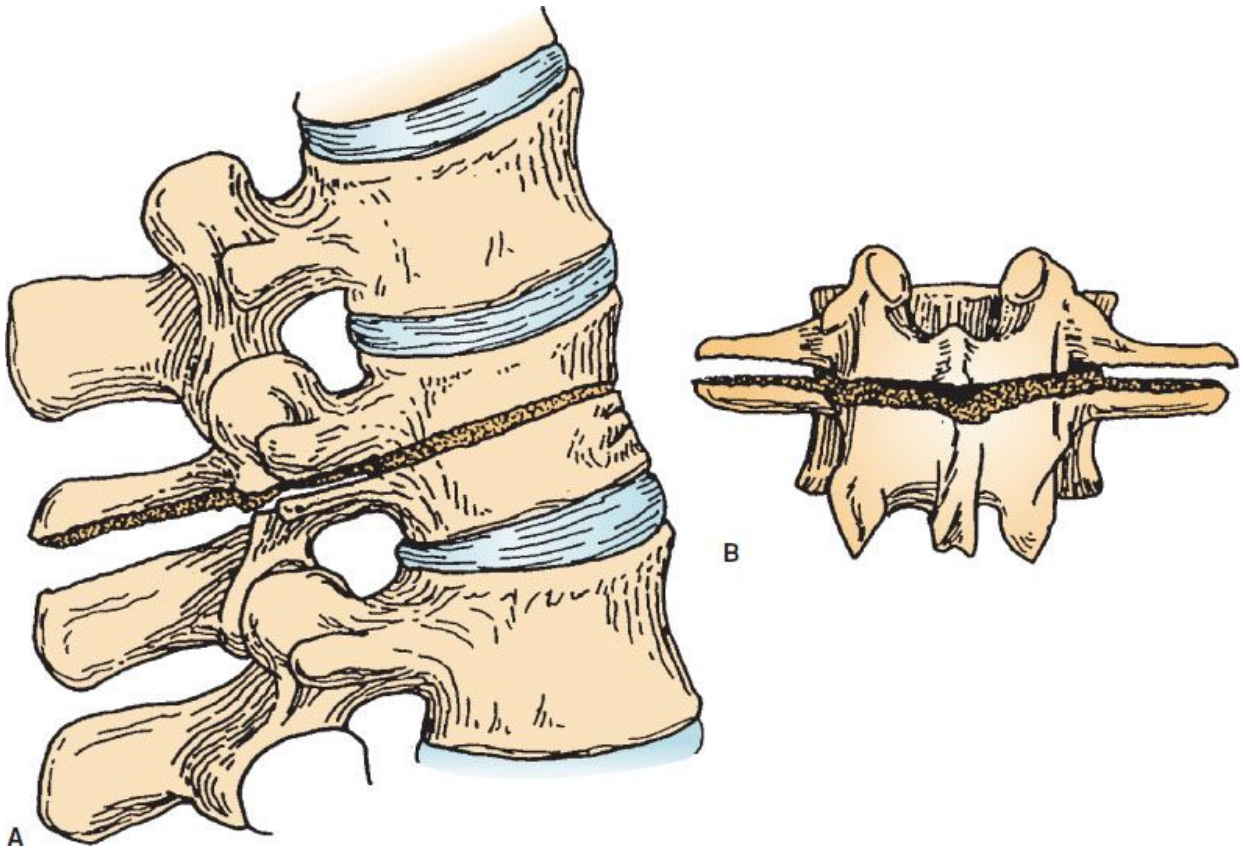

FIGURE 29.3 A "Chance" fracture created by a distraction mechanism. **A:** Lateral view. **B:** Posterior view. (From Fractures, dislocations, and major ligamentous injuries. In: Galli RL, Spaite DW, Simon RR, eds. *Emergency Orthopaedics the Spine.* Appleton and Lange; 1989, with permission.)

Burst Fractures

Burst fractures comprise 14% of all TLS injuries and result from a compressive force causing a fracture of the endplate, pressure of the nucleus pulposus on the vertebral body, and bone fragments being retropulsed into the spinal canal. Burst injuries with and without posterior element injuries occur in equal proportions, and those with posterior element involvement are at higher risk for neurologic deficits (11).

Burst fractures are most commonly associated with falls and motor vehicle accidents. All burst fractures should be considered unstable, since standard radiography misses a significant number of posterior

element fractures, and neurologic deficits are seen in 42% to 58% of these patients (11).

On lateral radiographs, a burst fracture demonstrates a loss of anterior and posterior vertebral height, and there may be a distorted posterior longitudinal ligament line (Fig. 29.4). Anteroposteriorly, there may be widening of the interpedicular distance (greater than 1 mm difference between the vertebrae above and below). Since retropulsed bone fragments often occur at the level of the pedicles, burst fractures may be difficult to visualize by plain radiography. Unstable burst fractures are, therefore, often misdiagnosed as stable anterior wedge fractures. Campbell et al. (12) demonstrated that of 53 thoracolumbar radiographs reviewed by 6 experienced radiologists, only 30 of 39 (83%) burst fractures were correctly identified. Thus, CT imaging is recommended if a burst fracture is suspected.

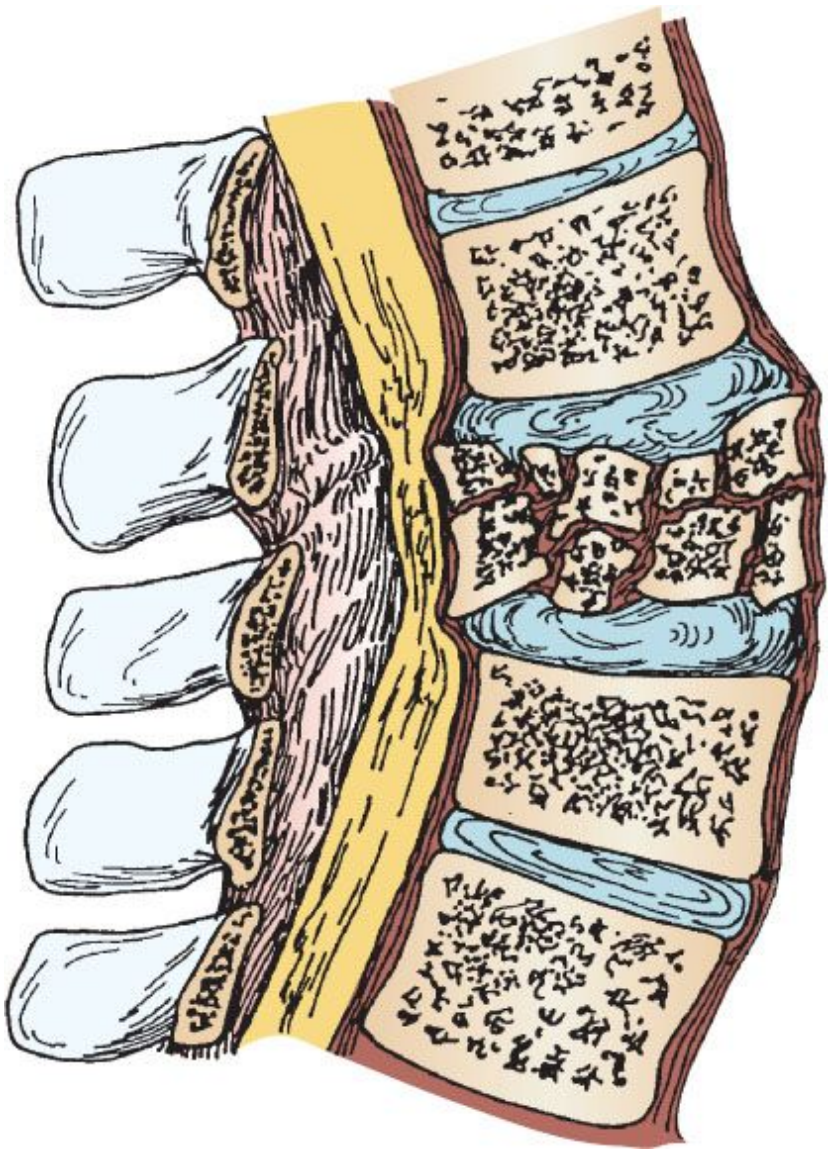

FIGURE 29.4 Burst fracture without posterior element disruption. Note retropulsion of bone fragments posteriorly into the spinal canal with cord injury. (From Fractures, dislocations, and major ligamentous injuries. In: Galli RL, Spaite DW, Simon RR, eds. *Emergency Orthopaedics: The Spine.* Appleton and Lange; 1989, with permission.)

Flexion–Distraction Injuries

Flexion–distraction injuries account for 10% of all TLS injuries. The forceful flexion component of the injury causes compressive failure of the anterior and middle columns and a tear in the posterior

longitudinal ligament. Since both middle and posterior columns are disrupted, this fracture pattern is unstable. Pure ligamentous disruptions also occur and account for 10% to 25% of flexion–distraction injuries (3).

Flexion–distraction injuries most frequently result from lap belt injuries in major motor vehicle collisions and airplane accidents, and thus, this injury is more commonly referred to as a seatbelt injury. While neurologic deficits are rare, associated intra-abdominal injuries, such as small and large intestinal perforations, are common.

Radiographic findings include anterior impaction with compression fractures of the vertebral body and increased posterior interspinous spaces caused by distraction. The hallmark finding is an increased length of the vertebral segment as a result of a distractive force. Because there is no significant rotational or translational component, displacement is unusual. As with Chance fractures, flexion–distraction injuries are frequently missed on routine axial CT scans since the disruption is oriented in the horizontal plane. Thus, it is important to obtain sagittal reconstructions of CT images if a flexion–distraction injury is suspected (4).

Translational Injuries

Translational injuries result in failure of all three columns from massive direct trauma to the back. This mechanism results in several injury patterns including the “slice” fracture, rotational fracture–dislocations, shear injuries, and pure dislocations.

The classic mechanism that creates flexion–rotation forces on the TLS, often resulting in a “slice” fracture, is a fall ending in the “tuck and roll” landing. The majority of these injuries occur at the level of the thoracolumbar junction (T-10 to L-2), and examination usually reveals tenderness at the fracture site. There may be significant kyphosis and a widening of the spinous processes at the level of the dislocation (4). Those with shear fractures in the lumbar region may present with large contusions in the lumbosacral area due to direct trauma. Patients with a complete vertebral dislocation usually have sustained massive trauma, and their examination will invariably demonstrate neurologic deficits.

Among patients who are rendered paraplegic from TLS trauma, the majority have sustained a fracture–dislocation injury. In fact, 60% to 80% of these injuries result in permanent neurologic deficits, and most patients also sustain serious trauma to other organ systems (3). Shear fractures and pure dislocations also result in severe neurologic sequelae, with complete paraplegia occurring in nearly all patients.

With plain radiographs, the classic "slice" fracture is best seen on the lateral view and appears as the superior segment being anteriorly subluxed on the inferior segment with a slice through the upper portion of the vertebral body below it. The spinous processes will appear widened due to posterior ligament rupture. If there is also a rotational component, the alignment of the spinous processes will be distorted (4). Pure dislocations are generally not subtle and appear as a complete displacement of the superior vertebrae on the one below it. CT scan is very helpful in evaluating these injuries, since it demonstrates and objectively quantifies the extent of spinal canal compromise and cord impingement.

Minor Spinal Fracture Patterns

Minor spinal fracture patterns account for 14% of all TLS injuries and include isolated transverse process fractures, spinous process fractures, facet or laminar fractures, bipedicular fractures, and fractures of the pars interarticularis.

Most minor spinal fractures occur in the lumbar region and are usually caused by direct blows, but sudden contraction of the psoas muscles may also result in avulsion of the transverse processes. While transverse process fractures are considered to be stable, it is important to realize that in high-velocity trauma, transverse process fractures frequently do not occur in isolation. In one retrospective analysis of 28 patients who initially appeared to have isolated transverse process fractures by plain radiographs, three patients were subsequently found to have compression and burst fractures by CT scan (13). In addition, high thoracic fractures may be associated with injury to the brachial plexus, and lumbar and sacral fractures may result in injury to the lumbosacral plexus. To ensure the appropriate

diagnosis and management of SCI, CT should be considered when transverse process fractures are seen on plain radiographs.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis in any patient who presents with back pain after trauma includes vertebral fractures, SCI, epidural hematoma, paraspinous hematoma, “lumbar strains” and “sprains,” spinal cord injury without radiographic abnormality (SCIWORA), major aortic disruptions (intimal tear or rupture of a preexisting aneurysm), retroperitoneal hematoma, intra-abdominal injury, and simple contusions. However, in patients on corticosteroids, those with metastatic cancer to the spine, or in the elderly who are at risk for compression fractures related to osteoporosis, the absence of a history of trauma should not dissuade the physician from considering a diagnosis of a TLS fracture. In addition, the most difficult diagnostic task for the emergency physician may be to correctly classify each of the fracture patterns and to assess spinal stability.

ED EVALUATION

TLS injuries should be suspected in victims of motor vehicle collisions, falls, and sport-related injuries who complain of mid to lower back pain, and in all trauma victims with a suggestive mechanism of injury who cannot be clinically assessed because of an altered mental status or other associated painful injuries (3). To assess for TLS injury, the back should be visually inspected for contusions, lacerations, and abrasions. The spine should then be palpated for evidence of deformity, tenderness, and muscle spasm. Palpation of the spine may reveal an interspinous gap, which may indicate posterior ligamentous disruption. The back should also be visually inspected for contusions, lacerations, abrasions, and open wounds over the spine. Next, the neurologic status of the patient should be determined and any associated neurologic findings and potential cord syndromes carefully documented. The neurologic examination should include a quantitative evaluation of motor function, and sensory testing must include an evaluation of the sacral dermatomes and an examination of anal sphincter tone. Dorsal and

ventral cord function should also be assessed, and serial examinations should be performed whenever deficits are found to identify patients exhibiting progressive neurologic dysfunction.

Although there has been much work done with regard to the clinical clearance of the cervical spine, there has been relatively little research into establishing guidelines for diagnosing and imaging TLS fractures. Stanislas et al. (14) have demonstrated that thoracic and lumbar spine fractures are missed in patients who sustain a high-velocity injury, have a decreased Glasgow Coma Scale (GCS) on admission, have an associated head injury, and have a pelvic or lower extremity injury. The presence of one vertebral fracture mandates radiographic evaluation of the entire spine, since there is a 5% to 15% risk of a second noncontiguous fracture (15). In the latest edition (ninth) of the Advanced Trauma Life Support (ATLS) manual, the authors state, “the indications for screening radiography of the TLS are the same as those for the cervical spine,” without stating explicitly which criteria. However, where available, CT scanning of the thoracic and lumbar spine can be used as the initial screening modality. AP and lateral plain radiographs with thin-cut axial CT scans through suspicious areas can detect more than 99% of unstable injuries (16).

A summary of the current literature reveals that TLS imaging is indicated for those who have sustained a high energy mechanism of injury (a fall greater than 10 ft (3.048 m), high-speed motor vehicle collisions, etc.) PLUS any of the following: (1) back pain or midline back tenderness; (2) abnormal neurologic signs; (3) any other spine fracture; (4) GCS <15; (5) major distracting injury; or (6) alcohol or drug intoxication (4,11,16,17). One case-control study demonstrated that in addition to cervical and lumbar spine injuries, the presence of rib fractures was found to also be positively associated with thoracic spine fractures (18).

Due to its less-accurate test characteristics, plain films are being used less frequently and the role of plain films may be limited to patients with minor trauma. In fact, there is now literature to support utilizing CT as the initial and only mode of imaging, rather than plain radiography in the severely injured blunt trauma patient

(19), as defined by a high-energy mechanism of injury (a fall greater than 10 ft, high-speed motor vehicle collision, auto vs. pedestrian, motorcycle collision, etc.). The advantages of CT over plain radiography include superior fracture-detection rates, spinal canal evaluation, paravertebral soft tissue assessment, and reduced manipulation of the patient. The sensitivity and specificity of CT for thoracolumbar spine fracture is excellent at 100% and 97%, respectively, whereas plain radiographs are 73% sensitive and 100% specific (1). In a retrospective observational study, Antevil et al. compared the diagnostic sensitivity, time required for radiographic imaging, costs, charges, and radiation exposure. CT was found to be obtained at a similar cost to plain radiographs, was more rapid, sensitive, and involved lower levels of radiation exposure (20). As noted above in the section on wedge compression and burst fractures, CT scan is recommended for all patients in whom spinal instability is in question, as plain radiographs do not adequately evaluate the posterior vertebral body cortex. If plain radiographs are obtained, unclear fractures or displacements on standard radiographs should be further evaluated by a CT scan. In addition, it has recently been noted that if a CT of the chest, abdomen, and pelvis has been ordered, there is no need to order reconstructions or a dedicated CT of the spine unless an abnormality is found on the nonreconstructed CT scan that warrants further elucidation (21).

Magnetic resonance imaging (MRI), with its superior resolution and definition of the spinal canal, multiplanar capabilities, and lack of ionizing radiation, has become the optimal imaging modality in the general evaluation of spinal disease. The primary advantage of MRI is its ability to directly image nonosseous structures, including ligamentous injuries, and intramedullary and extramedullary spinal abnormalities. However, plain films and CT are superior to MRI in evaluating osseous anatomy and fractures, particularly posterior-element fractures. MRI is also not universally available, and there are numerous contraindications to its use, such as the presence of a pacemaker, cerebral aneurysm clips, and metallic foreign bodies. Although there are no clear evidence-based indications for MRI after spinal injury, MRI should be considered in patients with neurologic

signs and symptoms and those with intractable pain that cannot be accounted for by osseous disruption on plain radiographs and CT (22).

KEY TESTING

- Perform a careful history and physical examination, including a thorough skin, musculoskeletal, and neurologic examination.
- Perform radiographic imaging of TLS in patients who have sustained a high mechanism of injury, PLUS any of the following: (1) midline spine tenderness; (2) neurologic deficits; (3) any other spine fracture; (4) GCS <15; (5) distracting injury; or (6) intoxication.
- Obtain a CT in cases where plain radiographs demonstrate and abnormality, or are inadequate.
- Rather than plain films, CT should be considered as the primary imaging modality, given its superior sensitivity and specificity for the detection of fractures especially in high-mechanism trauma.
- Obtain MRI if there are concerns about ligamentous injuries or intramedullary and extramedullary spinal abnormalities.

ED MANAGEMENT

The patient who has sustained TLS trauma has typically been subjected to high-energy forces, and initial resuscitation efforts should focus on the evaluation and treatment of life-threatening injuries. Stabilization of the patient's airway and hemodynamic status should precede any treatment to secure adequate oxygenation and tissue perfusion. A Foley catheter should be inserted, since patients with vertebral fractures commonly develop urinary retention. However, it is important to assure that resuscitative maneuvers do not compromise neurologic function. Patients should remain immobilized on a spine board with a rigid cervical collar until neurologic and radiographic evaluation can be performed.

Hypotension in a trauma victim may be due to SCI causing neurogenic hypotension, but this should be a diagnosis of exclusion. Other causes of hypotension, such as hemorrhagic shock, cardiac

tamponade, and tension pneumothorax must first be excluded. Neurogenic hypotension results in vasodilation and bradycardia, and mild cases (generally seen with TLS injuries) most often respond to fluid resuscitation, but occasionally require vasopressor support.

When treating a thoracolumbar spine fracture, the primary goals are to protect the spinal cord and prevent deformity and instability, and surgical management can often facilitate rehabilitation and decrease hospital length of stay. Neurosurgical consultation, if available, should be obtained promptly when neurologic deficits are present or when spinal instability is suspected. TLS fractures are rarely treated as an operative emergency, however, unless there is evidence of progressive neurologic dysfunction, or in the presence of a significant epidural hematoma with cord or cauda equina compression. In addition to instability, other indications for surgery include neurologic deficit, as well as kyphosis greater than 25 degrees. A TLICS score ≥ 5 also is an indication for operative intervention, and would also, therefore, warrant a neurosurgical consultation (8,9).

Pharmacologic agents, such as glucocorticoids, naloxone, thyrotropin-releasing hormone, insulin-like growth factor, dimethyl sulfoxide, calcium channel blockers, tirilazad mesylate, and GM-1 gangliosides have been found to improve neurologic outcome in experimentally induced SCI (23). Of these, only methylprednisolone was previously routinely used, and it is the only therapy shown to have efficacy in a randomized controlled trial (23). Although the National Acute Spinal Cord Injury Study (NASCIS) Group has published several studies showing that the administration of high-dose methylprednisolone improves neurologic outcome after blunt SCI, if it is administered within 8 hours, other studies have reported worse outcomes and higher rates of respiratory and gastrointestinal complications (24). In fact, the current ninth edition of ATLS (16) states, “at present, there is insufficient evidence to support the routine use of steroids in spinal cord injury.” Thus, in general, steroids cannot be recommended for routine use. Still, there is a great deal of practice variation among emergency physicians and

neurosurgeons, and this is indicative of the continuing controversy (25).

Intestinal ileus is common following TLS injury, and a nasogastric tube may be required to prevent gastric dilation. Urinary bladder atony, due to autonomic dysfunction, is also common. Thus, placement of a Foley catheter will help prevent bladder distension and monitor fluid balance. Since gastrointestinal bleeding from stress ulcers occurs in up to 20% of spinal trauma patients, ulcer prophylaxis is indicated. Denervated skin is especially susceptible to pressure necrosis, so the spinal immobilization backboard should be removed, or pressure points padded, as soon as possible. Frequent patient repositioning should be instituted if the patient is insensate and immobilized. Prophylaxis against deep venous thrombosis should also be provided.

CRITICAL INTERVENTIONS

- Provide spinal immobilization until an unstable fracture is excluded.
- Perform a thorough baseline neurologic examination followed by serial examinations.
- Order and interpret appropriate radiographs, CT scans, and MRI scans.
- Obtain prompt neurosurgical consultation if there is evidence of spinal instability (e.g., TLICS ≥ 5) or neurologic deficits.
- Provide adequate analgesia.
- Institute nasogastric suction if an ileus is present.
- Order Foley catheter drainage to help with fluid management.

DISPOSITION

Patient disposition depends primarily upon fracture stability. If a TLS fracture is deemed unstable, neurosurgical consultation is mandatory, and if not available onsite, immediate transfer must be arranged to a center that can provide these services. Patients with these fractures have commonly sustained multisystem trauma, and the extent of these other life-threatening injuries often determine

whether they need to be admitted to an intensive care unit or a monitored setting.

If plain radiographs demonstrate minor spinal fracture patterns and there is no neurologic deficit or associated ileus, then outpatient management may be possible. Treatment should include analgesics, and follow-up care should be arranged in all instances because even minor spinal fractures may be associated with prolonged disability. If there is any ambiguity regarding the extent of osseous injury or spinal stability on plain radiographs, a CT scan or MRI should be obtained to evaluate the extent of injury and need for neurosurgical consultation.

Common Pitfalls

- Failure to suspect thoracolumbar spine fractures in a multitrauma patient due to inability to evaluate neurologic deficits or back tenderness.
- Failure to appreciate the high false-negative rate of plain radiographs in diagnosing unstable burst fractures, along with failure to obtain a CT scan in questionable cases.
- Failure to obtain a complete spinal radiograph when a fracture at one spinal level is demonstrated.

CHAPTER 30

Spinal Cord Injuries

Brian D. Mahoney

The clinical spectrum of spinal cord injury varies from the awake patient complaining of pain, paresthesias, numbness, weakness, or paralysis to the unconscious patient (usually due to associated head injury) unable to give any clues about the severity of his or her injuries. In the United States, most spinal cord injuries are due to motor vehicle collisions (37%), followed by falls (29%), violence (14%), sports and recreational activities (9%), and other causes (11%) (10). Males comprise 81% of these patients with an average age of injury of 43 (10). In the United States, the annual incidence of spinal cord injuries is approximately 40 per million population (10). Many patients with spinal cord injury die soon after their injury because of either high cord injury or other associated traumatic injuries. Life expectancy is significantly below that of patients without spinal cord injury (10). Of those who survive their initial injury and hospitalization, illnesses with the greatest impact on life expectancy are pneumonia and sepsis (10). Direct lifetime expenses for a 25-year-old patient at the age of injury with high quadriplegia exceeds $4.5 million (10).

Normally, the spinal column ensures stability and protects the cord, the spinal roots, and the cauda equina from injury. Panjabi and White (11) defined spinal stability as “the ability of the spine, under physiologic loads, to maintain the relationships between vertebrae such as there is neither damage nor irritation to the spinal cord or roots, nor incapacitating deformity nor pain due to structural changes.” Injury can render the usually protective spinal column a threat to the cord and its roots. The cord can suffer injury through

compression, crush, laceration, penetration, stretch, inflammation, infection, hypoxia, or ischemia. In unusual circumstances, the spinal column can be rendered unstable by infectious or inflammatory causes, such as atlantoaxial dislocation in patients with rheumatoid arthritis or inflammation associated with pharyngeal infections.

The most mobile segments of the spinal column (C4, C5, C6, L1, L2) place the adjacent segments of the spinal cord at higher risk for injury. Spinal cord injury at discharge is as follows (10): incomplete quadriplegia 41%, incomplete paraplegia 19%, complete paraplegia 18%, complete quadriplegia 12%, complete neurologic recovery less than 1%.

The ribs buttress the thoracic spinal column, providing a relatively safe environment for the cord. However, when there is thoracic bony displacement or soft tissue swelling, the cord injury is usually devastating. The spinal canal is relatively narrow here, and the thoracic cord is an area of watershed circulation. At L2, the spinal cord ends and the spinal canal is filled with the cauda equina—a collection of spinal nerves passing from the cord to their respective lumbar and sacral foramina. Though certainly at risk for acute cauda equina syndrome, these peripheral nerves are relatively resistant to injury compared to the spinal cord.

CLINICAL PRESENTATION

The patient may describe pain or tenderness at the level of injury and weakness, numbness, or paresthesias distal to the injury level. Paresthesias at the time of injury are a sign that the cord or roots have been compressed. Late paresthesias may be a sign of instability of the spinal column and should lead to a comprehensive search for instability. History and physical examination establish motor (eFig. 30.1), reflex, or sensory deficits (eFig. 30.2 and eFig. 30.3), as well as fecal incontinence or urinary retention. Urinary retention may present as oliguria with overflow stress incontinence. Careful mapping of the level of sensory loss (including attention to areas around the anus for lower segmental reflexes and for sacral sparing) identifies the level of cord injury and the level at which radiologic studies should be focused (Fig. 30.1).

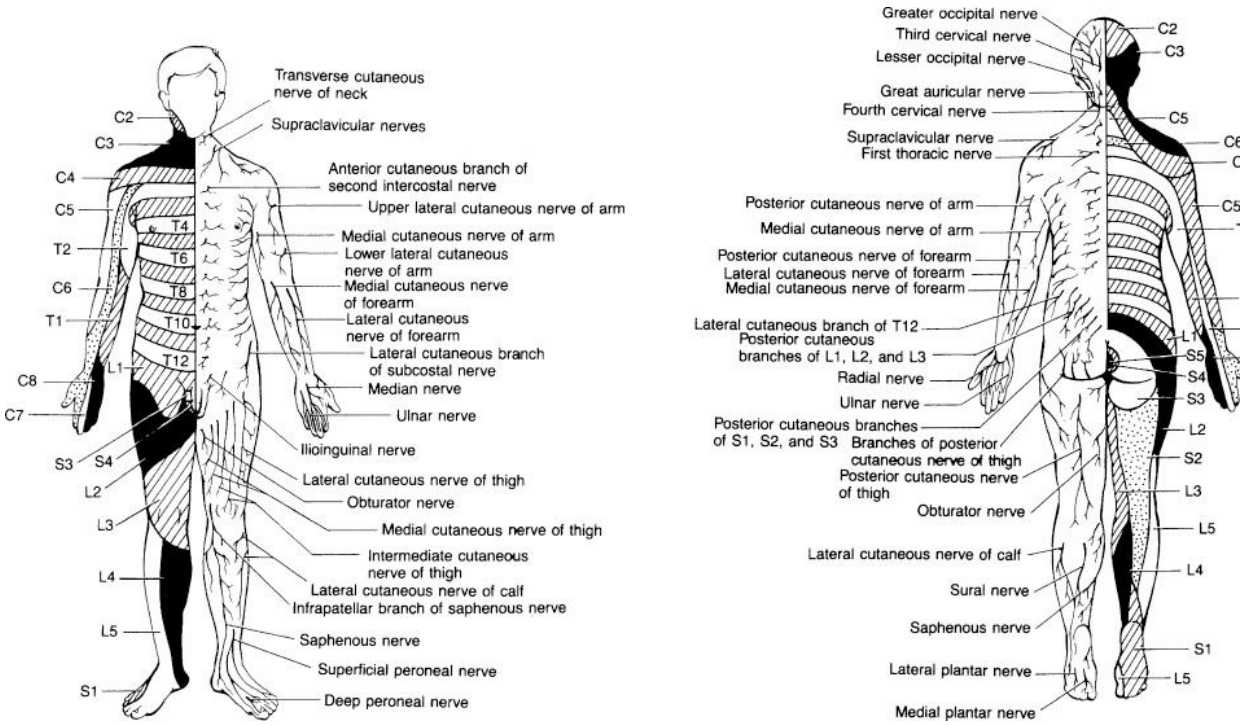

FIGURE 30.1 Sensory dermatomal segments: anterior view **(left)** and posterior view **(right)**. IDAMS Asset Name: 4766.101.001.tif Credits. (From Harwood-Nuss A, Wolfson, AB, Linden CH. *The Clinical Practice of Emergency Medicine.* 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

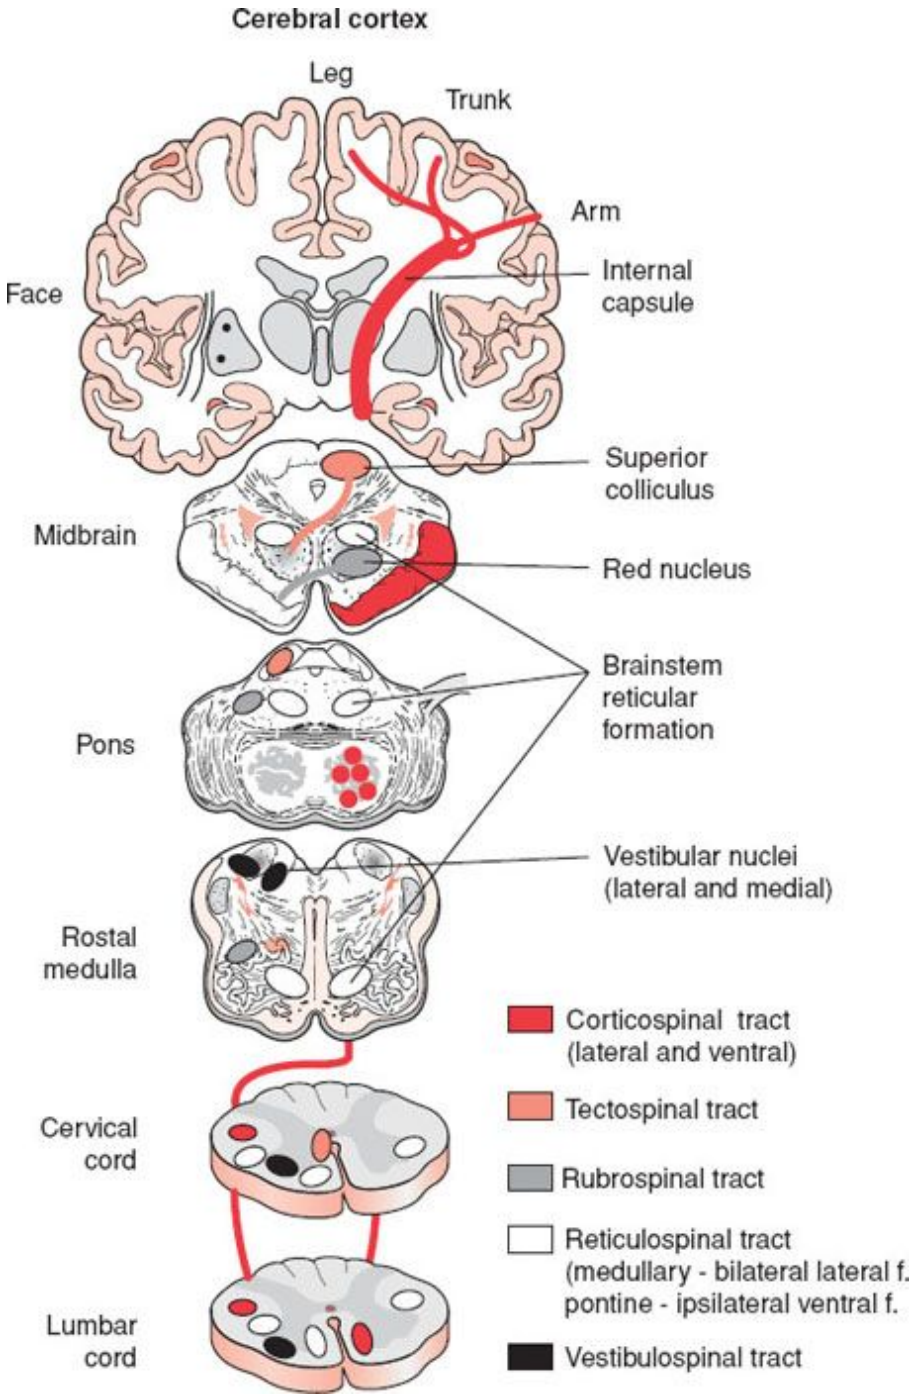
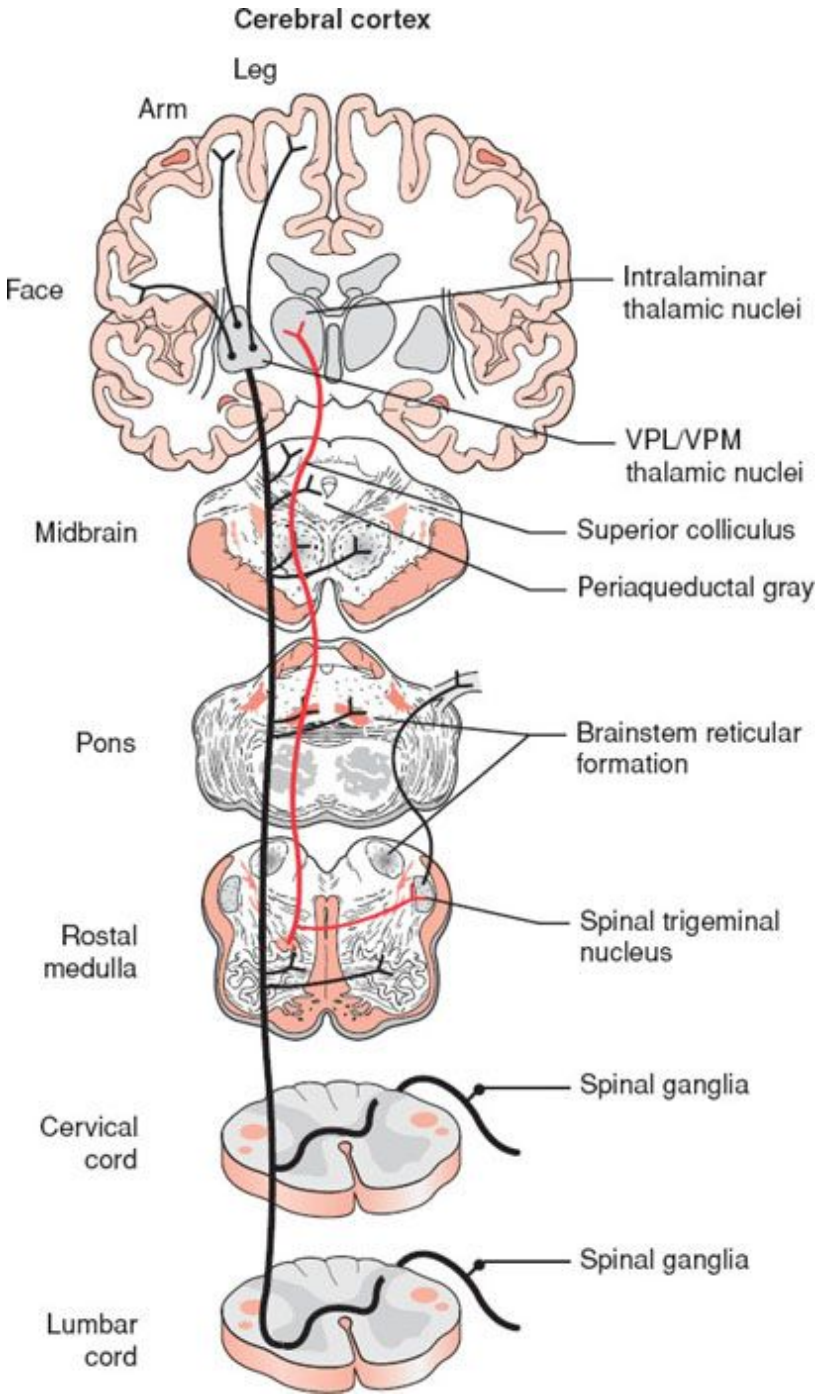
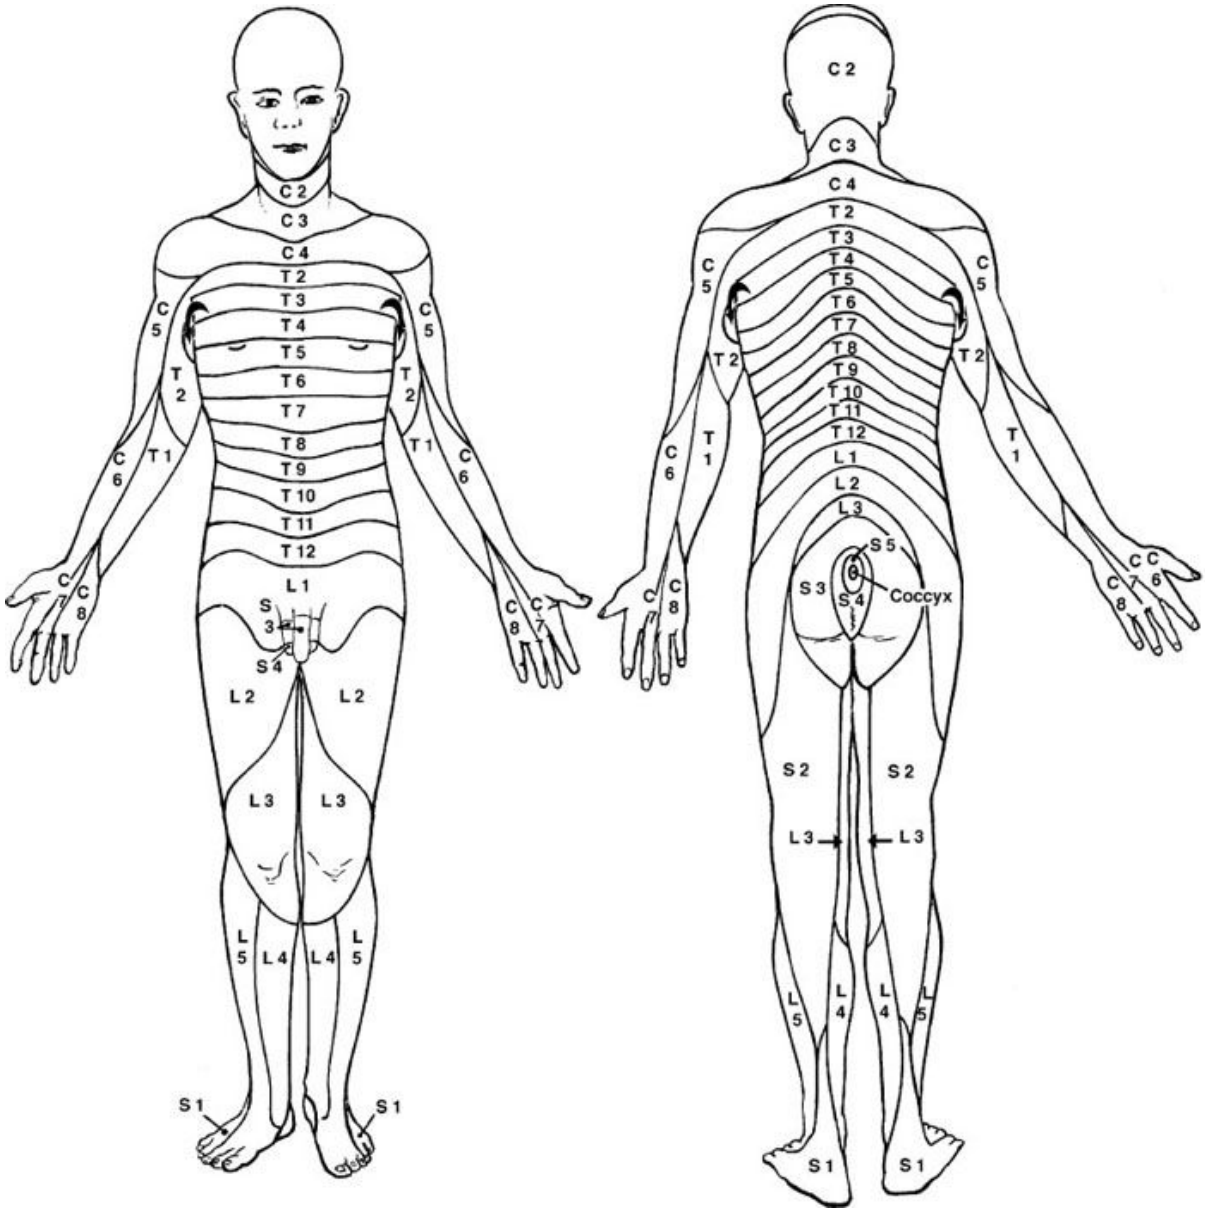


eFIGURE 30.1 A diagrammatic representation of the main descending motor pathways connecting the brain to the spinal cord for one side of the body. Approximately 90% of the corticospinal axons cross at the spinomedullary junction and comprise the lateral corticospinal tract. The remaining 10% form the ipsilateral ventral corticospinal tract. Axons from cells in the contralateral superior colliculus pass through the brainstem and enter cervical levels of the

spinal cord in the tectospinal tract. The red nucleus sends axons to the contralateral spinal cord in the rubrospinal tract. Neurons from many levels and both sides of the reticular formation form the reticulospinal tract. The medial and lateral vestibular nuclei send axons to the spinal cord in the vestibulospinal tract. This is mainly and ipsilaterally projecting pathway. (From Schwartz ED, Flander AE. *Spinal Trauma: Imaging, Diagnosis, and Management.* Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)



eFIGURE 30.2 The transmission of pain from the body to the brain occurs in the spinothalamic tract. Axons of the anterolateral system terminate in the several regions including the reticular formation throughout the brainstem, superior colliculus, periaqueductal gray, and several thalamic nuclei.

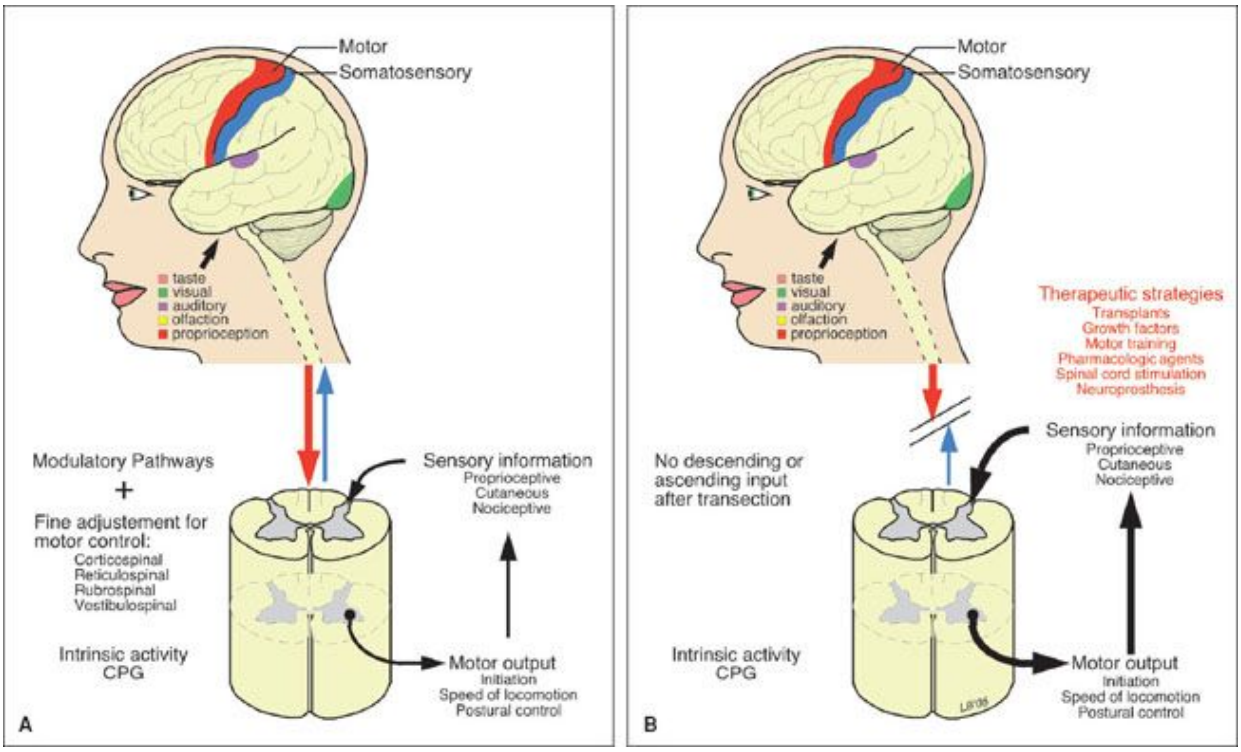


eFIGURE 30.3 Dermatomes represent the cutaneous distribution of territories innervated by spinal nerves. (From Schwartz ED, Flander AE. *Spinal Trauma: Imaging, Diagnosis, and Management*. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)

When the patient has no function of any segment of the cord below the level of injury, the injury is physiologically complete. Such a circumstance carries with it a grim but not hopeless prognosis for meaningful recovery. It is nearly impossible to accurately diagnose a permanent physiologically complete cord injury in the emergency

department (ED) because spinal shock may be a concurrent factor. *Spinal shock* is the temporary loss of spinal reflex activity that accompanies the motor and sensory losses. Males may exhibit priapism. Ditunno et al. (4) describe four phases of spinal shock lasting a variable amount of time, from a day to weeks.

- Phase 1: Flaccid paralysis, areflexic, lasts about 1 day.
- Phase 2: Return of polysynaptic reflexes, e.g., bulbocavernosus, 2 to 3 days.
- Phase 3: Return of monosynaptic deep tendon reflexes.
- Phase 4: Hyperreflexic spastic paralysis (eFig. 30.4).



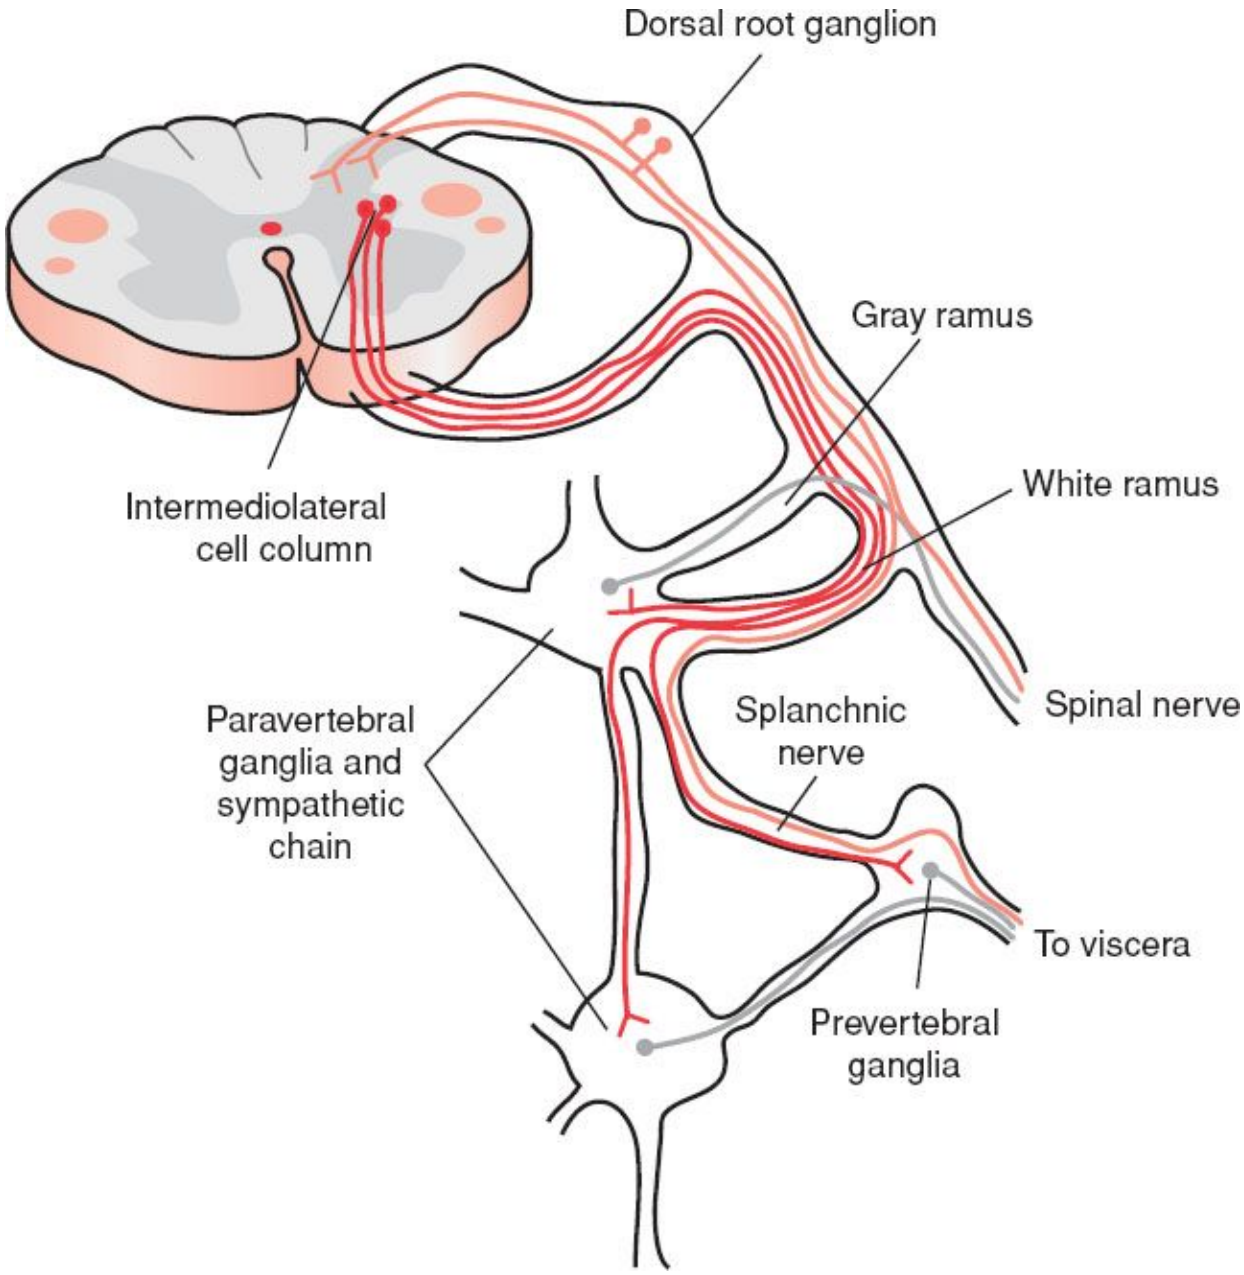
eFIGURE 30.4 Spinal transection creates a new spinal cord. Spinal transection results in considerable modification of the circuitry caudal to the lesion. Some of these changes may contribute to the deficits, while others may provide opportunities for therapeutic interventions. A: The intact spinal cord receives control and modulation from supraspinal systems and sensory input from primary afferents, which determines the activity of spinal circuits, including the central pattern generator. B: After SCI, descending pathways are lost, their denervated receptors up regulate, and

afferent pathways are enhanced, leading to hyperexcitable reflexes and spastic paralysis. Strategies targeting independent mechanisms are the bases of potential treatments. (From Schwartz ED, Flander AE. *Spinal Trauma: Imaging, Diagnosis, and Management*. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)

The bulbocavernosus reflex is elicited when squeezing or tugging on the glans penis causes reflex contraction of the anal sphincter. Some patients who initially appear physiologically completely paralyzed and have spinal shock may go on to remarkable recoveries after the initial phases of spinal shock have passed.

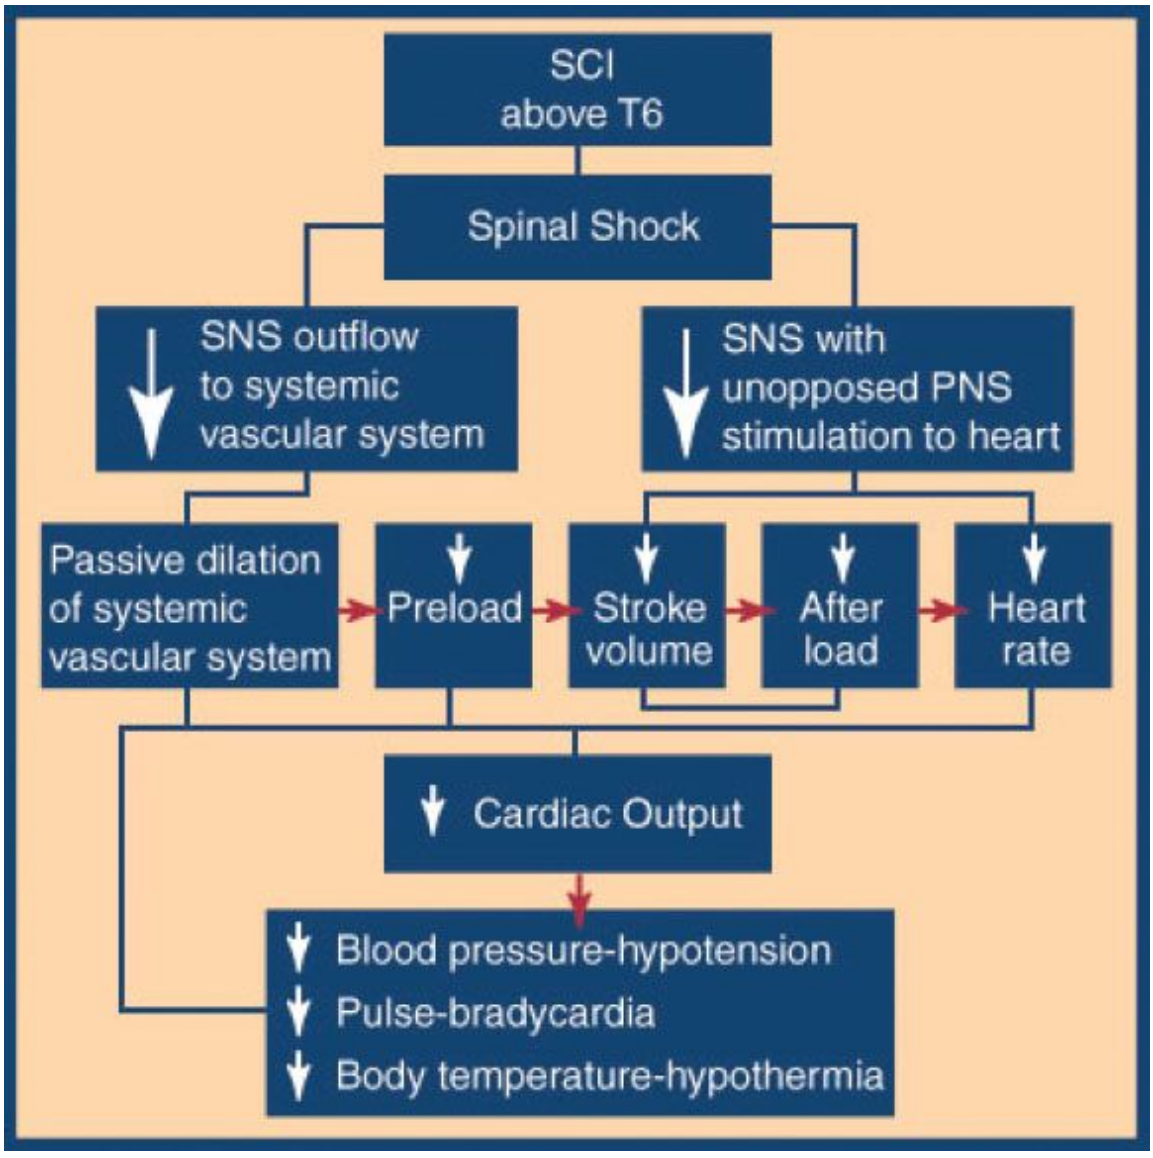
The patient with a cervical or high thoracic cord injury above T6 may present with relative hypotension due to the sudden loss of sympathetic tone below the level of the lesion (eFig. 30.5). The patient has warm, dry skin; normal capillary refill; and a paradoxical bradycardia. Labeling this condition *spinal neurogenic shock* (eFig. 30.6) helps to differentiate it from the aforementioned spinal shock. Spinal neurogenic shock in the patient with multiple injuries may be difficult to differentiate from other causes of shock. Hemorrhagic shock classically presents as hypotension, tachycardia, cool and moist skin, and delayed capillary refill. The hypotensive patient should be assumed to have hemorrhagic shock until all external bleeding is controlled and the search for occult hemorrhage in the chest, abdomen, retroperitoneum, and pelvis is complete. This search should include, at a minimum, chest x-ray, FAST cardiac and abdominal ultrasonography, urinalysis, and pelvic x-ray or abdominal and pelvic computed tomography (CT). After this survey is complete and no other explanation for shock is found, the hypotension may be attributed to spinal neurogenic shock. At that point, after adequate initial volume resuscitation of the vasodilated patient, fluid administration should be kept at maintenance levels and the hypotension should be treated with pressors as necessary to maintain perfusion of the brain and spinal cord. Excessive fluids may cause pulmonary edema and contribute to worsening spinal cord edema. Ischemia is a significant contributor to the ultimate degree of spinal cord injury. Unfortunately, there are no prospective controlled

human studies to determine what the optimal blood pressure is to maintain spinal cord perfusion and thus limit secondary injury to cord tissue. Typically, the patient is maintained at a blood pressure sufficient to sustain intact mentation and urinary output. Animal studies show that hypotension worsens neurologic outcome. For this reason it is recommended that systolic blood pressure below 90 mm Hg be avoided or corrected as soon as possible and that the mean arterial pressure be maintained at 85 to 90 mm Hg for the first 7 days (13).



eFIGURE 30.5 The sympathetic nervous system and its relationship to the central nervous system. Sympathetic preganglionic neurons (red) are located in the intermediolateral cell column of the thoracic spinal cord. Their axons leave the spinal cord via the ventral root and enter paravertebral and sympathetic chain ganglia on the ipsilateral side of the body through the white communicating ramus. Some fibers synapse within ganglia at the same segmental level, others travel up and down the sympathetic chain to other ganglia. Postganglionic sympathetic fibers arising from cells in the

paravertebral or sympathetic chain ganglia (green) join a spinal nerve by passing through a gray communicating ramus. These supply smooth muscle and glands of the body wall. Other postganglionic fibers travel through a splanchnic nerve to innervate viscera of the body cavities. Axons from sensory (pain) neurons (blue) supplying an internal organ may pass through autonomic ganglia, but they originate from neurons in the dorsal root ganglia. (From Schwartz ED, Flander AE. *Spinal Trauma: Imaging, Diagnosis, and Management*. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)



eFIGURE 30.6 Spinal neurogenic shock. Spinal cord injury above T6 impairs sympathetic nervous system activity caudal to injury and leaves unopposed parasympathetic nervous system activity.

In the past 20 years, the percentage of patients with complete spinal cord injuries has fallen while incomplete spinal cord lesions have increased. This has been attributed to improved management at the scene and in the hospital. There are several important partial cord syndromes (Fig. 30.2).

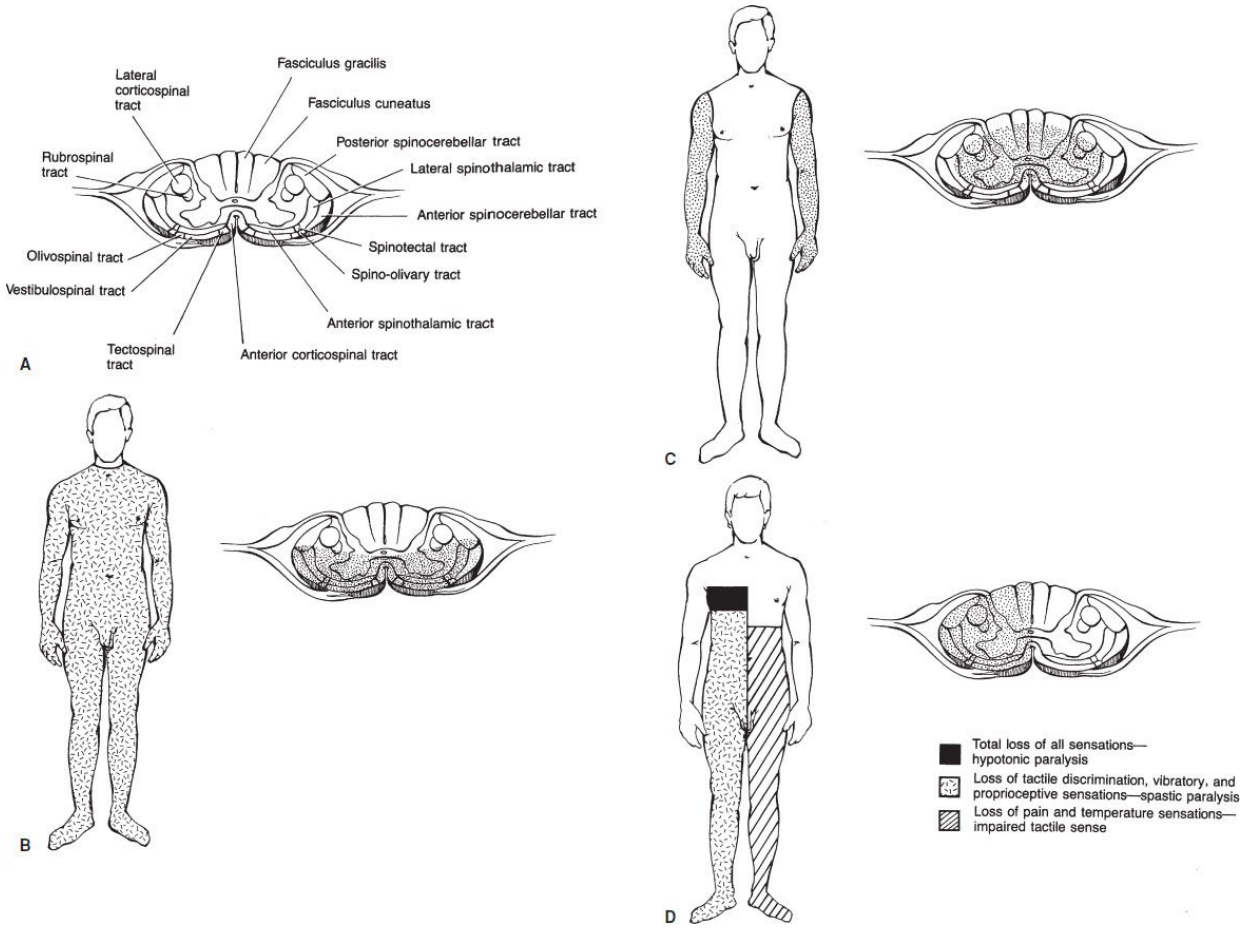


FIGURE 30.2 Transverse section of the spinal cord at the cervical level: the ascending and descending tracts **(A)**, tracts that may be damaged in the anterior spinal artery syndrome **(B)**, tracts that may be damaged in the central cord syndrome **(C)**, involved tracts and the superimposed areas of deficit from an injury at T4 **(D)**, resulting in the Brown-Séquard syndrome.

Anterior spinal cord syndrome (Fig. 30.2B) is the result of either direct blunt injury to the cord itself or compression of the anterior spinal artery by disc, bone, or hematoma, causing ischemic damage to the anterior cord. The patient presents with a loss of motor and pain sensation bilaterally below the level of the lesion, but posterior column function is preserved. Posterior column function is tested with a tuning fork for vibratory sensation or by plantar flexing and dorsiflexing the great toe to assess for gross proprioception. Early closed reduction is an important treatment option in the awake patient (6). After CT, in cervical cases, the patient may have an urgent attempt at reduction and reestablishment of the normal diameter of the spinal canal. This is typically performed by the neurosurgeon using Gardner–Wells tongs applying inline traction guided by serial x-rays and serial neurologic examinations after each incremental addition of weight. Endpoints are successful reduction, any sign of distraction that can cause additional cord injury, or the neurosurgeon's acceptable maximum weight limits for the level of the injury. Magnetic resonance imaging (MRI) or CT myelography may follow to assess for possible soft tissue masses, such as an extruded disc or hematoma that may continue to exert extrinsic pressure on the spinal cord or anterior spinal artery. If this is found, the neurosurgeon may attempt to relieve it by laminectomy. Unfortunately, the prognosis for recovery after this injury is poor.

The acute *central cord syndrome* (Fig. 30.2C) usually afflicts patients with a narrowed spinal canal. This may be due to degenerative spine disease causing bony ridges and thickened ligaments in the spinal canal, a congenital stenotic canal, acute fracture, or disc herniation. Degenerative spine disease is more common in the elderly but also may be present in younger patients. The mechanism of injury is usually hyperextension. The hallmark of this lesion is greater damage to the central portion of the cord than to the periphery. This leads to a variable sensory loss and bladder dysfunction but a predictable motor loss, with motor function of the upper extremities below the level of the lesion more impaired than that of the lower extremities. This is because the motor fibers in the lateral corticospinal tract lie in a lamellar fashion; cervical segments

are most medial and hence more damaged, and thoracic, lumbar, and sacral motor fibers are progressively more lateral. The diagnosis is confirmed by MRI. Management of this injury is usually nonoperative, although surgical decompression may be chosen by the neurosurgeon. There is a relatively good prognosis for recovery of at least partial neurologic function. Three-fourths of these patients are walking at 1 year; however, there is usually much less recovery of hand function.

The *Brown-Séquard syndrome* (Fig. 30.2D) is a hemicord injury that presents with a crossed sensory and motor deficit. Motor function is lost ipsilateral to the cord lesion, but sensory function is preserved on the ipsilateral side. Sensory function is lost on the contralateral side, where motor function is preserved. The crossed lesion is explained by the decussation of motor fibers in the medulla and the decussation of sensory fibers about two segments above the segment at which their sensory root enters the spinal cord. Causes include penetrating injuries, tumor, hematoma, and disc disease. The prognosis is poor with penetrating injuries.

DIFFERENTIAL DIAGNOSIS

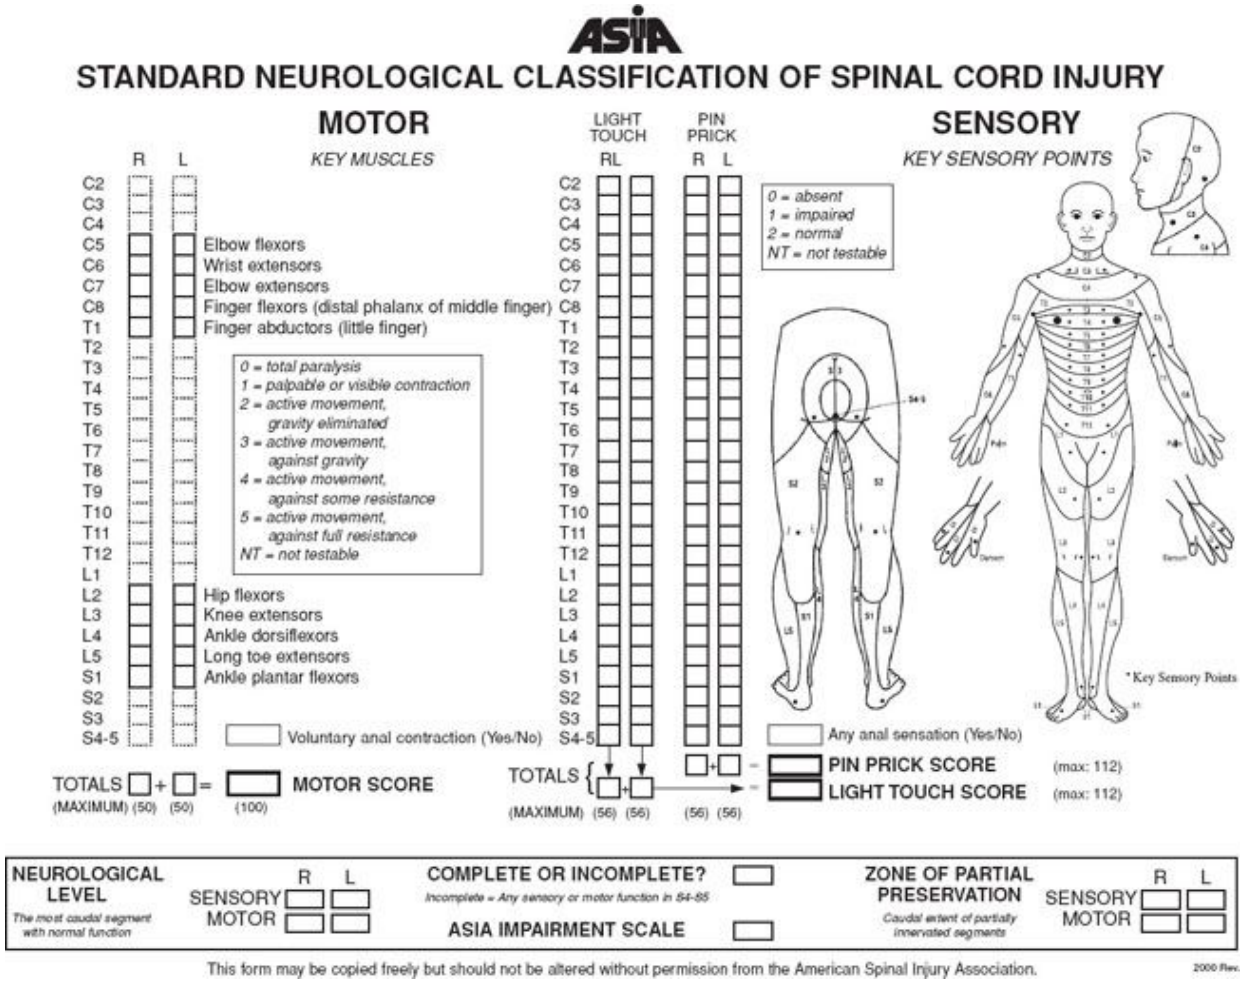
Determination of a cord injury is straightforward in the patient with acute quadri- or paraplegia. It becomes more difficult in patients with partial cord syndromes, particularly in those with acute central cord syndrome. This is due to both the patchy nature of the sensory loss and preservation of at least some motor function in the lower extremities. Evaluation for cord injury is also difficult in the unconscious patient. Most patients who present to the ED with complaints of neck or back pain or tenderness are found to have muscular strains or ligamentous sprains and no associated cord injury. The clinician should not be fooled by the absence of a fracture. A third-degree ligamentous sprain can render the spinal column unstable, allowing motion between vertebral bodies and subsequent cord or spinal root injury. In addition, mostly children, but also adults, may have *spinal cord injury without radiographic abnormality*. It is recommended that these patients have an MRI and external immobilization until spinal stability is confirmed by a

negative MRI followed by flexion–extension views; in addition, they should avoid high-risk activities for up to 6 months (12). See Chapter 28. The SCIWORA diagnosis was more common when diagnosis was based on x-rays. Now this diagnosis is less common since the MRI will often show an abnormality.

ED EVALUATION

The principles of evaluation are the same for all significantly injured patients. Initial attention should be paid to airway, breathing, circulation, disability, exposure, and environment (the ABCDEs), with simultaneous resuscitation involving high-flow oxygen, two large-bore intravenous lines delivering 20 cc/kg of crystalloid to the hypotensive patient, and a Foley catheter. Serial vital signs, bedside ultrasound of the inferior vena cava, urinary output, and pulmonary auscultation should be used to assess for the need of additional crystalloid. It is important to consider that excessive crystalloid may cause pulmonary edema. Early in their course, spinal cord–injured patients often have an atonic bladder. A Foley catheter is used to monitor urine output during the resuscitation and to prevent damaging distention of the bladder. Early in the hospitalization, the Foley catheter is removed and replaced by intermittent catheterization to decrease the chance of developing an ascending urinary tract infection. The patient is given nothing by mouth in anticipation of paralytic ileus. Physical and occupational therapy and psychological counseling are begun early during hospitalization.

In the critically injured patient, the primary survey should be followed by imaging (chest and pelvis films, as indicated), FAST ultrasound of the heart, lungs, inferior vena cava, and abdomen, and the secondary survey. In many trauma centers, the spinal cord–injured patient will have emergent CT of the head, entire spine, chest, abdomen, and pelvis. During the secondary survey, a careful neurologic examination must be performed. This examination is carefully recorded following the American Spinal Injury Association Scale (1, eFig. 30.7) so that an ascending lesion or deterioration in function can be identified by serial examinations. Motor function for all muscle groups is tested and recorded on a 0 to 5 scale.



eFIGURE 30.7 Standard neurologic classification form for spinal cord injury. (From: American Spinal Injury Association. *International Standards for Neurological Classification of Spinal Cord Injury*. Chicago: American Spinal Injury Association; Revised 2002, with permission.)

- 0: No voluntary muscle contraction
- 1: Flicker or trace of muscle contraction
- 2: Muscle activity apparent but cannot overcome gravity
- 3: Can overcome gravity but not active resistance
- 4: Active motion against mild to strong but reduced resistance from normal
- 5: Full normal active motion against resistance

The level of sensory loss is plotted to identify the level on which to concentrate radiographic imaging. Gross proprioception or vibratory function is measured to examine posterior column function. Deep

tendon reflexes, anogenital reflexes (bulbocavernosus, anal wink), and perianal sensation are elicited to identify spinal shock or sacral sparing. One common diagnostic error is performing an inadequate neurologic examination and specifically failing to examine for posterior column function (gross proprioception or vibratory sensation). A second error is failing to examine for sacral sparing, which is needed to differentiate a partial cord lesion from a physiologically complete injury. Serial neurologic examinations are performed to identify any important change in functional status, which would have a profound influence on the management of the patient by the neurosurgeon or orthopedic surgeon. Deterioration of function despite vertebral alignment implies the need for an MRI or CT myelogram to check for the presence of an extrinsic soft tissue mass compressing the cord, which might be surgically correctable. No specific laboratory studies aid in this evaluation.

After the history and physical examination have identified the level of the lesion, plain films, CT, and MRI help characterize the lesion. For a complete discussion of managing multiple trauma, x-rays, and spinal fracture management, see Chapters 21, 28, and 29.

KEY TESTING

- History and physical examination-–motor, sensory, reflexes, rectal tone and sensation, gross proprioception or vibratory sensation, urinary retention
- Search for occult hemorrhage—FAST, CXR, UA, pelvic x-ray or CT abdomen and pelvis
- CT of whole spinal column
- MRI when patient is able, if cause of patient's findings or deterioration not clearly defined on CT

ED MANAGEMENT

In the patient with a spinal cord injury, the immediate focus should be on identifying and managing life-threatening injuries, while avoiding secondary injury. The patient should remain supine in a semirigid collar using spinal precautions without applying traction

until after films carefully define the lesion. Traction that causes distraction on the cord or roots may cause severe, possibly irreparable neurologic damage. The first priority is to ensure that the patient survives, by attending to the ABCDEs. The second priority is to prevent secondary injury through unnecessary motion, hypoxia, hypotension, or infection.

The physician must not allow or cause the patient to have unnecessary motion of the unstable spinal column. However, at times, such motion may be necessary to preserve the patient's life, such as in the patient with an obstructed airway who needs immediate management when initial maneuvers have been proven unsuccessful. Inline immobilization with the Sellick maneuver should be used, allowing only as much motion as is needed to successfully control the airway. The physician should prepare to logroll and suction if the patient regurgitates, while keeping the patient's spinal column as straight as possible. Although x-ray studies show that logrolling is associated with some motion of the thoracolumbar spinal column, it must be done to prevent aspiration and obstruction in the patient who regurgitates without a protected airway. Later when such an immediate airway threat is not an issue, then multiple person vertical lifting and sliding techniques can be used to transfer the patient with less thoracolumbar spinal motion (14).

Prehospital spinal immobilization is moving toward a greater recognition of the risk–benefit of this therapy. There are no randomized controlled trials of spinal immobilization. Both the C-collar (16) and backboard (18) have come under critical review. This controversy will continue into the future. The American Association for Neurological Surgeons and the Congress of Neurological Surgeons 2013 Joint Guidelines (17) support the use of field triage to determine the need for immobilization of the awake patient with a known or suspected cervical spine injury using the five NEXUS criteria. They further support the use of C-collar and board with blocks for patients not passing those NEXUS exclusion criteria. The NAEMSP and ACSCOT position statement concludes the benefits of backboards are largely unproven, endorses the use of field triage as above and the use of spinal precautions using a rigid collar and

securing the patient to the EMS stretcher, rather than a board, if the patient is ambulatory, there is a long transport, or for those patients in whom the backboard is not otherwise indicated (18). Sundstrom et al. (16) question whether the C-collar should be used. They state its use should be rare such as during extrication and then be removed once the patient is on a spine board in blocks, and if unconscious without a protected airway, rolled into a left lateral position with the left arm raised above the head. Their extensive critical review found little evidence to support the use of a C-collar and an equal or greater amount of evidence opposing its use. They report studies that indicate it may contribute to neurologic injury higher in the cervical column, airway compromise and aspiration especially when used in conjunction with a spine board, and that C-collars raise intracranial pressure which may worsen outcomes in patients with significant traumatic brain injury.

Many patients will arrive immobilized with a long board and semirigid collar. The emergency physician should immediately perform the ABCDEs of the primary survey and resuscitation. Current practice is that the semirigid collar can be opened in a supine, immobilized patient, as needed, to examine the neck. When this examination is complete, the collar is replaced. It should otherwise be left on until clinical evaluation or imaging shows the cervical spine to be stable. The patient is removed from the spine board at the end of the exposure phase. The patient is managed with spinal precautions such as a sliding board, multiple person vertical lift, or logrolling after this.

The NEXUS study provides a reliable decision instrument to help the physician decide if the patient needs cervical x-rays after blunt trauma (8). The five NEXUS criteria are as follows: no posterior midline cervical tenderness; no focal neurologic deficit; the patient must be alert; the patient must not be intoxicated; no distracting painful injury. If the patient meets all five exclusion criteria, then the physician can reliably continue the evaluation without performing cervical spine x-rays. When the patient has none of these indications for cervical x-rays, the physician may remove the collar and gradually have the patient move the neck to assess for pain with

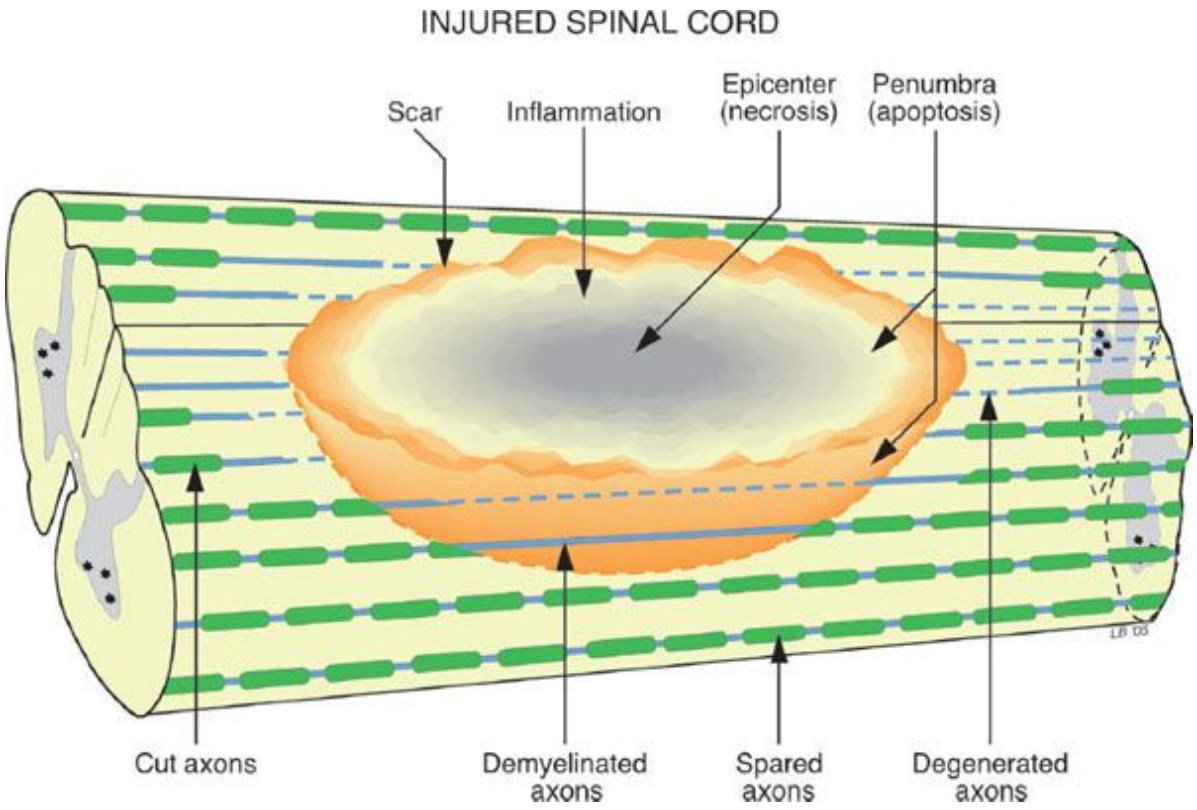
range of motion. An untoward amount of pain with motion should lead to replacing the collar and obtaining films. No similar national multicenter study has defined exclusion criteria for thoracic and lumbar spine x-rays. Domeier (5) used criteria similar to those of NEXUS above for a prehospital spinal injury assessment protocol applied to the entire spine. In it posterior midline tenderness was replaced by spinal pain or tenderness and distracting painful injury by suspected long bone fracture. Using those five criteria no patient without spinal immobilization had a spinal cord injury for lack of immobilization. An alternative approach for use in alert and stable trauma patients is to follow the Canadian cervical spine rules (14); see Chapter 28. Spinal immobilization of victims of isolated penetrating injury is not recommended (15,17,18).

Typically as the last step in the exposure phase, the patient is logrolled to examine the back. The backboard is then removed but the semirigid collar is left in place until either clinical evaluation or imaging has demonstrated stability. Further movement of the patient is accomplished using spinal precautions to move the patient as a unit, using sliding boards, logrolling, or multiple person vertical lifts. The long board is an important tool in immobilizing and protecting the spinal cord especially during early transportation. However it also can deliver significant forces to the spinal column potentially causing second injury to the spinal cord and serious complications such as aspiration, impaired ventilation, and decubitus ulcers. For these reasons, the patient should be removed from the long board as soon as is practical and other spinal precautions should be put in place.

The patient must be protected against unnecessary movement until the history, physical examination, and, if indicated, radiologic studies are complete that show that the spinal column is stable. The physician should not be fooled into thinking films are unnecessary by the fact that the patient was walking after the injury. If such a patient presents, the NEXUS or Canadian C-spine rules should be used to determine if the patient needs x-rays.

The phrenic nerve, providing motor innervation to the diaphragm, arises from the C3 through C5 segments of the spinal cord. An

otherwise healthy patient can maintain adequate long-term ventilation with diaphragmatic breathing alone. However, if a traumatic lesion affects C3 to C5, or if the level of the lesion ascends, as sometimes happens due to edema (eFig. 30.8), the patient may become ventilator dependent. In addition, the patient may need intubation and ventilation early on, despite preserved diaphragmatic breathing, if there are additional injuries that combine with the cord injury to make oxygenation or ventilation inadequate.



eFIGURE 30.8 Diagram of spinal cord following a contusion injury. A contusion injury induces hemorrhage. The epicenter is characterized by necrotic cell death and the lesion expands (secondary injury) into a penumbra region, with additional cell death due to apoptosis. The secondary injury is associated with entry of inflammatory cells and toxicity from dying spinal cord cells. Ultimately, the area of injury is surrounded by a dense glial scar. The injury destroys some axons, and damages others, leading to demyelination. Cut axons often retract (dieback). Some axons are usually spared by a contusion injury. (From Schwartz ED, Flander

AE. *Spinal Trauma: Imaging, Diagnosis, and Management*. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)

The ultimate outcome of any spinal cord injury is determined by a combination of the initial mechanical injury and a cascade of secondary injuries. Timely reduction of the displaced column is vital to achieve decompression of the spinal cord. Timely reduction has been associated with recovery from otherwise devastating spinal cord injury (2). The secondary vascular and biochemical injuries are the subject of numerous animal and human studies of their mechanism of injury and treatment. Various monotherapy and combination therapy protocols attempt to interrupt this cascade of injury at various points in its course. Pharmacologic therapy for acute spinal cord injury has been controversial for many years. The 2013 American Association of Neurologic Surgeons/College of Neurosurgeons (AANS/CNS) Guidelines state as a Level I recommendation that the "administration of methylprednisolone for the treatment of acute spinal cord injury is not recommended…" and that "high-dose steroids are associated with harmful side effects including death" (9). High-dose methylprednisolone is not indicated after penetrating spinal cord injury. There is insufficient data to support its use in children, or in patients with cauda equina, or spinal root injury.

CRITICAL INTERVENTIONS

- Ensure patient survival by attending to the ABCDEs and initial resuscitation.
- Perform inline immobilization for airway interventions.
- In the hypotensive patient with suspected spinal neurogenic shock, after completing a negative search for occult hemorrhage, use volume resuscitation and then pressors if needed to raise mean arterial pressure to between 85 and 90.
- Identify other injuries in the anesthetic or hypoesthetic patient. Because the patient cannot feel pain or tenderness below the lesion, common historical and physical examination findings will

be absent. The patient requires a very thorough examination, and areas with significant bruises should be imaged. Perform complete CT scans if available.

- Remove the patient from the backboard, while maintaining spinal precautions, as soon as practical to avoid decubitus ulcerations, pain, impaired respirations, and limit the risk of aspiration that results from being immobilized supine.
- Record an accurate baseline motor, reflex, sensory, posterior column, and rectal tone examination. Changes in these may lead to MRI or CT myelography (may be done if MRI not possible) and possible decompressive surgery.

DISPOSITION

The emergency physician must decide if a spinal column or cord injury exists. Next, the physician must decide whether the column is stable. Consultation should be obtained once cord or spinal nerve root injury is identified by physical examination or radiologic studies. The timing of consultation is urgent; it should be obtained while the patient is in the ED. It should be requested after attention is focused on the primary survey and initial resuscitation.

Patients are admitted if there is a cord injury or unstable column injury, for pain control, or for an anticipated complication such as the association of ileus with a thoracolumbar compression fracture. Patients with cord or unstable column injuries are admitted to the intensive care unit; rotating frames, or serial inflating beds are used to protect from pressure sores. Deep vein thrombosis is very common early in the hospital management of patients with acute spinal cord injury. Prophylaxis includes pneumatic compression stockings, as well as heparin when other injuries allow its safe administration, or an inferior vena cava filter.

Patients discharged home should be instructed to return immediately for a recheck if there is any sign of worsening, such as the development of numbness, weakness, hyperesthesia, paresthesias, cauda equina syndrome with urinary retention, fecal incontinence, or saddle hypoesthesia. Paresthesias are a sign of potential instability.

The patient should be transferred to a specialized trauma facility if the trauma team cannot meet all the special requirements for extensive rehabilitation and specialized care of the cord-injured patient. Deteriorating or unstable internal injuries are best managed before transfer. Transport personnel should be, at a minimum, Advanced Life Support Certified. For the emergent transfer, the patient should lie supine with a semirigid collar and moved using spinal precautions.

Common Pitfalls

- Applying cervical spine traction instead of immobilization. The patient is at the highest potential risk for traction injury during prehospital placement on a spinal board or during intubation when inline immobilization, not traction, should be used. Video laryngoscopy can facilitate intubation during inline immobilization.
- Attributing hypotension solely to spinal neurogenic shock without completing the search for occult injury.
- Attributing the subtle findings of partial cord syndrome to psychological, pharmacologic, metabolic, and infectious etiologies.
- Misreading x-rays or accepting inadequate films and failure to identify an unstable spinal segment.

CHAPTER 31

Blunt Chest Trauma

Richard L. Byyny

Blunt chest trauma (BCT) is a common emergency department (ED) presentation. The trauma can range from the most minor chest wall contusion to catastrophic and fatal intrathoracic injury. BCT is involved in nearly one-third of admissions to trauma centers and accounts for about 25% of all trauma-related deaths in the United States (1). Most of these injuries are the result of motor vehicle collisions or pedestrians who are stuck by automobiles. Unlike penetrating injuries, BCT usually occurs when a large force is applied to a relatively larger area. Injury kinetics include acceleration and deceleration forces as well as transmission of blunt force to internal structures. BCT is often associated with multiple system trauma; including injury to the abdomen, head, spine, and extremities. Therefore, BCT must be evaluated in the context of these other injuries and, at times, more imminent life threats.

CLINICAL PRESENTATION

Chest Wall Injuries

Chest wall contusions and rib fractures account for the majority of blunt chest wall trauma (2). Rib fractures make breathing painful and can increase the patient's morbidity and mortality by adversely affecting ventilation. Fractures typically occur at the site of the impact or the posterior angle where the rib is structurally the weakest. Fractures are more common in adults than children because of the relative inelasticity of the mature thorax. In fact the presence of rib fracture in children should raise the suspicion of child abuse

and heighten the concern for coexisting intrathoracic injury (3). Elderly patients have a higher morbidity and mortality associated with rib fractures than younger patients with each additional fracture increasing the risk of death by 19% and increasing the risk of developing pneumonia by 27% (3). Although the fourth through the ninth ribs are most commonly involved, there is a fourfold increase in splenic injuries with left-sided rib fractures 9 to 11 and a threefold increase risk of liver injuries in right-sided rib fracture 9 to 11 (4). Multiple rib fractures or the presence of a flail chest wall segment may be associated with intrathoracic injury, usually a pulmonary contusion.

Clinical findings typically include pleuritic pain, tachypnea, splinting, and point tenderness intensified by deep breathing or coughing. Bony crepitus may be palpable. Anteroposterior compression of the thorax produces referred pain to the fracture site; if fracture is absent, there should not be referred pain to the localized area of tenderness.

Sternal Fractures

Sternal fractures usually result from high-energy forces to the midanterior chest wall. This force most commonly occurs from motor vehicle collisions in which the chest strikes the steering wheel, dashboard, or shoulder belt at high velocity. This force may result in a sternal fracture or costochondral separation and, in rare instances, an anterior flail chest when the sternum is disarticulated from the ribs. Patient may have point tenderness on their sternum, hematoma, or deformity.

Flail Chest

Flail chest occurs when three or more ribs are fractured in two or more places. In a patient who is breathing spontaneously, the negative intrathoracic pressure with inspiratory effort results in a paradoxical movement of the chest wall (the flail segment moves in during inspiration and out during expiration). There is usually no significant ventilatory compromise caused by the flail segment *per se*.

In these patients, respiratory compromise is related to the degree of pulmonary contusion, which almost inevitably occurs when force is significant enough to cause a flail chest. However, in patients with large flail segments, the normal thoracic physiology is disrupted, causing respiratory failure requiring mechanical ventilation. All patients experience significant pain secondary to the respiratory movement of multiple rib fracture fragments and will often have tenderness, crepitus, and paradoxical movement of the chest wall. In some patients who are splinting or in those on positive-pressure ventilation, the flail segment may not be readily apparent. Palpation of the chest can help detect the injury. It is notable that in patients with flail segments the morbidity and mortality are increased when compared to patients with a similar numbers of fractures without a flail segment (5).

Pulmonary and Pleural Injuries

Blunt trauma may result in pneumothorax, hemothorax, or hemopneumothorax, usually secondary to a rib fracture penetrating the visceral pleura and lung parenchyma. Hemothorax usually results from disruption of an intercostal artery (see Chapter 32).

Pulmonary Contusion

The most common injury to the pulmonary parenchyma in BCT is pulmonary contusion. Among severely injured (ISS >15) blunt trauma patients approximately 27% had pulmonary contusion (6) and in children pulmonary contusion represents a large proportion of thoracic injuries (7). This injury results from transthoracic transmission of kinetic injury to the pulmonary parenchyma causing an alveolar–capillary membrane disruption and subsequent pulmonary edema. This injury results in areas of the lung that are perfused but not ventilated (i.e., a ventilation perfusion mismatch), resulting in hypoxia, hypercarbia, and acidosis.

Depending upon the extent, this injury results in minimal to life-threatening symptoms. A patient with a pulmonary contusion usually presents with dyspnea and tachypnea. There may be tenderness or

obvious ecchymosis and deformity over the injured chest wall. Large pulmonary contusions are associated with tachycardia, hypotension, cyanosis, and low oxygen saturation. Patients with multiple rib fractures or flail segments of the chest wall are more likely to have associated pulmonary contusion.

Tracheal and Bronchial Injuries

Tracheal and bronchial injuries are rare accounting for only between 0.1% and 2% of patients who present to the ED (8). The majority of these injuries occur within 2 cm of the carina or at the origin of the lobar bronchi (9). Symptoms are usually related to the size of the defect in the airways and whether there is communication with the pleural space. Occasionally minimal symptoms may occur, even with severe tracheal or bronchial injury. Hemoptysis may occur in up to 25% of cases and subcutaneous emphysema or pneumomediastinum is present in 35% to 85% of cases (8). Patients can also present with dyspnea, hoarseness, or aphonia. This injury should be considered if there is a persistent air leak from a properly positioned chest tube and difficulty in fully reexpanding the lung.

Blunt Cardiac Injuries

By virtue of its location in the chest, the heart is susceptible to injury from compression of the chest wall and upper abdomen and from deceleration forces. It is the cause of death in up to 20% of automobile collisions. There is no gold standard to make the diagnosis of blunt cardiac injury; therefore, the true incidence is unknown and evaluating literature on the topic is difficult with different authors using different diagnostic standards. Therefore, there is a wide range of reported incidence from 20% to 76% of blunt thoracic trauma patients.

The right ventricle is the most commonly injured portion of the heart because of its relatively vulnerable position immediately behind the sternum; however, injuries to multiple chambers occur in 50% of cases (10). Blunt cardiac injury encompasses a spectrum of

injuries including myocardial concussion, myocardial contusion, myocardial infarction, and myocardial rupture.

Myocardial concussion (*commotio cordis*) is a ventricular dysrhythmia or asystole secondary to a direct blow to the myocardium without pathologic evidence of cardiac injury. Myocardial concussion is the most common cause of sudden death in young athletes (11). Those patients who survive a myocardial concussion usually have little or no long-term sequelae from their blunt cardiac injury.

Myocardial contusion is characterized by localized edema and hemorrhage into cardiac muscle. This trauma may involve segments of the cardiac conduction system, most commonly the right bundle branches.

Traumatic myocardial infarction is rare but can occur from disruption of the coronary artery intima and subsequent thrombosis. The most severe form of blunt cardiac injury is cardiac rupture, which is a rare injury. These patients will present with hypotension or *in extremis* and usually have a right atrial or ventricular injury.

Physical findings in blunt cardiac injury may be nonspecific. Chest pain from either chest wall trauma or ischemia may be present. Seventy percent to 80% of patients with blunt cardiac injury have external signs of chest trauma including contusions, abrasions, palpable crepitus, and flail segments. The presence of a fractured sternum, once thought to be a marker for blunt cardiac injury, has not been shown to reliably correlate with the presence of a blunt cardiac injury (12). The most common vital sign abnormality is persistent sinus tachycardia after other causes have been treated. Hypotension is a serious sign and should raise the possibility of pericardial tamponade, myocardial rupture, or rupture of an internal cardiac structure such as a chordae tendineae or valve.

Great Vessel Injuries

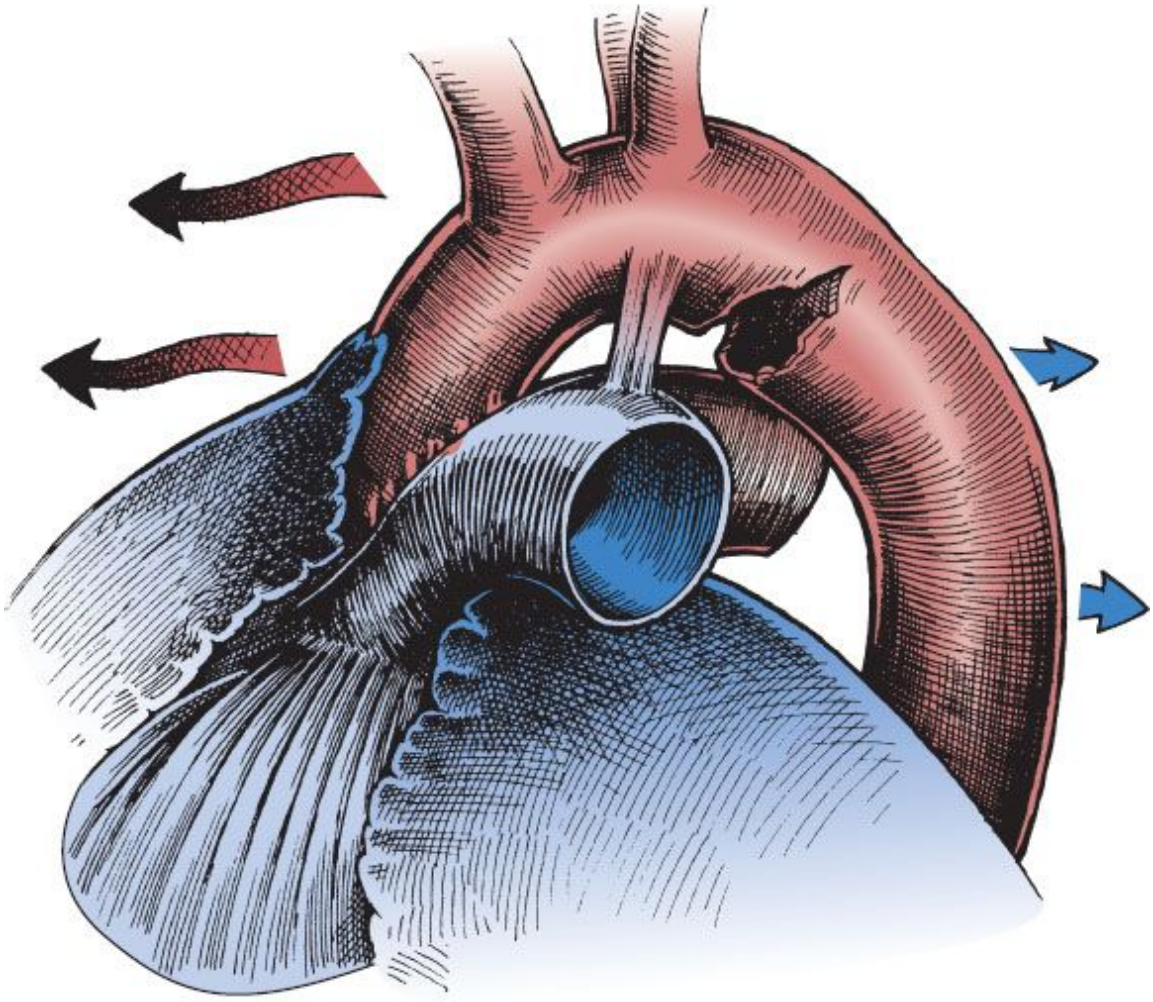
Blunt aortic injury accounts for approximately 8,000 deaths per year in the United States, and up to 15% of automobile fatalities are caused by traumatic disruption of the aorta (13). Eighty percent of patients with aortic injuries die in the field. The tear of the aorta is

usually a circumferential transverse laceration that disrupts the physical integrity of the intima and muscularis layers of the aorta. If the tear is complete, involving all three layers, this results in death caused by immediate exsanguination. In survivors, the adventitia remains intact, and blood is contained by a false aneurysm formed by the adventitia and surrounding mediastinal structures. If this injury is unrecognized, there is a significant risk of a free rupture and sudden death in the hours to days following this injury.

Disruption of the great vessels usually results from high-speed motor vehicle collisions, falls from a height, or ejection from motorcycles or other vehicles (13). The classic mechanism is a head-on motor vehicle collision, although the injury can occur after side or rear impacts. In seat-belted motor vehicle victims, descending thoracic tears are more common. Ascending aortic disruption is seen more often in unrestrained drivers or those who are ejected or fall from a height and experience vertical deceleration forces (14). Most often, these injuries involve the aorta but can involve the brachiocephalic artery and inferior vena cava. Patients with rupture of the vena cava have a poorer outcome because of continued, ongoing, significant blood loss and difficulty in controlling the bleeding and repairing the defect at surgery.

Several mechanisms have been postulated to explain aortic injuries. First, rapid horizontal deceleration produces shearing forces at the aortic isthmus just distal to the origin of the left subclavian artery. Ninety percent of traumatic aortic tears originate at this site. Anatomically, this frequency can be explained by the fact that the descending aorta is tethered by the ligamentum arteriosum and the intercostal arteries. The ascending aorta is relatively mobile and, during deceleration, continues to move forward while the descending aorta is held in place, resulting in shearing forces that cause a rent in the aorta (eFig. 31.1). The second proposed mechanism is that of the “water hammer” effect where a propagated wave of blood causes a surge in intraluminal pressure. Although the aorta may withstand intraluminal pressures of up to 350 mm Hg, this pressure may be surpassed leading to aortic injury (15). The final, and most likely, proposed mechanism is the “osseous pinch” model in which the aorta

is pinched between the sternum and the vertebral column, resulting in shearing forces that cause injury to the aorta (16).



eFIGURE 31.1 Rapid deceleration injury causing a tear in the thoracic aorta. The ascending (anterior) aorta tends to continue moving forward, while the more fixed descending aorta is held stationary. The rupture occurs just distal to the ligamentum arteriosum at the level of the isthmus.

The symptoms and signs of traumatic great vessel disruption are often absent or missed because of coexisting, significant injuries to the head, spine, abdomen, pelvis, and extremities. The most frequently recorded complaints are chest pain, dyspnea, and back pain. However, it is of note that only 25% of patients present with retrosternal pain or pain radiating to the upper back which is

considered typical of nontraumatic aortic dissection. Other symptoms include dysphagia, hoarseness, and ischemic pain of the extremities. Physical examination may reveal ecchymosis, abrasion, or tenderness of the anterior chest wall consistent with the impact of this area on a steering wheel. Thirty-one percent of patients with an aortic disruption present with the pseudocoarctation syndrome. In these cases, upper-extremity hypertension is present with decreased or absent femoral pulses because of compression of the aortic lumen by surrounding periaortic hematoma. Reflex stretching of the cardiac sympathetic fibers at the aortic isthmus may account for the observation that 72% of patients with aortic rupture manifest a relative hypertension (average blood pressure 152/98 mm Hg) (17). A harsh systolic murmur over the precordium or interscapular area (thought to be because of turbulent flow across the area of transection) has been reported to be present in 26% of cases (18). Unfortunately, the presence of great vessel injury cannot be confirmed or ruled out based on physical examination or history.

In confirmed cases of traumatic aortic injury, one-third to one-half of the patients have no external evidence of chest injury on initial presentation to the ED. Therefore, this injury should be suspected, even in the absence of these signs or symptoms, whenever there has been major acceleration–deceleration forces involving the chest (i.e., significant ejection mechanisms, falls from heights >10 ft, and motor vehicle collisions with speeds >30 mph, and a lack of proper vehicle restraints).

Diaphragmatic Injuries

Blunt traumatic diaphragmatic injury results from violent compression of the lower chest and upper abdomen and has an incidence between 0.5% and 8% of blunt trauma victims (15). Sixty percent to 90% of traumatic rupture of the diaphragm from blunt trauma occurs on the left side (19). Blunt trauma typically produces diaphragmatic defects of >10 cm on average and has a higher mortality rate than penetrating injury to the diaphragm because of the higher incidence of serious associated injuries to abdominal and chest structures.

Signs and symptoms of diaphragmatic rupture are highly variable depending upon the size of the defect, the mechanism, the abdominal viscus that herniates through the defect, and the degree of cardiopulmonary compromise. Common symptoms include cough, dyspnea, nonspecific chest or abdominal pain radiating to the shoulder, and the perception of peristalsis in the chest. Signs include an immobile left hemithorax, decreased breath sounds, and tympany or borborygmi in the left chest. Significant herniation of abdominal viscera into the thoracic cavity usually results in severe respiratory distress and may be clinically confused with a tension pneumothorax. A tension viscerothorax (gastrothorax) occurs when the resulting increase in intrapleural pressure causes shift of the mediastinum and hemodynamic collapse. Therefore, great care should be taken when performing a thoracostomy to verify a free pleural space before inserting the chest tube.

Esophageal Injuries

Esophageal injuries secondary to blunt trauma are rare occurrences yet critical to diagnose secondary to the high morbidity and mortality when treatment is delayed. They have been reported from sharp blows or when force is applied to the upper abdomen in which air and gastric contents are violently forced into the esophagus causing a perforation in the distal esophagus similar to those that results from retching and vomiting (i.e., Boerhaave syndrome). Injuries to the esophagus can also occur with compression of the esophagus against the spine, producing longitudinal tears in the upper thoracic esophagus and can be associated with laceration in the membranous (i.e., posterior) portion of the trachea, resulting in traumatic tracheoesophageal fistulas. Injuries to the esophagus can also occur from barotrauma, because the esophagus is a hollow, air-containing organ. An example of this is forceful insufflation of the esophagus from inhalation of aerosol cans, air compressors, or inflation devices or in children from the biting of inner tubes, and eruption of bottled carbonated beverages into the esophagus. Perforations of the esophagus can result from alkali ingestion, button

batteries, foreign bodies, and iatrogenic misplaced tubes or endoscopes.

Signs and symptoms of esophageal injury are subcutaneous emphysema (especially in the neck or supraclavicular fossa), unexplained tachycardia, dyspnea, dysphagia, odynophagia, cyanosis, pneumomediastinum, pneumothorax, pleural effusion (particularly on the left), and hematemesis.

Traumatic Asphyxia

Traumatic asphyxia occurs when the thorax is squeezed between two objects for a prolonged period of time. This results in compression of the vena cava with resultant prolonged increased venous pressure to the neck and head. This prolonged squeeze and compromised venous return results in intense cyanosis of the upper chest, neck, and face as well as petechiae and subconjunctional hemorrhage. Some patients may have retinal hemorrhage and loss of consciousness because of cerebral hypoxia. Sometimes there are associated chest wall and pulmonary parenchymal injuries such as pulmonary contusion and hemopneumothorax.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chest wall injuries includes rib fractures, flail chest, sternal fracture, costochondral separation, and chest wall contusion.

After blunt trauma, the differential diagnosis for pulmonary and pleural injuries includes pulmonary contusion, pneumothorax, hemothorax, hemopneumothorax, pulmonary contusion, tension pneumothorax, and acute pericardial tamponade. Tension pneumothorax must be differentiated from acute pericardial tamponade because both cause tachycardia, hypotension, and an elevated central venous pressure (CVP). In patients with tension pneumothorax breath sounds are absent or markedly diminished and pericardial ultrasound is normal.

The differential diagnosis of tracheal and bronchial injuries includes other traumatic causes of pneumomediastinum, such as a

ruptured esophagus or an iatrogenic perforation of the esophagus, posterior pharynx, or pyriform sinus during attempts at endotracheal intubation.

In patients with blunt cardiac injury, rupture of the valves or chordae tendineae may result in acute cardiac failure. In rare instances, blunt cardiac injury may cause acute pericardial tamponade. This injury can be differentiated from tension pneumothorax by the presence of a pericardial effusion on ultrasound, as well as by bilaterally equal breath sounds on physical examination.

The majority of patients who suffer from blunt thoracic aortic injury have coexisting serious injuries. These include fractures of the sternum and ribs, hemothorax, pneumothorax, hemopneumothorax, tracheobronchial disruption, diaphragmatic rupture, esophageal perforation, acute pericardial tamponade, and blunt trauma to the myocardium.

Traumatic rupture of the diaphragm can be confused with a pneumothorax or a tension pneumothorax when abdominal viscera have herniated into the thoracic cavity resulting in respiratory distress and diminished or absent breath sounds, usually on the left side.

ED EVALUATION

Chest Wall Injuries

After a history and physical examination including pulse oximetry, chest wall trauma can be evaluated with chest radiography. However, chest radiographs may not be necessary in isolated, localized chest wall trauma when there are no physical findings and no respiratory distress manifested by tachypnea or decreased oxygen saturations. Up to 50% of rib fractures are missed on the initial chest radiographs; 10% do not visualize radiographically for 1 to 2 weeks after the injury regardless of the views taken. Specific rib views are unnecessary and much of the time the presumptive diagnosis can be made without radiography. A chest radiograph is valuable when looking for complications of rib fractures such as hemothorax,

pneumothorax, pulmonary contusion, atelectasis, and pneumonia. Because elderly patients have a greater morbidity and mortality from complications of rib fractures, there should be a lower threshold for evaluating these patients with a chest x-ray and rib films (15).

Consideration should be given to observation, performance of the focused assessment with sonography in trauma (FAST) examination, or abdominal computed tomography (CT) in the presence of 9th through 11th rib fractures given the heightened risk for spleen or liver injury. Pain referred to either shoulder may indicate the presence of either hemothorax or pneumothorax or subdiaphragmatic hemorrhage from injury to the spleen or liver. Patients who present several days after their initial trauma with increasing pain, dyspnea, or fever following chest wall trauma should have a chest x-ray to ascertain if there are any late complications such as atelectasis or pneumonia.

Flail Chest

Patients with evidence of a flail chest on physical examination should be evaluated with oxygen saturation monitoring and a radiograph of the chest to detect the presence of underlying pulmonary contusion, pneumothorax, or hemothorax. Parenteral analgesics or regional nerve blocks are necessary for adequate analgesia.

Pulmonary and Pleural Injuries

Clinical signs of tension pneumothorax or massive hemothorax (decreased breath sounds or subcutaneous emphysema in association with hypotension, tachycardia, and respiratory distress) mandate initial placement of a needle or tube thoracostomy prior to obtaining chest radiography. Tension pneumothorax should be a clinical diagnosis and should not be captured on a chest x-ray. The extended focused abdominal ultrasound in trauma (E-FAST) has been more widely utilized to assist in the diagnosis of pneumothorax. In addition to usual components of the FAST examination (evaluation of the right upper quadrant, left upper quadrant, pericardium, and

retrovesicular space) the E-FAST also includes ultrasonography of the pleural surface using the high-frequency linear probe. It has been shown to have superior sensitivity to the supine chest x-ray and can expedite the diagnosis of pneumothorax (20). If the patient is hemodynamically stable, a portable chest radiograph is the initial study of choice; this will demonstrate hemothorax, pneumothorax, and pneumomediastinum.

Pulmonary Contusion

Radiographic evidence of pulmonary contusion may not be evident initially on the chest x-ray because these injuries tend to get worse over the ensuing hours following injury with the peak not being present until 72 hours after injury (6). Radiographic findings usually lag behind the clinical findings. A contrast-enhanced helical CT scan of the chest will detect the presence of pulmonary contusions before they become visible on standard chest radiographs. CT scans may be used to measure the extent of the pulmonary contusion and to determine the prognosis (6). All patients should be placed on oxygen and have continuous oxygen saturation monitoring. If the oxygen saturation is low, an arterial blood gas can be obtained to calculate an alveolar–arterial gradient and followed serially to determine subsequent therapy.

Tracheal and Bronchial Injuries

These injuries should be suspected when there is a persistent air leak despite the proper placement of a tube thoracostomy on the involved side. All patients should have a chest x-ray to rule out associated pneumothorax and to confirm that all the holes on the chest tube are within the thoracic cavity. Consideration should also be given to diagnostic studies that rule out the presence of an esophageal disruption (discussed later in this chapter). Surgical consultation should be obtained so that bronchoscopy can be performed for definitive diagnosis.

Blunt Cardiac Injuries

All patients in whom this injury is suspected should have cardiac rhythm and oxygen saturation continuously monitored. An electrocardiogram (ECG) should be obtained to ascertain the presence of any dysrhythmia, bundle-branch block, or new changes on the ECG (15). An initial ED ultrasound of the pericardium to detect the presence of pericardial effusion and to determine, if possible, the quality of cardiac wall motion should be performed. New murmurs or acute congestive failure after chest trauma should raise the suspicion of a ruptured interventricular septum, valve leaflet, or chordae tendineae. Traumatic ventricular septal rupture presents with a pansystolic murmur heard throughout the entire precordium, especially at the left sternal border. This murmur may not be appreciated until the patient has been resuscitated to a euvolemic state. In patients exhibiting hemodynamic instability and clinical signs of cardiac failure, a formal echocardiogram should be obtained to look for the presence of pericardial tamponade, valvular or chordae tendineae disruption, and to determine cardiac output.

Chest radiographs are not helpful in diagnosing cardiac trauma *per se* but may be helpful in identifying other thoracic injuries. Although nondiagnostic, multiple ECG abnormalities have been described that range from persistent sinus tachycardia to ST- and T-wave changes and bundle-branch blocks (the most common being right bundle-branch block). If ECG abnormalities are present, the patient should be admitted for 24 to 48 hours of continuous cardiac monitoring. The presence of a normal ECG confers a negative predictive value of 95% in ruling out myocardial contusion (12). Troponin I is helpful in making the diagnosis and in the stratification of those at risk for life-threatening conditions. If the troponin is not elevated at 4 to 6 hours post injury and the ECG is normal, the patient may be discharged from the ED conferring a negative predictive value of 100% (12). Neither nuclear testing nor echocardiogram is useful in diagnosing myocardial contusion.

Great Vessel Injuries

In patients with a major traumatic mechanism, a chest x-ray is a helpful screening tool in detecting not only great vessel injuries but

also other associated thoracic abnormalities. There are multiple radiographic features of great vessel injury (Fig. 31.1). The most sensitive finding in patients with aortic injury is a wide mediastinum (>6 cm upright and >8 cm supine anteroposterior view) (13). However, only 10% of patients with a wide mediastinum will end up having an aortic injury; other causes include sternal, rib, or spine fractures, and the supine radiography. Sitting the patient up after the cervical spine has been cleared will decrease the incidence of a wide mediastinum. Despite the many radiographic signs of traumatic aortic injury that have been described, in 7% to 28% of cases of aortic injury the chest radiograph is normal (eTable 31.1) (14). Therefore, it is prudent to consider further diagnostic studies, if there is a significant mechanism, even in the presence of a completely normal upright chest x-ray (13,21).

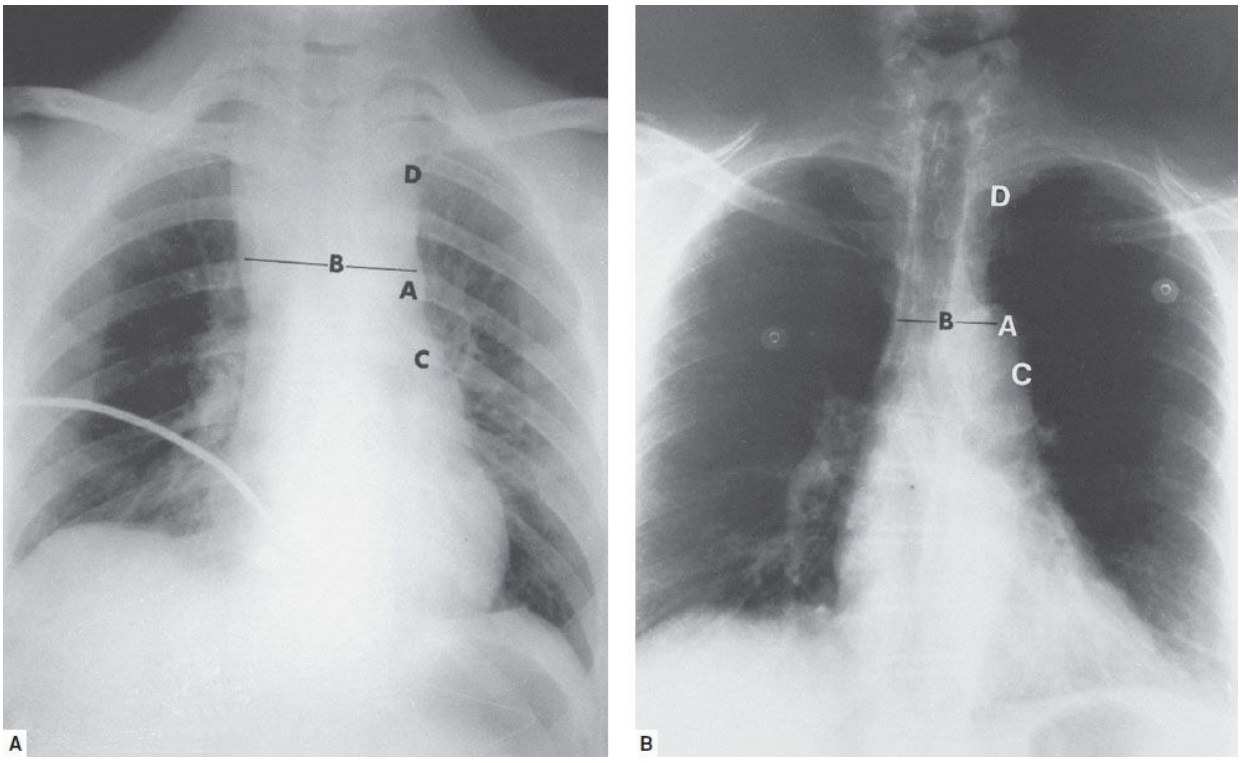


FIGURE 31.1 Upright posteroanterior chest radiographs of a 20-year-old man involved as a driver in a head-on motor vehicle collision (A) compared with that of a normal person (B). The first radiograph has several abnormalities suggestive of a great vessel disruption. A: Loss of detail of aortic knob with blurring of the aortic

outline. B: Widened mediastinum (mediastinal width to chest width ratio >0.28). C: Opacification of the clear space between the aorta and pulmonary artery (aortopulmonary window). D: Obliteration of the medial aspect of the left upper field. The aortogram revealed rupture of the aortic arch. (Radiographs courtesy of the Department of Radiology, St. Luke's Hospital, Milwaukee, WI.)

eTABLE 31.1
Radiographic Features of Great Vessel Injury

Widening of the superior mediastinum at the level of the aortic knob on an upright radiograph
Mediastinal width–chest width ratio of more than 0.25
Deviation of the trachea or endotracheal tube to the right
Deviation of the nasogastric tube (representing the esophagus) to the right
Narrowing of the carinal angle
Depression of the left mainstem bronchus
Irregularity of the aortic knob contour
Left apical cap
Opacification of a clear space between the aorta and pulmonary artery ("aortic pulmonary window")
Widening of the left or right paraspinous stripe
Hemothorax, sternal, or rib fractures

CT scanning of the chest with contrast has become the procedure of choice when the diagnosis of mediastinal great vessel injury is considered, with reported sensitivity and specificity of 96% to 100% and 98% to 100%, respectively (22,23). An added benefit to CT is the detection of other thoracic injuries. Furthermore, CT is noninvasive and can be completed in a short period of time. Contrast-enhanced CT of the chest should be performed in those patients who have any findings on chest x-ray associated with traumatic aortic injury, are hemodynamically stable, and have sustained significant acceleration–deceleration blunt-force chest trauma such as high-speed motor vehicle collisions or falls from a significant height. Positive criteria for the diagnosis of great vessel

injury include periaortic hematoma, an irregular aortic contour, change in caliber of the aorta, and intraluminal irregularity (intimal flap).

Transesophageal echocardiography (TEE) is reported to have a sensitivity and specificity comparable to helical CT in the diagnosis of blunt aortic injury (23). In contrast to CT, TEE can be performed at the bedside in an unstable patient. However, in contrast to helical chest CT, its availability is limited in most EDs. TEE may be performed in an ICU setting or the operating room to diagnose aortic injury in unstable patients and those with other life-threatening injuries. This technique is contraindicated in patients with esophageal injury or unstable cervical spine injuries.

Aortography was once considered the gold standard for making the diagnosis of traumatic aortic injury, but it is now only used in a small number of cases with equivocal findings on helical CT, when planning the surgery in some selected cases, and interventional radiographic endovascular stenting is being increasingly used to treat patients with aortic injury (24).

Diaphragmatic Injuries

An immediate chest x-ray should be obtained when blunt traumatic rupture of the diaphragm is suspected by the clinical examination (i.e., decreased or absent breath sounds on the involved side, bowel sounds audible in the chest, severe respiratory distress), and the patient has sustained major blunt-force trauma to the lower chest or upper abdomen. In most instances of blunt traumatic rupture, the left hemidiaphragm is not visualized on the radiograph, and stomach or bowel is often visualized in the left hemithorax. Small diaphragmatic tears may not be obvious on initial chest x-ray but may be diagnosed with contrast-enhanced abdominal CT.

Esophageal Injuries

The presence of particulate matter in chest tube drainage as well as the presence of pneumomediastinum should lead the physician to consider esophageal perforation. This diagnosis has a very high

morbidity and mortality if not recognized early and treated aggressively. When this diagnosis is suspected, it is imperative to move rapidly to a definitive diagnostic study to rule out this entity. The choice of the initial diagnostic procedure is somewhat controversial and is dependent upon the suspected injury. Some authors advocate esophagography, and others advocate esophagoscopy. Contrast esophagography has the disadvantage of potentially introducing contrast material into the mediastinum or peritoneum. Therefore, this study should first be performed with a water-soluble contrast material (i.e., Gastrografin), which has a much lower risk of mediastinitis or peritonitis than does barium. However, care should be taken in patients at risk for aspiration, as the entry of water-soluble contrast into the tracheobronchial tree can lead to pulmonary edema. If this study is negative, it can be followed by esophagoscopy, because Gastrografin will not obscure visualization of the lining of the esophagus. Ultimately, a barium esophagram may be needed to detect the presence of very small perforations.

Traumatic Asphyxia

Because these patients can sustain rib fractures and pulmonary contusions, one should consider chest CT to evaluate these injuries. Also, any patient with a neurologic deficit should have a CT of the head.

KEY TESTING

Test	Indication
ABG	• Pulmonary contusion for risk stratification
Troponin	• Suspected cardiac contusion
EKG	• Suspected cardiac contusion
Bedside ultrasonography	• Suspected pneumothorax or hemothorax
	• Suspected pericardial effusion
	• Rib Fracture 9–11 to assess for hemoperitoneum
Echocardiography	• Suspected valvular injury
	• Suspected injury to ventricular or atrial septum
Chest x-ray	• Focal tenderness
	• Chest wall crepitance
	• Pain with lateral or AP compression of the chest
	• Hypoxia
	• Absent or decreased breath sounds unilaterally
	• Paradoxical chest movement
	• Ejection from a motor vehicle
	• Falls >10 ft
	• Lack of Seatbelts
	• MVC at speeds greater than 30 mph
Chest CT	• Suspected pulmonary Contusion on CXR
	• Major mechanism accident
	• Ejection from a motor vehicle
	• Falls >10 ft
	• Lack of seatbelts
	• MVC at speeds greater than 30 mph
Esophagram	• Suspected esophageal injury
CT head	• Traumatic asphyxia with focal neurologic deficit
Bronchoscopy	• Continued air leak despite adequate chest tube placement
Aortogram	• Mediastinal hematoma on CT
	• Aortic irregularity on CT

ED MANAGEMENT

Chest Wall Injuries

Chest wall contusions and rib fractures with no underlying pulmonary parenchymal injury should be managed with adequate analgesics as well as careful aftercare instructions encouraging the patient to cough and deep breathe every hour while awake to

prevent the complications of atelectasis and subsequent pneumonia. Patients may be discharged with a spirometer to aid them in following these instructions. Consideration can be given to regional nerve blocks for multiple rib fractures, but these may only give significant pain relief for up to 12 hours. Admission, for pulmonary toilet and pain control, should be considered in the elderly especially those over 65 with rib fractures (3).

Flail Chest

Pain can be controlled with administration of narcotics, regional nerve blocks, or in severe cases, epidural anesthesia. Intubation should be considered if there is respiratory distress or ventilatory failure as manifested by a partial pressure of arterial oxygen (Pao_2) of <60 mm Hg on a nonrebreather bag reservoir mask at sea level or low oxygen saturation. In elderly patients with flail chest, the physician should have a lower threshold for intubation, as the patients' cardiac and pulmonary reserves are limited.

Sternal Fractures

Patients with suspected sternal fractures should have a standard posteroanterior (PA) and lateral chest x-ray. The lateral chest x-ray is the best view to determine if a fracture is present.

Pulmonary and Pleural Injuries

Tension pneumothorax, pneumothorax, and hemothorax should be treated emergently with tube thoracostomy (see Chapter 32). Patients with clinical evidence of tension pneumothorax should undergo immediate chest decompression prior to chest x-ray. Although this can be performed with a 14- or 16-gauge needle, in up to 30% of patients a standard needle will not reach the pleural space in the anterior second intercostal space and up to 18% of patient it will not reach the pleural space in the midaxillary line (25). Therefore, preference should be given to rapid decompression of the chest in the midaxillary line with eventual placement of a 28- to 36-French chest tube for adults or a 16- to 24-French chest tube for

children. Alternatively clinicians can also place a pigtail catheter (26,27). Small (<15%), simple pneumothoraces or those visualized on CT only (occult pneumothorax) can often be observed and treated without thoracostomy (15). Patients with occult pneumothorax who will undergo transfer in an ambulance or helicopter are at risk for development of a larger pneumothorax (or tension pneumothorax), clinicians should consider tube thoracostomy. Although positive-pressure ventilation was once considered an absolute indication for tube thoracostomy, there exist more recent literature suggesting that it may be possible to observe patient with occult pneumothorax (28).

Patients with pulmonary contusions should be placed on continuous, high-flow oxygen via a nonrebreather bag reservoir mask, and their oxygen saturation should be continuously monitored. Patients with more severe injury can undergo a trial of noninvasive positive-pressure ventilation; however, those patients who exhibit falling oxygen saturations or hypercarbia should be considered for rapid sequence intubation (RSI) and positive-pressure ventilation (6). Independent lung ventilation with low tidal volume and positive end-expiratory pressure (PEEP) has been reported to be efficacious in the treatment of unilateral pulmonary contusions.

Patients with an initial thoracostomy tube output of >20 mL/kg or an ongoing blood loss of >7 mL/kg/h are candidates for operative thoracotomy.

Tracheal and Bronchial Injuries

In a patient who clinically has a major airway disruption or problems maintaining adequate oxygen saturation, endotracheal intubation should be performed. In some instances, selective intubation of the nontraumatized mainstem bronchus is indicated. All tracheobronchial lacerations and disruptions require a surgical consultation, further diagnostic studies (bronchoscopy), and definitive management.

Blunt Cardiac Injuries

All patients should be on oxygen and monitored for dysrhythmias. Any dysrhythmias should be treated per advanced cardiac life support (ACLS) guidelines. Care must be taken not to fluid overload patients with myocardial contusion as their compromised cardiac output may lead to pulmonary edema. Patients who remain hemodynamically compromised after adequate volume resuscitation may benefit from pressor support with dobutamine. Unstable patients with pericardial tamponade require pericardiocentesis or ED thoracotomy. Patients with abnormalities detected on echocardiography such as chordae tendineae or valvular disruption should be referred to a cardiac surgeon for definitive repair of these lesions. In those rare instances where blunt cardiac trauma results in myocardial infarction from intimal disruption and thrombosis of the coronary artery, patients should undergo emergency angioplasty because the use of thrombolytics is contraindicated. The last option for refractory cardiogenic shock is placement of an intra-aortic balloon pump. The prognosis for patients with blunt cardiac trauma is most closely correlated with the severity and number of other associated injuries, as most patients who have an isolated myocardial contusion do well.

Great Vessel Injuries

In patients in whom a traumatic aortic injury is strongly suspected or proven via CT scan of the chest, blood pressure should be controlled via the use of a β-blocker (usually intravenous [IV] esmolol) and an afterload-reducing agent (usually IV nitroprusside) (13). β-blocking agents are usually started first. The objective of lowering blood pressure is to decrease the shearing forces of the pulse pressure, thus decreasing the possibility of free rupture. Using nitroprusside without a β-blocking agent may result in a reflex tachycardia and increased intraluminal pressure. The systolic blood pressure should be maintained between 100 and 120 mm Hg with a heart rate of 55 to 65 beats/min. In patients with bleeding and associated hypotension, judicious resuscitation to a mean arterial pressure between 65 and 80 mm Hg is adequate. All patients must be emergently referred for definitive therapy. Although all of these

patients have traditionally been treated surgically, endovascular stent placement using interventional radiographic techniques has been used successfully as well; it appears to have a lower risk of complications, and in some centers it has replaced open thoracotomy for the repair of aortic injuries. The decision on which therapy is best for the individual patient should be made in consultation with a surgeon and interventional radiologist. Many patients with aortic injury have associated life-threatening injuries that require management before repair of the aorta.

Diaphragmatic Injuries

A nasogastric tube should be placed and emergent surgical consultation for operative repair of the diaphragm should be obtained. Some of these patients may require RSI intubation, sedation, and mechanical ventilation if there is significant respiratory compromise. Unstable patients with tension viscerothorax should undergo careful tube thoracostomy placement. It is advisable to place the thoracostomy tube at a higher intercostal space to avoid injury to the bowel or introduction of the tube below the diaphragm.

Esophageal Injuries

Once the presence of an esophageal injury is confirmed by a contrast study of the esophagus or by esophagoscopy, surgical consultation for definitive surgical repair and drainage should be obtained to minimize the subsequent morbidity and mortality of this lesion. IV antibiotics should be administered preoperatively.

ED Thoracotomy

For patients with blunt trauma who sustain cardiac arrest prior to arrival in the ED, an ED thoracotomy is a futile procedure. Those patients who arrest after arrival in the ED and undergo ED thoracotomy have a 1.4% survival rate and thus are potential candidates for ED thoracotomy. Patients with isolated cardiac or pulmonary injuries have the best chance of survival after ED thoracotomy (29).

CRITICAL INTERVENTIONS

- Perform tube thoracostomy immediately for patients with clinical signs of tension pneumothorax or massive hemothorax (decreased breath sounds or subcutaneous emphysema in association with hypotension, tachycardia, and absent breath sounds).
- Obtain an ECG in patients with a mechanism consistent with potential myocardial contusion.
- Obtain an echocardiogram in unstable patients with clinical signs of cardiac failure to detect pericardial tamponade and valvular or chordae tendineae disruption.
- Administer esmolol, then nitroprusside, to control blood pressure in patients in whom a traumatic aortic injury is strongly suspected or proven by CT scan.

DISPOSITION

Patients with contused ribs and isolated rib fractures may be discharged from the ED. Patients should be instructed to return if they develop any increasing shortness of breath, fever, chills, cough, or other new symptoms. Patients with multiple rib fractures should be admitted for continued monitoring, observation, and, in some selected circumstances, consideration of epidural anesthesia for pain. In particular, elderly patients with rib fractures should be admitted for pain control and appropriate management to prevent pulmonary complications.

All patients with flail chest should be admitted to the hospital and carefully monitored via continuous oxygen saturation for an evolving pulmonary contusion, which almost always accompanies this injury. In addition, these patients have significant pain and usually require parenteral analgesics and consideration of regional or epidural nerve blocks.

Patients with fractures of the sternum sometimes need admission for analgesics because of associated injuries to the bony thorax and intrathoracic cavity. If the fracture is displaced, surgical reduction may be required. However, patients with isolated nondisplaced

sternal fractures may be discharged after appropriate measures have been taken to rule out the presence of other thoracic injuries.

Patients with pneumothorax, hemothorax, hemopneumothorax, and tension pneumothorax should be admitted to the appropriate inpatient surgical service for continued observation and treatment. Most patients with a pneumothorax and hemothorax only require a tube thoracostomy and do not require subsequent thoracotomy. However, in those patients in whom active, continued bleeding occurs or a persistent air leak is present, additional studies and surgery may be necessary.

All patients with a suspected or proven pulmonary contusion should be admitted to the hospital for continued monitoring and treatment because most pulmonary contusions will gradually worsen over the first 24 hours.

Patients with tracheal and bronchial injuries must be admitted and often require surgical repair if the injuries do not spontaneously resolve.

Patients who have sustained blunt anterior chest trauma, who have no associated injury necessitating admission, and who have a normal ECG may be discharged from the ED. The prognosis of patients with blunt cardiac injury is related to the magnitude of the initial trauma, the preexisting condition of the heart, the size and location of the cardiac injury, and the patient's other traumatic injuries; thus, those who are elderly or have coronary artery disease, significant dysrhythmias, a positive troponin, or any new abnormality on an ECG should be admitted for continuous monitoring for 12 to 24 hours. Patients with operable blunt trauma to the heart, such as myocardial and valve rupture or acute pericardial tamponade, need early and aggressive cardiac surgical treatment.

Traumatic disruption of the great vessels is potentially immediately life threatening; as soon as the diagnosis is suspected or confirmed, trauma or vascular surgery and interventional radiology should be consulted. After other more immediate life threats have been treated, these lesions should receive definitive surgical or interventional radiographic repair.

All patients with diaphragmatic injuries must be admitted to a trauma surgeon for definitive repair of the tear in the diaphragm as well as repair of associated intra-abdominal and intrathoracic injuries that often accompany these injuries.

Patients with confirmed esophageal perforation require antibiotics, admission, and immediate surgical consultation. Patients should be transferred to an appropriate surgeon and facility if resources for this definitive management are not available.

Those patients who have sustained traumatic asphyxia but have no evidence of significant chest wall, intrathoracic, or neurologic injury may be discharged home. Those patients with associated intrathoracic or neurologic injury should be admitted for continued observation and treatment.

Patients who must be transferred to another trauma facility for definitive treatment or critical care management should undergo a chest x-ray prior to transfer. Tube thoracostomy should be performed prior to transfer in patients with pneumothorax, hemothorax, or those with an occult pneumothorax detected only by CT. Patients with significant chest wall trauma or flail chest, especially the elderly, should be intubated prior to transfer. Any BCT patient with suspected aortic injury should be transferred to a trauma center.

Common Pitfalls

- Failure to appreciate a serious deceleration mechanism of injury.
- Failure to recognize the potential morbidity of rib fractures in the elderly.
- Delaying transfer of a patient to an appropriate level trauma center for definitive management of aortic injury.
- Failure to consider esophageal perforation in any patient with mediastinal emphysema.
- Insertion of a chest tube into an abdominal viscus in patients with a ruptured diaphragm.
- Overzealous fluid administration in patients with pulmonary or myocardial contusions.
- Failure to provide adequate analgesia and pulmonary care to patients with rib fractures, leading to the development of

atelectasis and pneumonia.

CHAPTER 32

Penetrating Chest Trauma

Stephen J. Wolf

Although it is occasionally the result of mechanical accidents or impalements, penetrating trauma to the chest is often the result of interpersonal violence. Given the nature of the weapons encountered in the civilian population, injuries will typically be limited to tissues within the direct course of the penetrating implement. In military settings, penetrating trauma generally results in tissue injury as a result of transmitted compression waves or the formation of temporary cavities that are associated with higher-energy ballistics. These are all distinct from the shear injuries caused by acceleration–deceleration mechanisms and from the contusions and crush injuries resulting from forces dispersed about large contact areas, as seen in blunt thoracic trauma.

CLINICAL PRESENTATION

Pneumothorax

A common injury in penetrating thoracic trauma, *pneumothorax* is the collection of air in the potential space between the parietal and visceral pleura. The precise incidence varies across series and is largely dependent upon mechanism but has been reported to be significantly more common in penetrating trauma than blunt trauma (1). The clinical presentation depends on the patient's overall condition as well any underlying illnesses. Although multiply injured patients or those with decreased mentation may not report cardiopulmonary symptoms, the typical presentation includes pleuritic chest pain, dyspnea, and air hunger. Physical examination

may reveal tachypnea, tachycardia, and hypoxia, as well as the classic findings of decreased breath sounds and hyperresonance to percussion. Vital signs may deteriorate as the size of the pneumothorax increases. *Simple* pneumothoraces—confined collections of air within the pleural space—often result from direct injury to the pulmonary parenchyma and escape of air from bronchioles and alveoli. It has traditionally been thought that simple pneumothorax is likely to progress in the setting of positive-pressure ventilation, although the frequency of this occurrence has since been questioned. *Open* pneumothoraces result from an injury mechanism that creates a continued external communication to the pleural space. If the chest wall defect affords less resistance than the upper airways, air moves preferentially through the defect and gas exchange is impaired. *Tension* pneumothorax results from an expanding collection of intrapleural air. In the setting, increased intrathoracic pressures result in pulmonary collapse on the ipsilateral side first through direct pressure, then the contralateral side through mediastinal shifting. As a result tidal volume is compromised considerably. Ultimately, there is a significant decrease in venous return due to the compressive forces with resultant decreased cardiac output. Simple or open pneumothorax may progress to this grave clinical state if air continues to enter the pleural space from an external or bronchopulmonary source and is unable to escape. Clinical findings may include progressive tachypnea and tachycardia with hypotension and hypoxia. Physical examination may reveal jugular venous distention and absent breath sounds ipsilaterally. Tracheal deviation is a late finding and suggests impending cardiopulmonary collapse.

Tracheobronchial Injuries

Most tracheobronchial injuries occur superior to the thoracic inlet within the cervical trachea, where this structure is more superficial and in a relatively unprotected position. Although blunt trauma is a more common cause of tracheobronchial injuries, a penetrating mechanism is often associated with injury to other vital mediastinal structures (2). Pneumomediastinum is frequently seen and may be

associated with pleuritic chest pain, dyspnea, or Hamman sign—a "crunching" sound on cardiac auscultation. Other concerning clinical presentations are hemoptysis or an air leak from a penetrating neck wound. Injury to a bronchus may lead to a bronchopulmonary fistula and pneumothorax. In this case, tube thoracostomy reveals a large air leak and may exacerbate respiratory distress because of an increased loss of inspired air (2). Concomitant disruption of a bronchus and a major vessel may result in venous air embolism.

Hemothorax

Hemothorax is a common finding in penetrating thoracic trauma and is often associated with pneumothorax. Direct injury to intercostal vessels, pulmonary parenchyma, mediastinal structures, great vessels, and the internal mammary artery are possible etiologies. The presentation is occasionally subtle, with no associated pneumothorax and minimal associated blood loss. More significant injuries result in respiratory distress and symptoms consistent with hemorrhagic shock or tension physiology, as up to 1.5 L of blood can accumulate in the hemithorax. Physical examination may reveal abnormal vital signs, dullness to percussion, and diminished breath sounds dependently. The presence of these findings has an excellent positive-predictive value for hemothorax in penetrating trauma, but physical examination has been demonstrated to be insensitive for this injury, and the absence of these findings does not exclude a clinically significant hemothorax (1).

Mediastinal Injuries

The mediastinum has a dense arrangement of critical structures, and penetrating trauma to this anatomic region can result in profound injury. The presentation may vary from only local physical complaints to full traumatic arrest. Penetrating mediastinal injury holds the potential for serious delayed complications.

Esophageal Injuries

The majority of penetrating injuries to the esophagus occur in the cervical region (see Chapter 27, Penetrating Neck Trauma). Thoracic esophageal injuries may present with subtle clinical findings yet can potentially progress rapidly to mediastinitis. The clinical presentation is often dominated by injuries to adjacent vital structures, but isolated esophageal injuries may produce odynophagia, dysphagia, and hematemesis. Progression to mediastinitis is associated with fever and worsening chest pain over time. Physical examination frequently reveals no specific findings of esophageal injury, but Hamman sign is classically described.

Cardiac Injuries

Penetrating wounds to the heart are commonly fatal. The majority of patients sustaining these injuries are hemodynamically unstable as a result of hemorrhage, cardiac tamponade, or a mixed pathophysiology. Up to 80% of cardiac stab wounds present with cardiac tamponade, but the majority of critical patients with cardiac gunshot wounds present in hemorrhagic shock (3). The specific location of the cardiac injury, as well as the presence or absence of associated injuries to the great vessels and pericardium, determines the course of the disease. Because of the position of the heart within the chest, the right side of the heart is most often injured (ventricle > atria), followed by the left-sided chambers (ventricle > atria). Major coronary arteries are also at risk for injury, presenting with regional electrocardiographic abnormalities, dysrhythmias, tamponade, or hemothorax. Cardiac injuries associated with defects in the pericardium that are small or effectively obstructed by epicardial fat or clot are more likely to progress to tamponade physiology, and injuries of the higher pressure chambers are associated with a more rapid progression to clinical instability. Hemorrhage of as little as 50 to 100 mL into the pericardium may result in decreased stroke volume and cardiac output. Tachycardia and hypotension are common in both hemorrhage and tamponade, but the patient with cardiac tamponade may demonstrate a pulsus paradoxus and jugular venous distention. A small proportion of patients may be hemodynamically stable at presentation, with only

local symptoms and without evidence of cardiopulmonary compromise.

Great Vessel Injuries

Although only a minority of victims of penetrating thoracic trauma sustain injuries to the great vessels, up to 90% of injuries to the major thoracic vessels are the result of penetrating trauma (4). The associated mortality rate has been reported to be as high as 92%, with poorer outcomes associated with delayed recognition (5). In contrast to blunt mechanisms, most injuries are to the subclavian vessels, with associated mortality rates of 65% (4). Thoracic aortic injuries carry a high rate of associated vascular and nonvascular injuries. The clinical presentation depends on the degree of vascular disruption and the tissues supplied by the injured vessel, ranging from prehospital arrest to minimal local symptoms with a normal neurovascular examination.

Venous air embolism is an important complication of the disruption of any major vein that is in contact with a source of air. An example is a fistula between the pulmonary vein and a main bronchus. Valsalva or positive-pressure ventilation, may establish a pressure gradient that favors entry of air into the venous circulation, which then travels to the heart or more distal targets. In venous injuries other than those to the pulmonary vein, air emboli are confined to the right heart and pulmonary vascular bed in the absence of a preexisting right-to-left shunt. The presenting signs and symptoms may include hemoptysis, chest pain, evidence of end-organ ischemia (e.g., central nervous system deficits, myocardial ischemia), and cardiovascular collapse. Dramatic findings of “frothy” arterial blood gas samples and a machine-like murmur on auscultation have also been reported.

Diaphragmatic Injuries

Injury to the diaphragm must be considered in all thoracoabdominal gunshot wounds and in all stab wounds between the umbilicus and intermammary line anteriorly and up to the inferior tips of the

scapulae posteriorly. Suspected injury to the diaphragm mandates consideration of both intra-abdominal and thoracic pathology. Contrary to previous teaching, recent reports suggest that diaphragmatic injury may be more common in penetrating rather than blunt trauma, with an incidence as high as 42% in patients with penetrating wounds to the left thoracoabdominal region (6). Concomitant injuries—cardiothoracic, intra-abdominal, neurologic, and musculoskeletal, in decreasing frequency—are the norm. Herniation of intra-abdominal structures into the thorax is a complication of diaphragmatic injury and may occur acutely, subacutely, or even years after an identifiable traumatic insult. This delayed presentation occurs because of the difficulties in diagnosing diaphragmatic injury, as well as the poor rate of healing of diaphragmatic defects because of the pressure gradient across this structure.

In an acute traumatic injury to the diaphragm, the clinical presentation is most often dictated by associated injuries to adjacent thoracoabdominal structures but may be associated with minimal symptoms. Referred shoulder pain may be reported, as well as respiratory distress from herniation of abdominal contents into the left hemithorax. There may be ausculatory findings of decreased breath sounds or borborygmi in the chest. A large herniation may result in a tension viscerothorax (shift of the mediastinum and hemodynamic collapse) and may be difficult to distinguish from tension pneumothorax.

The delayed presentation of diaphragmatic injury is associated with upper abdominal pain occasionally radiating to the shoulder. The signs and symptoms vary depending upon the segment of hollow viscus that has herniated. Classic signs and symptoms of bowel obstruction develop only with distal small bowel and colonic herniation. Delayed recognition and development of strangulation or incarceration is associated with significant morbidity and mortality.

DIFFERENTIAL DIAGNOSIS

The initial differential diagnosis in penetrating chest trauma is broad. Simple pneumothoraces are frequently detected; they are associated

with local symptoms and may produce respiratory distress. Progression to tension pneumothorax is associated with worsening respiratory difficulty, hemodynamic instability, and the late finding of tracheal deviation. Findings of immobility of the chest wall, decreased breath sounds, and hyperresonance to percussion may aid in the diagnosis. Hemothorax, which often accompanies a pneumothorax, should be suspected when significant dullness to percussion is appreciated in the dependent portions of the thorax. Significant hemothorax can be associated with hemodynamic compromise and hemorrhagic shock.

Tracheobronchial injuries are most common with concomitant penetrating injuries to the neck or with missile trajectories that pass into the cervical region. Suspicion for this condition may be increased by findings consistent with pneumomediastinum (Hamman sign), hemoptysis, or a large persistent air leak after chest tube placement. Injuries to the mediastinal esophagus may also be associated with a “crunching” sound on cardiac auscultation but are likely to result in hematemesis or bloody output from suctioning of oral secretions or from a gastric tube.

Cardiac tamponade is classically associated with Beck triad of hypotension, jugular venous distention, and muffled heart sounds. Beck triad is present in less than half of patients with tamponade, however. Detection of pulsus paradoxus may contribute to a bedside evaluation for suspected tamponade, but it lacks sensitivity and specificity and may be present in a number of cardiopulmonary disorders. In the patient with hemodynamic instability and the possibility of a transmediastinal injury, however, hemopericardium and tamponade remain the diagnostic entities of greatest concern.

The emergency physician must consider injury to structures outside the confines of the thoracic cavity. The dome of the diaphragm extends superiorly to the nipple line, placing this structure, as well as intra-abdominal structures, at risk for injury from penetrating trauma. Injuries to the vertebral spine and associated neurologic injury must be considered (see Chapter 30). Finally, it must be emphasized that the trajectory of missiles is

remarkably unpredictable; thoracic entry wounds may be associated with exit wounds in the abdomen, neck, and extremities.

ED EVALUATION

Physical Examination

Assessment begins with a primary survey of the airway, which is performed as continuous cardiac monitoring and pulse oximetry are instituted. Sinus tachycardia—although potentially secondary to pain—is a common and early finding in injuries causing hemodynamic compromise. The physician should direct attention to the thorax, noting chest wall asymmetry or the use of accessory muscles of respiration and listening for the presence and equality of breath sounds. Palpation of the chest wall may reveal crepitus, focal tenderness, or obvious instability. Thoracic wounds should not to be probed, as this is of uncertain diagnostic value and may cause further injury. Cardiac auscultation should be performed to discover muffled heart sounds or murmurs associated with direct cardiac injury. Jugular venous distention is an indicator of the elevated right-sided pressures seen in pericardial tamponade. Conversely, flat jugular veins are more consistent with hemorrhage and hypovolemia. A careful abdominal examination should also be performed, given the possibility of associated abdominal and diaphragmatic injuries. An extremity pulse deficit or focal neurologic deficits may indicate great vessel injury to the subclavian or common carotid arteries, respectively. Finally, there must be a thorough inspection to identify wounds to the thorax, abdomen, and extremities, as well as the axillae and gluteal cleft.

Unfortunately, physical examination is insensitive for hemo- and pneumothorax, and abdominal tenderness is reportedly lacking in a significant proportion of patients with documented diaphragmatic injury (1).

Chest Radiography

Chest radiography remains a critical tool in the evaluation of patients with penetrating thoracic trauma. An initial examination is most

often performed anteroposteriorly (AP), at the bedside, in a supine or sitting patient. This examination may reveal large hemo- or pneumothorax and may provide information regarding missile trajectory by showing the location of a foreign body relative to external wounds (as indicated by radio-opaque markers). At least 200 mL of blood must be present for a hemothorax to be reliably detected on this examination, and small pneumothoraces are commonly missed. Larger pneumothoraces may be detected by a "deep sulcus sign" in the costophrenic angle (Fig. 32.1), but a normal study offers little reassurance because up to 67% of traumatic pneumothoraces are missed with this technique (7). A traditional posteroanterior (PA) film with an accompanying lateral view has a higher diagnostic yield; expiratory views may help in detection of small pneumothoraces. Traditionally, a negative initial chest radiograph was repeated after 6 hours to rule out the development of pneumothorax. However, literature now supports using a 3-hour repeat chest radiograph, or an immediate computed tomography (CT), to exclude occult injury (8). CT is recommended for select cases of significant diagnostic uncertainty (9).

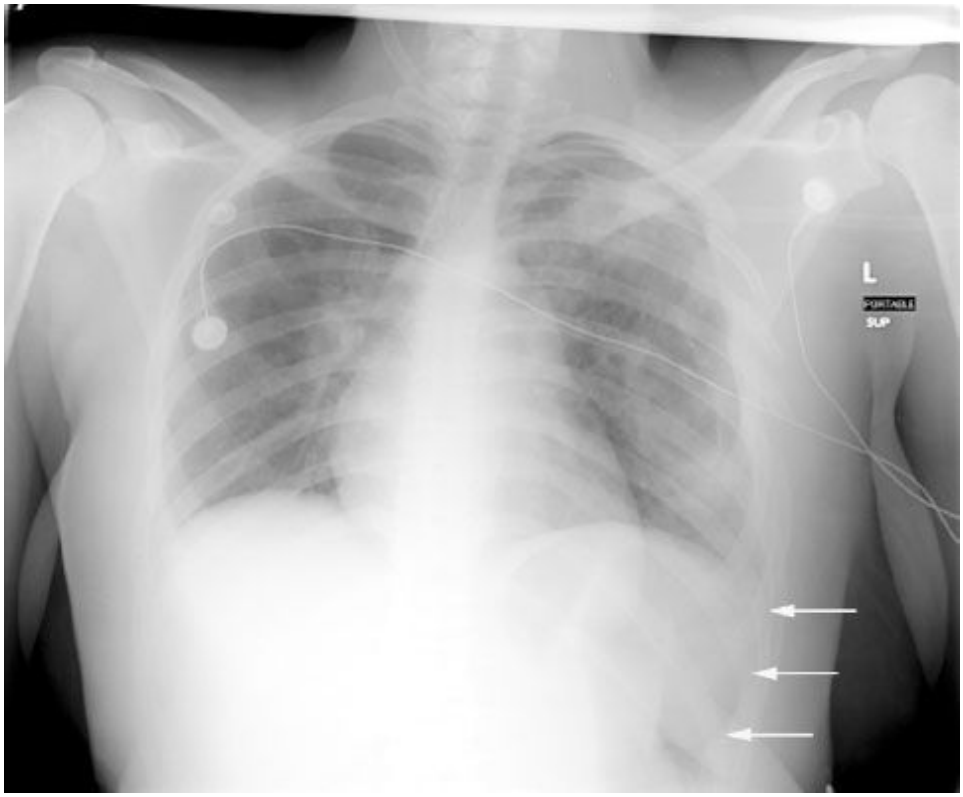

FIGURE 32.1 Chest radiograph. Portable, supine anteroposterior chest radiograph in a patient with thoracic trauma demonstrating a deep sulcus sign on the left. The relative lucency visualized over the left hemidiaphragm (indicated by white arrows) is suggestive of a pneumothorax. (Image courtesy of James F. Holmes, MD.)

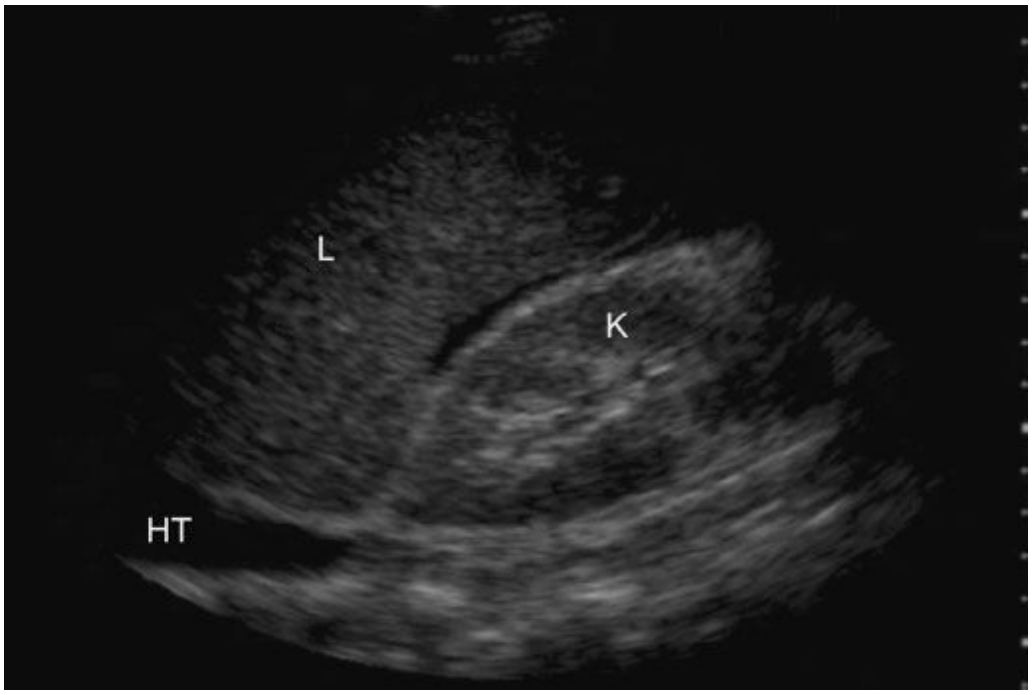
Ultrasonography

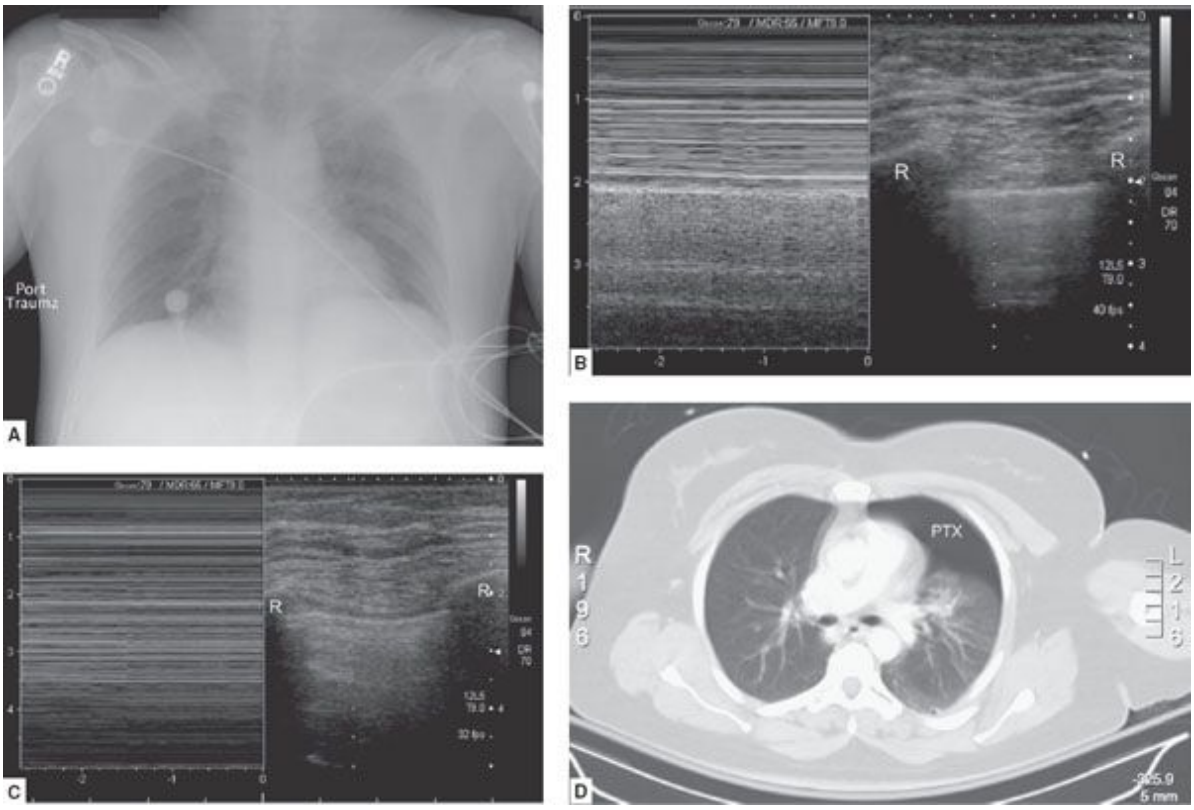
The *focused assessment with sonography in trauma* (FAST) provides the clinician with a rapid, noninvasive, repeatable diagnostic study that can detect intraperitoneal, intrathoracic, or pericardial fluid. The *extended FAST (eFAST)* examination is described to include evaluation for pneumothorax in addition. In unstable patients with injuries at or below the nipple line, or who have missile trajectories that cause concern for peritoneal violation, use of the FAST examination allows the clinician to determine whether hemorrhage into the peritoneum is responsible. Furthermore, bilateral upper quadrant windows visualize the most dependent portions of the

thorax (eFig. 32.1) and provide greater sensitivity than chest radiography for the detection of hemothorax (10).



eFIGURE 32.1 Focused assessment with sonography in trauma (FAST). Right upper quadrant coronal plane imaging liver (L) and right kidney (K) with anechoic wedge of hemothorax (HT) visualized just cephalad, in the most dependant portion of the thorax. Morison pouch is also positive, with a small anechoic stripe present between the liver and kidney.

Bedside ultrasound is accurate in the detection of intrapleural air (7,11). It is of particular utility in identifying occult pneumothoraces —those not apparent on initial plain radiography but detected on serial plain films or subsequent CT. Small anterior pneumothoraces in the supine trauma patient are particularly at risk for going undetected on supine AP plain radiographs (eFig. 32.2).



eFIGURE 32.2 Chest radiograph (A) of a patient with thoracic trauma demonstrating left clavicular fracture but no evidence of pneumothorax. Bedside ultrasound during real-time imaging demonstrated the absence of pleural sliding and comet tail artifacts on the left anterior thorax. M-mode displayed to the left of each image: B: normal-appearing right thorax with a granular—or sandy—appearance deep to level of the pleural interface that courses between ribs (R). C: Note this granular appearance is lost on the left thorax, consistent with the presence of a pneumothorax. D: Chest CT confirming anterior pneumothorax.

An early bedside cardiac ultrasound allows for rapid evaluation for hemopericardium and some cardiac injuries. It has become the preferred initial diagnostic modality. Emergency physicians and trauma surgeons trained in the use of bedside ultrasound can detect hemopericardium (Fig. 32.2) with excellent sensitivity and specificity (12). As little as 20 mL of fluid may be detected on this examination, but the presence of epicardial fat, associated hemothorax, or clotted blood in the pericardial space may lower the specificity for less

experienced users. Nevertheless, the use of bedside ultrasound reduces the time to diagnosis and is associated with a reduction in morbidity and mortality associated with penetrating chest trauma (13).

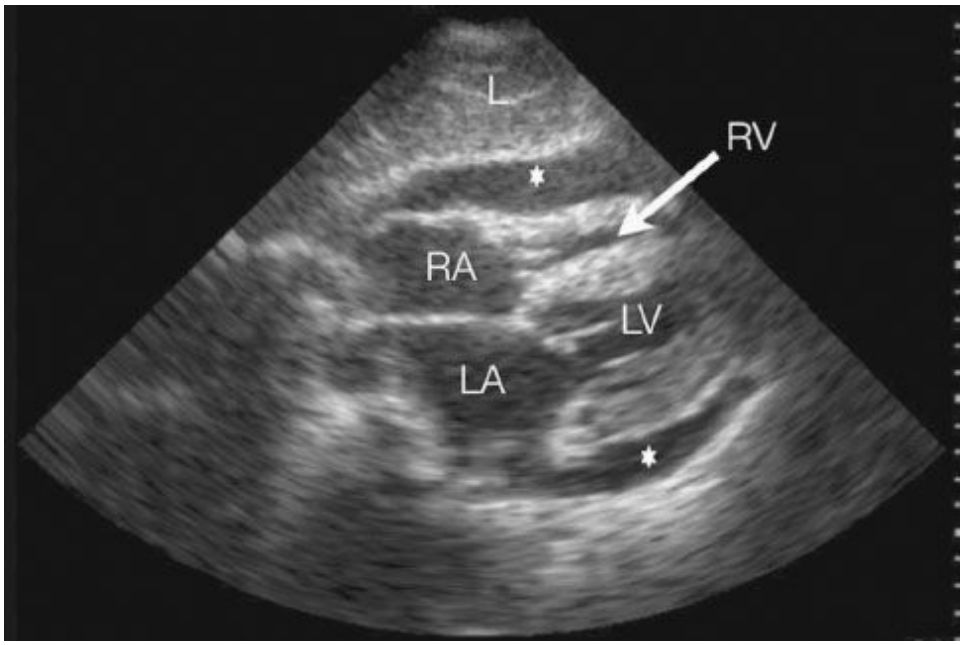


FIGURE 32.2 Cardiac ultrasound. Subxyphoid window imaging through acoustic window of the liver (L) demonstrating four-chamber view (RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle) and moderate, circumferential hemopericardium denoted by asterisks (*).

Limitations to the use of ultrasound in the setting of penetrating chest trauma include operator dependence, decreased sensitivity for small amounts of intraperitoneal free fluid, clotted hemorrhage, and inability to reliably assess for diaphragmatic or bowel injury.

Computed Tomography

Between 2006 and 2011, the use of chest CT scan in the evaluation of patients with penetrating thoracic trauma increased 3.5-fold (9). However, there is debate regarding its added benefit, particularly when balancing competing concerns of cost and radiation exposure against the benefit of diagnostic accuracy. When mediastinal

structures are not felt to be at risk, its conservative use is reserved for patients with abnormal chest radiography (initial or 3-hour repeat), serial physical examinations, or eFAST examination (9). In mediastinal penetrating trauma, authors propose that CT be used as an initial screening examination in hemodynamically stable patients (14).

While chest CT is excellent for the detection of hemo- and pneumothoraces, its role in other thoracic injuries remains to be defined. Esophageal and tracheobronchial injuries can be identified, as can some secondary findings suggestive of injury, but the sensitivity has not been established. Although hemopericardium is generally assessed with echocardiography, CT has been reported as an alternative diagnostic evaluation in the hemodynamically stable patient at risk for cardiac injury (15). Diaphragmatic injuries are inconsistently identified and evaluated on CT because of the position of the dome within the imaging plane.

Bronchoscopy

Bronchoscopy remains the diagnostic modality of choice for tracheobronchial injuries that are suspected because of pneumomediastinum, significant air leak on tube thoracostomy, persistent pneumothorax, hemoptysis or injuries to adjacent structures. Indirect signs of injury that may be identified on CT include chest wall discontinuity, endotracheal tube misplacement, paratracheal air, and pneumomediastinum. However, the overall sensitivity of CT for tracheobronchial injuries is unacceptably low.

Esophagography

Because of the profound morbidity and mortality associated with delayed recognition of esophageal injury, a high level of clinical suspicion must be maintained. Chest CT may identify direct evidence of esophageal injury, but its role in excluding injury or in precisely characterizing injury has not been established. When there are suggestive findings on physical examination, chest radiography, or CT, further evaluation may begin with esophagography. Because of

the potential for introduction of contrast material into the mediastinum, initial examinations should be performed with water-soluble contrast. This can be followed by barium contrast (at the discretion of the interpreting radiologist), if the initial study is negative.

Esophagoscopy

Identification and characterization of esophageal injuries may be accomplished with direct endoscopic visualization. The sensitivity of this examination approaches 100% and should be undertaken despite a negative contrast study when the pretest probability of injury is high.

Angiography

The gold standard for the diagnosis of great vessel injuries is contrast angiography. In the case of direct or indirect signs of injury on CT, angiography may be required to further characterize the defect in the aorta or other great vessels. Although transesophageal echocardiography has a role in blunt aortic injury and in detecting nontraumatic aortic pathology, it does not visualize the ascending aorta and major aortic branches well enough to make it as useful in penetrating thoracic trauma.

Diagnostic Peritoneal Lavage

With increased use of FAST and CT in the assessment of trauma patients, DPL is performed less and less frequently. Diaphragmatic injuries are detected with poor sensitivity when the traditional diagnostic threshold (100,000 RBC/mm^3 of lavage fluid) is used. Sensitivity is improved by decreasing the threshold to 5,000 RBC/mm^3, but some injuries will still be missed, and the rate of false-positive evaluations is higher.

KEY TESTING

- Pulse oximetry
- Hemoglobin/hematocrit

- Chest radiography
- eFAST
- Computed tomography of the chest (when indicated)
- Bronchoscopy (when indicated)
- Esophagography (when indicated)
- Esophagoscopy (when indicated)
- Angiography (when indicated)
- Diagnostic peritoneal lavage (when indicated)

ED MANAGEMENT

Patients with penetrating thoracic trauma often present in extremis, requiring rapid resuscitation with diagnostic and therapeutic interventions occurring in parallel. The clinician must be prepared to identify and effectively manage respiratory failure, cardiopulmonary collapse, tension pneumothorax, cardiac tamponade, and hemorrhagic shock.

Airway Management

Definitive airway management is indicated in a significant portion of patients presenting with penetrating thoracic trauma. Alteration of mental status, excessive secretions, or associated injuries to the face and neck may impair the patient's ability to protect the airway. Impending respiratory failures due to disturbance of chest wall mechanics, massive hemo- or pneumothorax, or cardiopulmonary collapse are also indications for endotracheal intubation. Other factors that may contribute to the decision to intubate include mental status depression, agitation, polytrauma, significant comorbidities or advanced age, hemodynamic instability, and the need for imminent operative intervention. Following intubation and the establishment of positive-pressure ventilation, the clinician must anticipate progression of any disease process associated with injury to the respiratory system. Simple pneumothoraces may progress to a tension pneumothorax, and airway injuries adjacent to venous disruptions may result in venous air emboli once sufficient pressure gradients occur.

Needle Decompression

Percutaneous decompression of the chest is indicated for a pneumothorax sufficient to cause impending respiratory failure or if there is hemodynamic compromise associated with tension physiology. This may be accomplished using a 14-gauge angiocatheter and is performed at the second intercostal space in the midclavicular line; the fourth or fifth intercostal space in the anterior to midaxillary line is an acceptable alternative and may be preferable based on body habitus. A rush of air confirms appropriate placement, although failure to reach the pleural space and kinking of the catheter after removal of the needle are both potential causes of a failed procedure. Alternatively, if the equipment is readily available, tube thoracostomy can be performed.

Tube Thoracostomy

In contrast to blunt thoracic trauma in which $<20\%$ of patients will require tube thoracostomy, up to 85% of patients with penetrating thoracic injuries will undergo this procedure (16). Successful performance of tube thoracostomy drains intrapleural air and blood, allowing for lung reexpansion and improved ventilation. It also provides an assessment of the degree of blood loss into this space and may decrease further blood loss via pressure applied to the source by the reexpanded lung parenchyma. The procedure is performed via a sterile incision in the fourth or fifth intercostal space in the midaxillary line, directing a 32- to 40-French catheter posteriorly toward the apex.

The complication rate for tube thoracostomy approaches 25% (17). Complications include improper placement into the pulmonary parenchyma, subcutaneous tissues, hilum, or intra-abdominal organs; failure to adequately drain intended collections; and infections such as empyema. Proper technique and maintenance of sterile technique will decrease this complication rate. Despite this over 3% of tube thoracostomies for penetrating chest trauma develop a posttraumatic empyema. A recent systematic review found that infectious complications are almost three times less likely to develop when

antibiotic prophylaxis is administered to patients with thoracic injuries requiring chest drains after penetrating injury (18). A first-generation cephalosporin should be used to target gram-positive organisms.

For isolated, simple pneumothoraces, there is increasing use of smaller bore thoracostomy tubes (28 to 32 French) as well as percutaneous catheter introduction kits. The latter may be placed anteriorly in the second intercostal space if the location of the pneumothorax and body habitus allow. Neither technique is appropriate for hemopneumothoraces, because maximal internal diameter is essential for adequate drainage in these scenarios.

Traditionally, massive hemothorax—defined as initial thoracostomy output of 1,500 mL, persistent output of 250 mL/h, or associated hemodynamic instability—has indicated operative thoracotomy. Persistent hemothoraces may be addressed by placement of a second tube thoracostomy. In the case of suspected organization of the hemorrhage, operative thoracotomy may be indicated. However, studies suggest thoracoscopy may provide an effective alternative associated with a shorter length of stay and decreased costs (19).

Pericardiocentesis

Pericardiocentesis is not an ideal diagnostic modality because of its poor test characteristics and the increasing availability of bedside ultrasound for detection of hemopericardium. Application of this procedure for therapeutic purposes in trauma is a temporizing measure, at best, and should be performed in coordination with aggressive resuscitation and preparation for definitive operative intervention. When possible, ultrasound guidance should be used to identify the maximal collection of blood and determine the appropriate needle course.

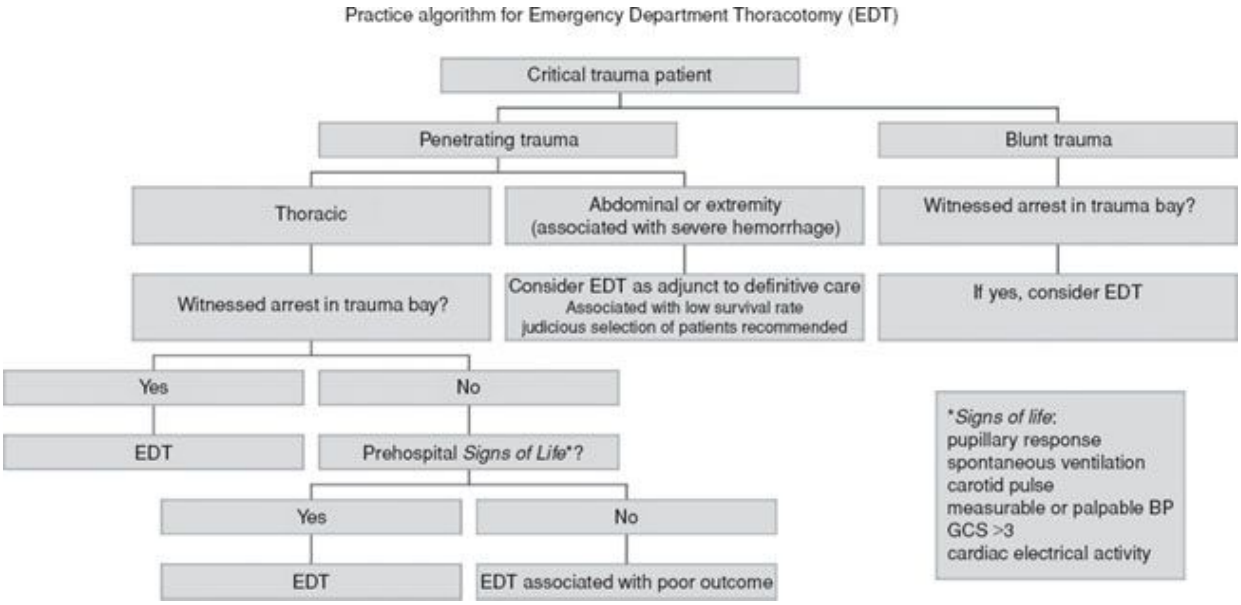
Central Venous Access

If the patient is persistently hypotensive or does not have sufficient peripheral venous access, then placement of a central venous

catheter may be necessary. Depending upon type and location of catheter placement, advantages include the ability to administer rapid resuscitative fluids as well as detection of the central venous pressure (CVP). In the event that bedside ultrasound is unavailable, an elevated CVP in an unstable patient with penetrating thoracic trauma also may support the diagnosis of hemopericardium and tamponade. If concern exists for great vessel injury, attempts at central venous access should be established via the femoral vein; otherwise placement should be established on the ipsilateral side to the penetrating injury to minimize the risk of additional injury to the lung.

Emergency Department Thoracotomy

Emergency department thoracotomy (EDT) is a potentially life-saving procedure utilized in moribund trauma patients. This procedure is historically associated with a poor rate of functional neurologic recovery. Furthermore, the procedure may place healthcare providers at risk for potential infectious exposure. The reported survival rates of EDT range from 1% to 35% in a recent report, with mechanism of injury and physiologic status of the patient strongly correlated with outcomes (20). The American College of Surgeons Committee on Trauma (ACS-COT) performed a comprehensive review of the literature on EDT, reporting survival rates of 7.8% overall and 11.2% in the setting of penetrating trauma (21). The highest rate of survival was documented in patients with penetrating cardiac injury (31.3%). Besides the type of injury, the patient's physiologic status during the prehospital course and upon emergency department presentation has a direct correlation with outcomes; those with witnessed signs of life in the ED have the greatest chance for survival following EDT (22,23). Despite this data, there is a lack of consensus on the indications for EDT. eFigure 32.3 presents a clinical approach consistent with the recommendations provided by the ACS-COT, considering mechanism and physiologic status of the patient.



eFIGURE 32.3 Practice guidelines for emergency department thoracotomy. (Adapted from recommendations by the American College of Surgeons Committee on Trauma (2).)

Several critical interventions are possible during a thoracotomy. After exposure is achieved, pericardiotomy should be performed to relieve tamponade. Delivery of the heart from the pericardium allows inspection and identification of cardiac injury. Direct pressure may be applied to control small, simple myocardial defects. More significant lacerations may be amenable to approximation with skin staples or pledgeted sutures. Extensive injuries may be challenging to approximate with these measures, and a Foley catheter may be placed through the defect into the corresponding cardiac chamber. After inflation of the catheter's balloon with saline, gentle traction may be applied in an attempt to prevent further hemorrhage as long as the inflated balloon does create an obstruction to chamber filling or cardiac output. This technique should be performed as a temporizing measure. Completion of a purse string suture may be attempted around the catheter and tightened concurrently with deflation and removal. Definitive repair then occurs in the operative suite.

Noncardiac intrathoracic injuries may be directly addressed via EDT. Significant arterial bleeds may be controlled with direct

pressure or vascular clamps. In the event of severe pulmonary parenchymal destruction, hemorrhage, or venous air embolism, the hilum may be clamped pending definitive repair. The descending aorta may be cross-clamped to address distal hemorrhage in polytrauma patients, increasing afterload and cardiac and cerebral perfusion.

Resuscitation may be continued once EDT has been performed. Internal cardiac massage provides more effective circulation than external, closed cardiopulmonary resuscitation (CPR) and should be initiated after delivery of the heart from the pericardium. Direct defibrillation or cardioversion may also be performed using internal paddles. Intracardiac administration of resuscitation medications is an acceptable alternative and likely offers improved drug delivery compared to peripheral intravenous access. If central venous access has been established, drug administration via this route is equally acceptable and avoids introduction of another sharp instrument into the field.

Mediastinal Injuries

The evaluation of suspected mediastinal injuries has traditionally involved an investigation including chest radiography, esophagography and esophagoscopy, aortography, and bronchoscopy, given the morbidity associated with delayed diagnosis of injuries to these structures and the frequent absence of localizing signs and symptoms on presentation. The potential for more selective evaluation using chest CT as a screening modality was discussed previously.

Tracheobronchial injuries are often managed nonsurgically with endotracheal intubation and broad-spectrum antimicrobials including anaerobic coverage. Careful consideration of the nature of the injury, patient condition, and associated delayed complications are factors in determining the need for urgent operative intervention.

Suspected esophageal injuries should be treated with early antimicrobial therapy—broad spectrum, including anaerobic coverage—in an attempt to prevent the complication of mediastinitis. The diagnosis is based on contrast or endoscopic examinations.

Operative intervention follows adequate characterization of the injuries.

Penetrating trauma with injury to the aorta or great vessels often manifests during the initial assessment and resuscitation, with evidence of abnormal vascular examinations or hemodynamic collapse. In cases necessitating EDT, the source of hemorrhage may be identified directly, guiding further management. Great vessel injury can be controlled locally with vascular clamps pending operative repair. Patients with aortic or great vessel injuries identified by or suspected on physical examination or cross-sectional imaging often require evaluation with angiography, as the role of CT angiography has yet to be defined as a definitive diagnostic modality. Open, operative repair remains the standard approach, although the application of endovascular techniques is reported in traumatic injuries to the thoracic aorta and great vessels (24).

Diaphragmatic Injuries

Management of penetrating wounds to the diaphragm is particularly challenging in the diagnostic phase. Herniation of abdominal contents into the thorax and tension gastrothorax may be identified in the resuscitation bay. The physician should consider diaphragmatic injury in the right clinical situation and be careful when performing tube thoracostomy to avoid intraperitoneal placement. However, diaphragmatic injury with herniation of abdominal contents is far more common after blunt trauma or as a delayed presentation after penetrating injury. Because of the difficulties in accurate diagnosis as described previously, definitive diagnosis may require laparoscopy or thoracoscopy. In the setting of penetrating trauma to the left thoracoabdominal region and nondiagnostic imaging, laparoscopy is the preferred diagnostic modality. This technique may also allow minimally invasive repair (25).

CRITICAL INTERVENTIONS

- Perform rapid primary and secondary surveys, including complete exposure and thorough inspection for wounds.
- Decompress tension pneumothoraces immediately—without radiographic confirmation—by needle thoracostomy or standard tube thoracostomy.
- Perform early endotracheal intubation using Rapid Sequence Intubation (RSI) in patients with hemodynamic instability, impending respiratory failure, depressed mental status, or multiple trauma.
- Perform tube thoracostomy in a patient with a small pneumothorax who will undergo positive-pressure ventilation or transfer in an aircraft.
- Perform an emergency department thoracotomy on any patient with a chest stab wound who loses vital signs en route to the ED or in the trauma bay.

DISPOSITION

While many patients with penetrating thoracic trauma are admitted to the hospital, those with isolated stab wounds to the chest who have a negative initial evaluation may be observed in the ED. If repeat chest radiography is negative at 3 hours after initial examination in a patient who remains asymptomatic and has normal vital signs, pneumothorax can be excluded, and the patient can be discharged home with follow-up within 48 hours (9). Patients with identified hemo- or pneumothoraces should be admitted. In the case of small, simple pneumothoraces, these patients may be observed with cardiopulmonary monitoring and serial chest radiography. Pneumothorax with associated hemothorax requires tube thoracostomy.

Suspected mediastinal injuries should be admitted to the hospital. Cardiac, great vessel, and aortic injuries require further diagnostic evaluation and, typically, operative repair (14). Tracheobronchial injuries often require bronchoscopy and operative intervention but are occasionally successfully managed medically; however, this requires inpatient observation and parenteral antibiotics. A suspicion of esophageal injury should prompt admission for parenteral

antibiotics, serial examinations, and a full diagnostic workup. Patients with confirmed or suspected diaphragmatic injury should be admitted; laparoscopy may be required for definitive diagnostic evaluation.

Common Pitfalls

- Failure to provide early definitive airway management via endotracheal intubation.
- Failure to expeditiously recognize and treat tension pneumothorax.
- Failure to investigate for diaphragmatic and intra-abdominal injuries, particularly with injuries sustained below the nipple line or the inferior border of the scapula.
- Failure to decompress a pneumothorax adequately by needle thoracostomy or failure to follow this procedure with tube thoracostomy.
- Failure to administer prophylactic antibiotics for emergency department tube thoracostomy.
- Attempting to probe a penetrating thoracic wound.
- Underutilization of bedside ultrasound in the diagnosis of hemopericardium, hemothorax, and pneumothorax.

CHAPTER 33

Blunt Abdominal Trauma

Eric L. Legome and Joseph P. Freedman

Blunt abdominal trauma (BAT) accounts for a minority of all traumatic deaths but represents an important source of morbidity. The variety of clinical presentations, limitations of the physical examination, and the absence of consistent clinical markers make patients with BAT a particularly challenging population. Death owing to abdominal injury may be prevented by early recognition of intra-abdominal hemorrhage. After initial resuscitation, one of the primary objectives of the emergency physician (EP) is to decide which patients require early intervention and timely consultations. Although injuries to solid organs are most frequently involved after BAT, the clinician must also search for the more subtle injuries to the bowel, mesentery, and pancreas. The history and physical examination continue to be essential components of the evaluation, however, a significant portion of patients will require imaging. *Focused assessment with sonography for trauma (FAST)* and abdominal computed tomography (CT) scanning are paramount in both ruling in and excluding intra-abdominal pathology and planning definitive treatment.

CLINICAL PRESENTATION

The signs and symptoms of BAT are highly variable, and obtaining a complete and accurate history and physical examination may be unreliable due to concomitant head injury, medications, substance abuse, multisystem trauma, distracting injuries, spinal cord injuries, or shock. Though historical factors and physical findings should

guide decision making, the presence or absence of many findings is neither sensitive nor specific (1,2).

Although hypotension in the field or on arrival increases the likelihood of severe bleeding, vital signs may be normal upon presentation to the emergency department (ED). Injuries that produce minimal bleeding, for example, diaphragm perforation, and those isolated to the retroperitoneum typically result in a paucity of physical findings.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of injury in BAT includes both intra-abdominal and extra-abdominal etiologies. The most common intra-abdominal concerns are the solid organ injuries of the spleen or liver. Next most commonly injured are the hollow viscous organs, that is, the small and large bowel. These comprise less than 10% of intra-abdominal injuries. The gallbladder, pancreas, or vascular structures may also be injured, although these injuries are infrequent and are usually found in combination with hollow or solid viscous injuries. Occasionally there is an isolated injury to the bowel mesentery.

In addition to these intra-abdominal injuries, there may be extra-abdominal findings that mimic intra-abdominal injury. These include muscle strains, contusions, or rectus sheath hematomas. Muscle injuries tend to cause pain mainly over the involved muscular area and do not lead to hemodynamic instability; the pain may intensify when palpation is performed on the contracted muscle. However, these findings may coexist with an intra-abdominal injury and the presence of these findings cannot exclude an intra-abdominal injury.

ED EVALUATION

The assessment of the blunt trauma patient must be performed within the context of the patient's hemodynamic status and potential for life- or limb-threatening injuries. The ABCs of resuscitation are rapidly performed on arrival. The secondary

survey, including the abdominal examination, proceeds after the primary survey is complete. In general, the more critically injured the patient, the faster the EP must determine the need for laparotomy, blood transfusion, or angiography, and obtain early surgical consultation.

History

Upon arrival, a brief history is obtained. One common approach is the AMPLE format (*a*llergies, *m*edications, *p*ast medical history, *l*ast meal, and *e*vents surrounding the injury). In addition, the patient should be questioned about specific areas of pain. Obtaining the history also allows the EP to judge the patient's mental status.

Other valuable sources of information are the prehospital care providers and witnesses or passengers who may arrive with the patient. After a description of the mechanism and events of the injury, most paramedic reports indicate mental status changes, vital signs, evaluation of the ABCs, significant complaints, and interventions. Certain historical factors, such as prehospital vital signs and mechanism of injury, have classically been associated with a greater chance of serious injury. Mechanism alone tends to be poorly predictive of the need for operative intervention or advanced therapeutic maneuvers (3–5). On the other hand, a history of prehospital hypotension, a requirement for significant volume resuscitation, declining mental status, the presence of a femoral fracture, or the need for either prehospital or ED intubation increases the likelihood of intra-abdominal injury (6–8).

Physical Examination

Despite the necessity of a directed physical examination, the EP must be aware of its limitations. The physical examination is not sensitive enough to diagnose all patients with operative intra-abdominal injuries, nor is it specific enough to rule in an injury, even in patients with guarding and rigidity. The literature has cited a wide variability in the physical examination. For example, one study found the examination to be 65% accurate in the setting of

BAT, whereas another trauma center reported abdominal examination alone as adequate in only 35% of patients (4,9). A recent systematic review suggested that the physical examination alone is probably insufficient for excluding intra-abdominal injury; however the presence of rebound tenderness, distention, and a seat-belt sign can increase the likelihood of BAT (1).

To perform the physical examination, the patient should be completely undressed and life threats addressed first. Concomitant evaluation and therapeutic interventions of the airway, breathing, and circulation are the first priority. The abdominal examination should begin with inspection for abrasions or ecchymosis. Ecchymosis over the lower abdomen in a lap-belt distribution is suspicious for hollow viscous injury and vertebral fractures. Although Cullen sign (ecchymosis around the umbilicus) and Turner sign (ecchymosis of the flanks) are associated with retroperitoneal bleeding, they are highly insensitive and often take hours to manifest. Auscultation for bowel sounds has not been formally studied but probably has no utility in the initial examination.

Palpation of the abdomen begins with examination of the lower chest. Lower rib fractures, especially with high-energy trauma, are associated with a significant rate of associated intra-abdominal injury (10,11). The abdomen should be carefully palpated, paying particular attention to the right and left upper quadrants (RUQs and LUQs). The finding of Kehr sign (pain in the shoulder unrelated to shoulder tenderness or range of motion) is associated with the presence of blood irritating the diaphragm and is often secondary to splenic or liver injury.

Pelvic stability is assessed by palpating and applying distraction and compressive forces over the iliac crest and over the symphysis pubis. Care should be taken not to use excessive force to avoid disrupting an unstable fracture and increasing bleeding. Patients with pelvic fractures have a significant incidence of intra-abdominal injury, ranging from 30% to $>$50% in those with severe or unstable fractures (12).

Rectal examination is rarely useful in blunt trauma patients. It may provide some added information in seriously injured patients

with pelvic fractures or concern for gastrointestinal disruption; however, it is highly unlikely to be helpful, and its inaccuracy may confuse the clinical picture. It may demonstrate a high-riding or boggy prostate in patients with urethral disruption. Gross blood on rectal examination may indicate gastrointestinal rupture and mandates surgical consultation. Stool evaluation for occult blood has not been shown to be predictive of traumatic injury (13). In addition, trauma patients find the rectal examination the most uncomfortable part of the physical examination, so if performed, it should be limited to those patients with a reasonable expectation of pathology (14). The external genitalia should be inspected for blood at the meatus, scrotal hematoma, or urethral outlet bleeding, which may signify a bladder or urethral injury. The patient should then be log-rolled with palpation of the lumbar and thoracic area. Lumbar fractures, particularly those in conjunction with the seat-belt sign, are markers of hollow viscous injury.

Plain Radiographs

The plain abdominal radiograph has no utility in the evaluation of BAT. It is not reliable in diagnosing intra-abdominal pathology and therapeutic interventions should not be planned on the basis of the results. A chest radiograph should be performed to assist in evaluating the aorta, lungs, and rib cage. It may show evidence of a ruptured diaphragm in anywhere from 20% to 80% of patients with this injury (15,16). Pelvic films should be obtained based on the reliability of the examination and on physical findings. The current evidence shows that in the stable and alert blunt trauma patient without distracting injuries, a normal clinical examination can rule out a clinically important pelvic fracture (17–19). On the other hand, a patient with hemodynamic instability or in whom there is a reasonable suspicion of a fracture by examination or mechanism should have one performed early in the course. In stable patients with no evidence of instability who will be rapidly undergoing a CT scan of the abdomen and pelvis, it is reasonable to forego the plain film for the more sensitive CT.

Laboratory Tests

Laboratory analysis of most trauma patients is generally more extensive than necessary and rarely offers insight into diagnosing an occult injury. Though laboratory testing based on clinical parameters is cost effective without compromising care, most trauma centers use some type of protocol to standardize and speed the laboratory evaluation of patients. The patient who is fully awake and alert, has sustained minimal trauma, and has no distracting injury may not require any testing. Rational laboratory analysis in most patients with BAT can be limited to a complete blood count, basic electrolytes, blood type and screen, and urinalysis. Women of childbearing age should have a pregnancy test performed.

The hematocrit value is influenced by many factors, including the rate of blood loss, dilutional effects of intravenous fluids, fluid shifts from the interstitium to the intravascular space, and preinjury level. Though an initial low hemoglobin <8 g/dL may be useful to prognosticate major injury and outcome (20), the main value is as a baseline blood count. Leukocytosis may be present but is a nonspecific finding. Baseline chemistries provide information regarding blood glucose, creatinine, and evidence of acidosis. Gross hematuria is significant and should prompt evaluation of the genitourinary (GU) tract. The presence of microscopic hematuria is of less clear significance, as it has been found to be poorly sensitive or specific for significant GU injury and, in the absence of a pelvic fracture or unexplained hypotension, does not mandate workup (21).

Other studies to consider, mostly for the severely injured patient or elderly patient, include liver function studies, coagulation profiles, arterial blood gas, and alcohol and drug screening. Liver enzymes that are significantly elevated to two to three time normal may represent hepatic injury, although it is unclear how much they add to objective radiologic testing based on mechanism and physical examination (22). Coagulation studies are useful in anticoagulated patients, those with a history or stigmata of liver disease, pregnant

patients, or those with the possibility of disseminated intravascular coagulation owing to shock.

Analysis of the arterial or venous blood gas may provide diagnostic and prognostic information in the major trauma patient. Those patients with base deficits less than –6 (i.e., –7 or greater) have an increased risk of intra-abdominal hemorrhage. High initial lactates have been associated with significantly increased mortality in several trauma database reviews (23). Serial base deficits or serial lactates indicate trends in patient status. Monitoring the deficit for improvement or normalization helps discern whether ongoing resuscitation is effective. The failure to normalize a base deficit by several hours predicted a significantly greater morbidity and mortality in one study (24,25).

Serum amylase and lipase are inaccurate for pancreatic injury. One study showed that 53% of BAT patients had at least one elevation during an initial or subsequent measurement, yet $<2\%$ had a pancreatic injury. Other studies have confirmed the lack of utility of a screening amylase or lipase in the blunt trauma patient (26).

Ethanol levels and drug screens may provide additional information about the reliability of the physical examination.

Diagnostic Peritoneal Lavage

Diagnostic peritoneal lavage (DPL) is a rapid and accurate test for determining the existence of intraperitoneal blood. Although it is invasive, DPL has a low ($<1\%$) complication rate of bleeding, perforation, or infection. Once part of the standard evaluation of BAT patients, it has been largely replaced by CT scan in the stable patient and by ultrasound for the unstable patient. DPL still has utility in the unstable patient with an unclear or indeterminate ultrasound result or in the stable patient with a significant concern for a hollow viscous or mesenteric injury, either by examination or after an equivocal CT scan. DPL also plays a major role when CT scan and ultrasound are not available, and therefore remains an important diagnostic tool for the EP.

The two main techniques are open and closed. The *closed* technique is faster and is not associated with a significant increase in complication rate. The *open* technique relies on direct visualization and incision of the peritoneum, whereas the closed technique is performed using the Seldinger technique after skin incision. Though generally performed in the infraumbilical area, a supraumbilical approach should be performed in patients with pelvic fractures or previous surgical scars and in the pregnant patient. In some cases, a *semi-open* technique may be performed. With this technique, the skin, and sometimes the fascia, is incised, and the catheter (placed over a trocar) is inserted blindly into the peritoneal cavity. Most centers perform either the open or the closed technique. The sensitivity and specificity of DPL for intra-abdominal blood are both in the 95% to 99% range, with accuracy ranging between 92% and 98%. The specificity of DPL for predicting the need for a therapeutic laparotomy is somewhat lower, and it should be interpreted in light of the overall clinical picture. A positive DPL in a hemodynamically stable patient should not automatically lead to laparotomy. It had previously been estimated that up to 30% of grossly positive lavages lead to nontherapeutic laparotomies. With the advances in nonoperative management of solid organ injuries, this number is probably higher. The lavage is insensitive for retroperitoneal injuries, is not specific for site and extent of injury, and may diagnose injuries that do not require operative intervention. The only absolute contraindication for DPL is the need for emergency laparotomy.

Criteria for a positive test after blunt trauma include an initial aspirate of >10 mL of blood (grossly positive lavage) or $>100{,}000$ RBC/mm^3 in the lavage fluid. Patients with a grossly positive lavage (initial aspiration of 10 mL of blood) who are unstable should undergo immediate laparotomy. If <10 mL is aspirated, this amount of blood should be added back into the peritoneal cavity and counted toward the final lavage fluid red blood cell (RBC) determination. Generally, patients with RBC counts between 25,000 and 100,000 RBC/mm^3 should undergo CT scan and patients with counts $>100{,}000$ RBC/mm^3 should be seriously considered for CT

scanning if they remain hemodynamically stable. However, this is more of a historical remnant as most of these patients today would have had a CT as the primary test rather than a DPL. Other lavage criteria based on the leukocyte count and amylase are less sensitive and more controversial and should be interpreted in light of the clinical examination. Gross bile or fecal material should be considered a positive lavage.

Computed Tomography

CT scan of the abdomen and pelvis is the best method for radiographic evaluation of the stable patient. Owing to limitations in the physical examination of the trauma patient, most patients except the minimally injured will require some sort of diagnostic test or observation. The CT offers the ability to perform, in a relatively rapid fashion, a quantitative and qualitative diagnostic test.

Abdominal CT after blunt trauma is indicated in patients with an unreliable physical examination. This includes patients with altered sensorium, spinal cord trauma, or distracting injuries or when general anesthesia is planned for another injury and there is a concern for intra-abdominal injury. CT also evaluates for suspected retroperitoneal, small bowel, renal, or pancreatic injury. It also provides excellent visualization of pelvic and spinal fractures. CT images may also reveal a pneumothorax or hemothorax and rib fractures missed on initial plain radiograph. With each generational improvement in CT scanners, image reconstructions are greatly enhanced with thinner slices, higher spatial resolution, and increased speed. Artifacts caused by motion, respiration, and pulsations are significantly decreased.

Multidetector CT (MDCT) images more anatomic area as the IV contrast material travels through the body, resulting in better detail of structures. Thus, because of the greater anatomic coverage during optimal IV contrast material opacification, vascular structures and parenchymal organs are imaged more effectively, and the ability to construct 3D reformations is greatly enhanced (27,28). A common

approach some trauma centers are using is to perform a CT from head to pelvis, that is, “the pan scan,” in the multitrauma patient. Though seemingly cost prohibitive, it may actually be less expensive given that the extra time to perform the scan takes minutes, there is no increased use of film when images are stored on a picture archival retrieval system, and scans of the bones can be included, obviating the need for plain films. This approach, however, must be balanced by the radiation load incurred and the long-term potential, although low, for radiation-induced carcinomas (29). Currently, this approach remains controversial as clinicians attempt to balance the cost, radiation, and resource utilization with the efficiency of the “pan scan” (30).

Some controversy remains regarding abdominal CT and the need for oral contrast medium to opacify the bowel. Although the major disadvantages (the delay to scan and possibility of aspiration) are very small, it remains unclear exactly how much it contributes to care. It can assist in diagnosing bowel and pancreatic injury, although the incidence of injury to these structures is low. Extravasated contrast is a pathognomonic finding; however, it has a low sensitivity. Contrast improves the ability to see bowel wall thickening, although most patients with this finding alone do not need intervention. Although several reviews and studies have led to mixed conclusions and its use remains an institutional preference, increasingly the evidence suggests that it is probably not needed (31,32). The most recent American College of Radiology Appropriateness criteria also agrees with this approach, no longer recommending oral contrast in CT studies of BAT (33). Given its limited assistance, if oral contrast is administered, CT should not be delayed while waiting for passage of the contrast material, unless there is a strong suspicion for bowel or pancreatic injury and the patient is stable.

Another major limitation of abdominal CT scan is the decreased sensitivity for bowel, mesenteric, and pancreatic injury. Hollow viscous injury has historically been one of the most elusive diagnoses to make by CT in trauma. It is found in approximately 1% to 5% of patients with significant BAT and may be higher with

certain mechanisms such as a seat-belt injury. Air, extravasated contrast, active mesenteric bleeding, or bowel injury with mesenteric hematoma are indications for surgical intervention. Unfortunately, these are relatively insensitive and rare findings. The significance of isolated free intraperitoneal fluid is more controversial. Several studies have found a high likelihood of bowel or mesenteric injury and others document a low likelihood (34,35,37). In general, it should probably be taken seriously, and the EP should strongly consider admitting or observing the patient with this finding in addition to obtaining surgical consultation. Findings such as mesenteric infiltration or hematoma or bowel thickening are often seen in patients with less serious lesions; these patients may often be safely observed. In the past, reported sensitivities for diagnosing bowel injury with CT were as low as 41%. The newer scanners have improved resolution and provide better diagnostic accuracy (32,36).

Pancreatic injury remains a difficult diagnosis. Elevations of amylase or lipase are inaccurate for detecting this injury. Though the incidence of pancreatic injury in BAT patients is $<1\%$ and the need for operative intervention is even lower, CT is only 50% to 78% sensitive and tends to underestimate the extent and magnitude of the injuries. These patients, however, often undergo exploration for other concomitant injuries (39).

Diaphragmatic injuries, though relatively uncommon, remain diagnostic dilemmas. Studies of helical CT in diaphragmatic injury have found it better in the acute phase and with visceral herniation. Pathognomonic signs for this injury include the “collar sign”—a waist like constriction of the abdominal viscera, intrathoracic herniation of abdominal contents, and discontinuity of the diaphragm. In one small study of helical CT, these signs were highly specific, with a moderately high sensitivity; CT detected approximately 80% of left-sided and 50% of right-sided herniations. The newer scanners have improved sensitivity and specificity, with values reaching 84% and 77%, respectively, using coronal and sagittal reconstructions. Familiarity and greater use of MDCT should improve the ability to make this diagnosis in the acute phase (38).

CT is the diagnostic test of choice in the stable patient with a high suspicion for intra-abdominal injury or with an unreliable examination. It is also being used with increasing frequency in the patient who is moderately stable (i.e., the patient who is able to maintain vital signs, although they may be fluctuating, or the patient with ongoing hemorrhage who can be adequately resuscitated) in whom nonoperative management is still a possibility. A multi-institutional prospective study of 2,774 patients with suspected BAT found that a negative CT scan has a negative predictive value of 99.63%. This has tremendous implications for cost savings. A patient without other significant injuries, pain or social concerns with a normal abdominal CT can be safely discharged. The chance of a missed significant abdominal injury is extremely low (39). Despite the high sensitivity of CT scanning BAT patients, recent studies and ACEP guidelines have focused on identifying a population of patients with BAT who are at low risk of adverse outcomes, in whom CT scanning may increase radiation dose without adding valuable clinical information (1). These patients are those who have no abdominal tenderness, hypotension, altered mental status, costal margin tenderness, abnormal chest radiograph, hematocrit under 30%, and hematuria. The clinical prediction rule has yet to be externally validated but may help limit CT usage on BAT patients with a low likelihood of intra-abdominal injury.

While the pendulum has swung in the last decade toward increasing use of CT scan with BAT to provide efficient clinical care with a high sensitivity for all intra-abdominal injuries, research is now looking to help define the patient populations in which historical and physical factors can safely exclude important BAT without imaging.

Ultrasound

The advent and increasing usage of ultrasound represented a paradigm shift in the evaluation and management of the blunt trauma patient. The FAST examination is a directed assessment of

the abdomen and pericardium with the goal of detecting hemoperitoneum or pericardium. Although operator dependent, it is a rapid bedside test that can be done at the bedside with the secondary survey. The FAST examination is performed on the supine patient with the examiner positioned on the patient's right side. Four locations are scanned: (a) the RUQ, (b) LUQ, (c) the suprapubic region, and (d) the pericardium. The examiner looks for unclotted blood, which appears black or anechoic on the ultrasound screen. The RUQ view is generally the initial view. This view detects blood in Morison's pouch, a dependent space between the kidney and liver. Although this location has the greatest yield, the addition of all abdominal views has been found to significantly increase the sensitivity by up to 40%. The LUQ is examined next, specifically looking for blood in the splenorenal space. Either view of the upper quadrants may also reveal a hemothorax or pneumothorax. Trendelenburg positioning may improve the sensitivity of either of these views. The suprapubic view evaluates the cul-de-sac between the rectum and bladder (the pouch of Douglas), and the heart and pericardium are examined by a subxiphoid view. The suprapubic view should be performed before the Foley catheter is placed, as the full bladder acts as an acoustic window and enhances visualization of peritoneal fluid (40,41).

The FAST examination has become a standard part of the EP and trauma surgeon's evaluation of the blunt trauma patient. In many centers it is considered the first-line diagnostic study to identify or exclude significant hemoperitoneum. Clear benefits of ultrasound are that it is rapid, noninvasive, inexpensive, repeatable, and relatively portable. The test can be performed in conjunction with resuscitation, usually takes <5 minutes, and has a relatively steep learning curve. Its sensitivity and specificity range from 81% to 98% and 94% to 98%, respectively. The sensitivity and specificity vary somewhat depending on the amount of free fluid present and the expertise of the examiner (42,43). Though ultrasound is moderately sensitive for as little as 100 to 200 mL of fluid, sensitivities increase to $>90\%$ with volumes of fluid close to 700 mL. In other words, ultrasound is highly sensitive in patients with enough blood loss to

cause hemodynamic instability, although one cannot fully exclude an intra-abdominal lesion based on a negative ultrasound in an unstable patient. The sensitivity of the FAST examination also increases when serial examinations are performed, separated by 30 minutes. Accuracy has been reported to range between 96% and 98% (34). The level of accuracy is independent of whether an EP, surgeon, radiologist, or ultrasound technician performs the study; they all have comparable results. Though there is controversy over the exact number of studies and instructional time needed for proficiency, current studies appear to support that several hours of instruction, and roughly 20 hands-on studies lead to excellent accuracy in defining hemoperitoneum (44–46).

In US, FAST has largely supplanted DPL, especially in unstable patients, and has been used as a diagnostic adjunct in the stable patient in conjunction with physical examination or, more commonly, CT scan. Compared to DPL, ultrasound allows for a quicker, safer, and noninvasive test without interference with other resuscitative procedures. Unlike DPL, it does not require extra time or modification for the pregnant patient or patients with pelvic fractures, previous surgery, or coagulopathy.

Most centers use some variation of the algorithm from Denver published in 1997 (47). The initial test in all BAT patients is the ultrasound. If the patient is unstable and the FAST is positive, immediate laparotomy is performed. In the unstable patient, if the FAST is negative or equivocal and intra-abdominal injury is a concern, a DPL is performed. A CT scan follows a positive ultrasound in a stable patient. A negative ultrasound is followed by a CT scan or by serial ultrasounds, physical examinations, and a 6-hour hematocrit. A concerning change in physical examination, ultrasound findings, or significant drop in hematocrit is followed by either a CT scan or laparotomy. Although outcome studies are limited, literature has shown that implementation of point-of-care sonography protocol can limit CT scans, and minimize the time to definitive intervention in BAT patients (47,48). This must be balanced, at least in the Denver study, with the increased time of observation of the patients who were observed after ultrasound.

Though ultrasound clearly is valuable in the unstable patient, it has some disadvantages compared to CT scan in the stable patient. Although highly sensitive for large amounts of hemoperitoneum, it is less so with small amounts, and it is not reliable at providing a qualitative assessment of a solid organ injury. The sensitivity of ultrasound for identifying solid organ injury is approximately 30% when performed by sonographers trained for limited bedside ultrasound. It also does not provide information about bowel or pancreatic injury or evaluate the retroperitoneum (34). Patients at significant risk for intraperitoneal injury such as those with abdominal abrasions, lower rib fractures, multiple traumatic injuries, pelvic or long-bone fractures, or inability to be clinically followed up may be poor candidates for ultrasound as the only modality for evaluation. At a minimum, these patients should not be evaluated using a single examination at a single point in their course.

Overall, ultrasound provides a very useful initial test in BAT. Though it can potentially predict the need for surgical repair based on the amount of fluid observed, its main utility has been in the unstable patient as a replacement for DPL. As it does not reliably grade or even diagnose solid organ injury, it is most valuable as an adjunct to CT in the stable patient. In most centers, given the increasing availability of CT and the high negative predictive value, a negative or equivocal ultrasound is often followed by abdominal CT scanning. However, from the beginning of the resuscitation, ultrasound alerts the team to the presence of intraperitoneal injury within seconds to minutes and can be used to rapidly triage patients to the operating room or radiology suite. In addition, owing to its portability and accessibility, ultrasound can be repeated to detect hemoperitoneum if the hemodynamic status of the patient changes.

Angiography

Interventional angiography is increasingly important and more frequently employed in the treatment of hemodynamically stable BAT patients. As the technology of CT improves, active hemorrhage

is increasingly identified faster and more accurately. If an actively bleeding spleen, liver, or kidney is visualized and the patient is clinically stable, a dedicated angiography team may be able to intervene to rapidly embolize the lesion and avoid laparotomy. Angioembolization, along with close observation and serial examinations, has been shown to increase the effectiveness of nonoperative management of BAT patients. The precise population of BAT patients who will benefit from nonoperative management, and specifically, angiography, has yet to be fully elucidated (28,49,50).

KEY TESTING

- Type and screen/cross match.
- Liver function testing, amylase, lipase rarely useful. Serial hematocrits more useful than single.
- CT imaging for stable BAT patients with suspicion of injury or unreliable examination.
- FAST examination for unstable BAT patients.

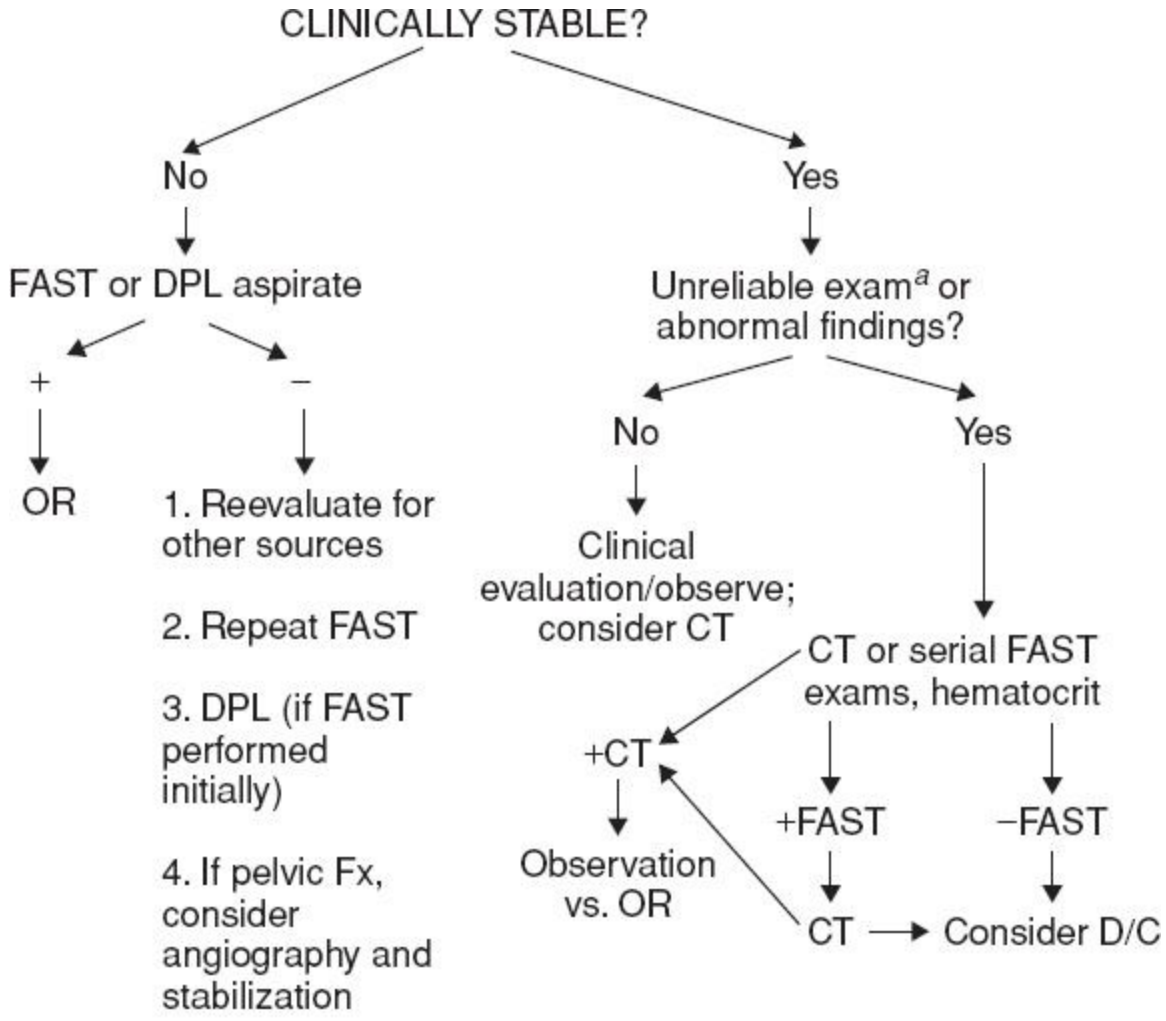
ED MANAGEMENT

In level I trauma centers, prehospital criteria such as vital signs, level of consciousness, and mechanism of injury will alert a trauma team before arrival of the patient. In most hospitals, however, the EP is solely responsible for initial trauma management. The *seriously* injured patient with BAT should undergo standard advanced trauma life support resuscitation.

Unstable Patients

In the hypotensive or tachycardic patient, the cause must be presumed to hemorrhagic until proven otherwise. Vascular access with large-bore intravenous lines should be inserted, and the patient should receive crystalloid bolus as a temporizing measure while the source of hemorrhage is sought and blood products are ready to be administered. Although beyond the scope of this chapter, the proper balance between avoidance of prolonged hypoperfusion and

overshooting an appropriate BP end point and exacerbating hemorrhage is still an ongoing debate (51). The optimal ratios of blood product administration is still unclear, but evolving research supports an approach of a balanced ratio between packed red cells, platelets and clotting factors, approximating the constituents of whole blood. A nasogastric or orogastric tube should be inserted as well as a Foley catheter, after ensuring that there is no urethral injury. Patients with hemodynamic instability in whom an abdominal injury is clearly the source, such as an injury with a traumatic bowel wall hernia and abdominal wall ecchymosis, should be taken directly to the operating room. For unstable patients, particularly those with multisystem trauma in whom intra-abdominal injury is a possibility, the primary method of evaluating the abdomen should be FAST, however, DPL or laparotomy remain important options in the indeterminate study or negative study where there remains a high suspicion of intra-abdominal hemorrhage. Special consideration should be given to the unstable patient with significant pelvic fractures (52) (eFig. 33.1).



eFIGURE 33.1 Blunt abdominal trauma algorithm.

For unstable patients in whom a FAST examination is not available, the peritoneal aspirate component of the DPL remains a primary tool for investigation. An initial aspirate of >10 mL of blood is an indication for surgery. Despite the improved speed of the current generation of scanners, CT does not have a role in the persistently unstable victim of BAT.

Though the ranking of priorities in patients with head, chest, and abdominal injuries is still very difficult, there are some advantages from the modern spiral or MDCT scan speed. The speed of the newer CT scan may allow a few quick cuts of the head and chest to screen for obvious pathology. The time of the scan is now often measured

in seconds to minutes. This may enable a quick assessment of the head en route to the operating room for laparotomy. In general, the critical ordering is to manage injuries to the abdomen first, and then the head, and then aorta but, obviously, decisions must be colored by the actual pathologies present.

Stable Patients

For the hemodynamically stable patient with BAT, the approach to management is guided by several factors. Victims of BAT who are awake and alert with a reliable, benign abdominal examination can be followed up clinically with serial examinations. For stable patients with positive abdominal findings, an unreliable examination, significant distracting injuries, or possible retroperitoneal injury, abdominal CT is the diagnostic test of choice. Some patients with a significant mechanism of injury may undergo CT or a period of observation, in spite of negative clinical findings.

Although an initial FAST examination should generally be performed, a subsequent CT is indicated in most patients. Some centers, however, follow up patients with serial ultrasounds, physical examinations, and hematocrits. CT can often help determine whether underlying injury can be managed nonoperatively. CT in patients with a negative FAST examination may identify significant injuries that have not resulted in significant intra-abdominal bleeding such as bowel injury. In addition, it will detect injuries in the retroperitoneum, pelvis, spine, and lower chest.

CRITICAL INTERVENTIONS

- Address the basic ABCs of resuscitation prior to examination of the abdomen.
- In stable patients with significant pain, tenderness, or an unreliable examination, perform a CT scan or serial physical examinations and ultrasounds.
- In unstable patients, perform an ultrasound to evaluate for intra-abdominal hemorrhage.

- Obtain surgical consultation early in hemodynamically unstable patients or those with intra-abdominal pathology by examination, ultrasound, or CT scan.

DISPOSITION

For stable patients who require evaluation by CT, disposition can be made based on a combination of historical factors, physical findings, and some combination of imaging modalities. Patients with a normal CT scan and a brief period of observation in the ED can be safely discharged from the ED (28). Patients who are awake and alert, have a reliable, benign abdominal examination, and are not candidates for CT can be followed up clinically with serial abdominal examinations in the ED over a 4- to 6-hour period. Those with low mechanism who are fully alert and appropriate can most likely have a shorter evaluation period, although the optimal time is not clear from the literature.

Operative delay is the primary cause of preventable deaths in patients with BAT. At a very early stage, the EP should evaluate the services available at his or her institution and determine whether a patient is a candidate for transfer. It is imperative that a patient is initially resuscitated prior to transfer with careful attention paid to the airway and hemodynamic status. In consultation with the receiving institution, a decision is made to have a patient transferred on the basis of the primary and secondary surveys alone. Multiple diagnostic studies at the transferring hospital will only delay care; therefore, only essential tests should be ordered. Two large-bore intravenous lines and a Foley catheter should be placed in most patients with reasonable suspicion of serious injury. A chest x-ray should be obtained and chest tubes placed for hemothorax or pneumothorax.

Common Pitfalls

- Failure to obtain early surgical consultation in the unstable patient.

- Attributing hypotension to extra-abdominal causes, such as chest trauma, spinal shock, or external blood loss.
- Failure to evaluate the abdomen in the patient with an unreliable physical examination. All patients who have multiple injuries, altered mental status, or a distracting injury should be considered to have an unreliable examination.
- Performing an abdominal CT scan in the hemodynamically unstable patient.
- Relying on a negative ultrasound to rule out intraperitoneal injury.
- Delaying transfer while performing unnecessary studies.

CHAPTER 34

Penetrating Abdominal Trauma

Michael J. Breyer

Penetrating trauma to the abdomen continues to be a major cause of trauma and mortality in the United States. Death resulting from trauma is greatest in 15- to 34-year-old African Americans closely followed by Hispanics of the same age and is usually the result of homicide. In 2010, the Centers for Disease Control and Prevention reported homicide was the second leading cause of death in the 15- to 24-year-old age group and remains in the top four leading causes of death in all reported age groups from 1 to 44 years old (1).

Stab wounds (SWs) are three times more frequent than gunshot wounds (GSWs); however, GSWs account for approximately 90% of the deaths related to penetrating abdominal injury. A GSW carries significantly greater force, with injury and cavitation extending along the missile tract. Although bullets are the most common missiles, flying glass objects, lawn mowers, severe weather, and grenades can also create missiles.

During the US Civil War, conservative management was the treatment of choice, with laparotomy reserved for penetrating wounds with evisceration. In World War I, surgical exploration became standard of care, resulting in a survival rate of 75% for patients with GSWs to the abdomen. However, by the middle of last century, surgeons began to employ selective laparotomy with serial observation in some patients sustaining penetrating abdominal trauma. Since then, conservative management, coupled with certain diagnostic procedures, notably ultrasound (US), computed

tomography (CT), diagnostic peritoneal lavage (DPL) and local wound exploration (LWE) have gained widespread acceptance in the medical community.

The primary goals for managing penetrating abdominal injury center on expedience and accuracy. Because of the wide range of scenarios and possible injuries, the emergency and trauma teams play critical roles in the treatment of these patients, carefully integrating clinical gestalt, history, physical examination (PE), DPL, LWE, US, and CT. Notably, the evaluation, resuscitation, and method of diagnosis depend on the type of penetrating injury, the zone of penetration, and, most importantly, the hemodynamic status of the patient.

CLINICAL PRESENTATION

Patient assessment is frequently complicated by the presence of alcohol or drugs, which can mask important signs and symptoms even in the presence of major injury. Furthermore, other systems may also be involved and contribute to vital sign abnormalities. For these reasons, the American College of Surgeons (ACS) advises a 50% overtriage rate to maintain a 10% undertriage rate with studies noting 12% of patients triaged to trauma centers suffer serious injury (2). Often, prehospital providers obtain valuable information regarding the type of implement used to inflict the wound, the number of shots heard, and the position of the patient during the assault. These vital parts of the history, coupled with familiarity of the pathophysiology for penetrating abdominal trauma, can help guide Emergency Department (ED) evaluation and treatment.

There are four anatomic zones of the abdomen: anterior abdomen, low chest, flank, and back. The anterior abdomen is demarcated by the anterior axillary lines from the costal margins to the groin creases. Approximately one-third of penetrating trauma in this zone will violate the peritoneum. The low chest or thoracoabdominal area is defined by the nipple line/fourth intercostal space anteriorly and the inferior scapular tips/seventh intercostal space posteriorly to the inferior costal margins. The flank lies between the inferior

costal margins and the iliac crests between the anterior and posterior axillary lines bilaterally. The back is bordered by the inferior scapular tips and the iliac crest between the posterior axillary lines (3).

Penetrating abdominal injuries can be divided into three subtypes: SWs, GSWs, and shotgun wounds (SGWs). In patients suffering SWs, the most commonly injured organs are the liver and small bowel. Knives, ice picks, coat hangers, and screwdrivers can all be used to create SWs. Typically, SWs occur in the upper abdominal quadrants, and, as most assailants are right handed, the patient's left side is violated more frequently. In 20% of cases there are multiple wounds, and 10% of patients may have SWs involving the chest. This complicates the clinical approach as wounds in the lower chest region have a high incidence of diaphragm injury, as well as a 15% rate of intra-abdominal injury. Flank SWs injure peritoneal structures in 44% of the time, whereas back SWs cause intraperitoneal injury in 15% of patients. Nevertheless, the practitioner must remain diligent to the possibility of serious bodily injury with SW in any area of the patient's abdomen and torso.

GSWs impart a large amount of energy which generates increased tissue destruction and potential for organ injury. The most commonly injured organs are the small bowel, colon, and liver. Tissue resistance and viscoelasticity, combined with missile stability, velocity, and distance all affect the pathology created by GSWs. At medium (1,100 to 2,000 ft/sec) and high ($>$2,000 ft/sec) velocities, such as those imparted by AK-47 guns, there is an additional explosive effect of the missile. Diagnostic confusion can be caused by the closure of the tract immediately after passage, thus obscuring injured areas, as well as fragmentation of the bullet which can create additional trajectories.

SGWs differ from GSWs in velocity and missile trajectory. There is an initial rapid decrease of velocity of the pellets; thus, long-distance SGW injuries are associated with a lower morbidity and mortality. Pellet size and number, powder type, and length of the choke barrel combine to determine the potential for injury. At a range of 10 yards, 19% of pellets will cluster in a 9-in diameter

area, whereas at 20 yards (25% loss in velocity), pellets will spread out over an 18-in diameter area. SGWs are categorized based on distance and pattern of injury. Type I wounds are >7 yards from the victim and typically cause minor to moderate tissue damage. Type II wounds occur at a distance of 3 to 7 yards, have a pellet spread of 10 to 25 cm, and create deeper wounds, frequently into the thoracic or abdominal cavities. Finally, type III wounds (<3 yards) create massive destruction of tissue and organs due to their close range.

Differential Diagnosis

Although there may be an obvious penetrating abdominal injury, additional wounds to the head, neck, and extremities should also be sought. Hemodynamic instability may be caused by intra-abdominal hemorrhage, but other etiologies, such as tension pneumothorax, pericardial tamponade, hemothorax and massive arterial or venous bleeding, should also be pursued. For these reasons, a prompt assessment, including history, PE, US, x-ray, and CT are crucial to the care of the trauma patient with penetrating abdominal injury.

ED Evaluation

All patients with suspected trauma must be completely undressed and carefully examined as the scalp, axilla, and perineum can hide seemingly innocuous but deep and life-threatening wounds. History in these cases may at times be confusing or even misleading and therefore reports of a single wound should not be accepted until a thorough pursuit for additional wounds has been undertaken.

Determining the presence of organ injury necessitating immediate laparotomy is the primary initial decision point in the care of the patient with penetrating abdominal injury. For patients without clinical indications to proceed to the operating room (OR), additional testing including focused assessment with sonography for trauma (FAST) scan, laboratory data, CT, and serial PE are typically utilized.

KEY TESTING

- Complete blood count
- Basic metabolic panel
- PT/INR
- Point of care glucose
- Lactate
- Urinalysis
- Urine pregnancy test
- Type and screen, type and cross
- Blood alcohol level
- Bedside x-ray studies, including CXR and pelvis x-ray
- FAST U/S
- DPL as indicated
- CT if hemodynamically stable

ED MANAGEMENT

Ideally, all patients with an SW or a GSW to the abdomen are triaged from the point of injury directly to the nearest appropriate trauma center. When this does not occur, transfer to such a center at the earliest opportunity is advisable. Only life-saving maneuvers such as endotracheal intubation, tube thoracostomy, pericardial aspiration, fluid resuscitation and emergent surgical stabilization are indicated before initiating transfer.

When possible, prehospital personnel should attempt to notify the trauma center of their arrival. Information gleaned from prehospital communication is usually sufficient to activate the appropriate resources, including ED staff, the trauma team, OR staff, radiology staff, and blood bank.

Stab Wounds

While peritoneal violation occurs in 50% to 70% of anterior abdominal SWs, laparotomy is required in only 25% to 30% of patients who sustain SWs to their abdomen. Not surprisingly, management (conservative versus operative) depends on the type of

injury, severity of injury, and hemodynamic stability of the patient (4). Three sequential questions form the basis for an algorithm for patients with SWs to the abdomen (Fig. 34.1).

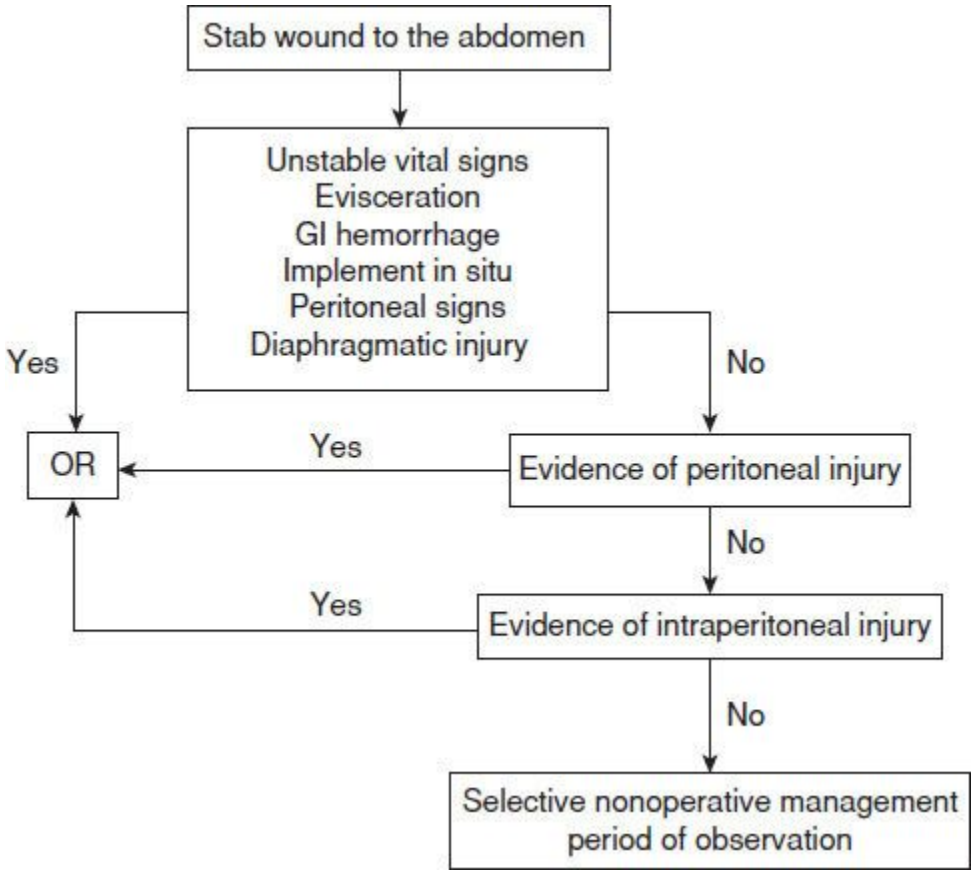

FIGURE 34.1 Algorithm for the management of patients with stab wounds to the abdomen.

Are There Indications for Immediate Laparotomy?

There are six clinical scenarios that suggest a high likelihood of intraperitoneal injury requiring laparotomy after an anterior abdominal SW. If one or more of these is present, then immediate surgical consultation should ensue with likely operative management to follow.

Unstable Vital Signs

Any patient with unstable vital signs has a potential major visceral or vascular injury that requires immediate surgical consultation.

While other causes of hemodynamic instability, such as tension pneumothorax or cardiac tamponade should also be considered and ruled out, preparation for laparotomy should begin immediately.

Evisceration

In patients with evisceration of abdominal contents, approximately 75% have concomitant intraperitoneal injuries that require operative intervention (5). With the high likelihood of significant injury, many surgeons proceed to the OR; however, others will reduce the bowel at the bedside and perform other diagnostic studies to determine the need for laparotomy. This practice is supported by a recent study that found in hemodynamically stable patients with evisceration, admission and serial examinations were associated with shorter lengths of stay than in patients managed with laparotomy (6).

Peritoneal Signs

Peritoneal signs on PE may indicate the need for exploratory laparotomy (7). However, as these signs are neither sensitive nor specific, it is important that the most seasoned physician or surgeon available perform a PE that determines the need to proceed to the OR.

Diaphragmatic Injury

Diaphragmatic injuries due to SWs are often small and thus difficult to discern using routine chest x-ray and PE. These may lead to significant morbidity or mortality due to herniation of abdominal contents into the chest, which can occur months or even decades following the initial injury. With these reports, some centers conduct mandatory laparotomy or thoracotomy for SWs to the left lower chest or left upper quadrant of the abdomen to avoid missing diaphragmatic tears, whereas other centers use diagnostic laparoscopy (DL) or DPL to evaluate for diaphragmatic injury instead of mandatory laparotomy (7). Of note, the presence of the

liver on the right side of the abdomen makes right diaphragmatic injury far less common.

Gastrointestinal Hemorrhage

Evidence of upper gastrointestinal (GI) hemorrhage after SW suggests hollow visceral injury, particularly to the stomach or duodenum, and the need for operative intervention.

Implement In Situ

To limit hemorrhage and remove an impaled foreign object in a controlled fashion, most surgeons proceed to the OR for implement in situ. There are exceptions to this axiom. Patients with severe comorbid illness or pregnant women may sustain greater harm from general anesthesia and therefore their foreign body removal may be safer at the bedside. Furthermore, in rare instances, it is necessary to remove the implement to provide adequate prehospital or ED resuscitation.

Is There Evidence of Peritoneal Violation?

If there is no indication for immediate laparotomy, the practitioner should next assess the wound tract to determine presence of peritoneal penetration. Caution should be used when determining whether to proceed to the OR when managing wounds that affect the upper abdomen as injury to structures in this area may not manifest with clinical peritonitis (8).

Plain Radiographs

The presence of free air on an upright chest or left lateral decubitus radiograph establishes the stabbing implement penetrated the peritoneal cavity which caused a track that brought air inside the peritoneal cavity. It does not, however, identify that a hollow viscus injury has necessarily occurred. Upright chest radiographs, while often the first test of choice, are neither sensitive nor specific and therefore must be weighed against the overall clinical picture of the patient.

Local Wound Exploration

With proper anesthesia, LWE can be safely performed on the anterior abdomen, flank, or back. A negative LWE establishes that the end of an SW tract is anterior to the rectus fascia. Such patients may be safely discharged from the ED after appropriate wound care and period of observation (9). Patients with multiple wounds, significant muscle mass, or morbid obesity may not be suitable candidates for LWE.

Computed Tomography

CT scans for SWs of the abdomen can be helpful in excluding peritoneal violation, predicting the need for laparotomy with a sensitivity of 96% and specificity of 97% (10). However, its exquisite sensitivity for diagnosing free intraperitoneal air may lead to unnecessary operations.

Ultrasound

US is helpful in evaluating the intraperitoneal, pleural, and pericardial spaces in wounds that may have violated the mediastinum or diaphragm. A positive FAST examination may mandate laparotomy or thoracotomy depending on whether intraperitoneal or intrapericardial hemorrhage is discovered and the clinical status of the patient. However, a negative FAST examination does not rule out injury, particularly to hollow viscera and the diaphragm, as these tend to bleed minimally.

There is an evolving role for US in the detection of peritoneal violation in penetrating abdominal trauma. A recent study evaluating the use of US to identify fascial violation deep to the SW found excellent specificity in identifying peritoneal penetration (11).

Diagnostic Laparoscopy

DL can be used to evaluate the depth of a wound tract, and although it compares favorably with LWE, it is more invasive and can only be performed by a surgeon trained in its use. Therefore, DL is primarily relegated for inspecting the diaphragm in left low chest and upper

abdominal wounds. In addition, it may allow immediate repair of diaphragmatic and certain organ injuries, often decreasing the cost and length of stay of patients who would otherwise have gone for an exploratory laparotomy (12). Although in some medical centers DL is used as a screening tool for patients with abdominal SWs, for most it represents a novel approach and remains controversial (13).

Is There Evidence of Intraperitoneal Injury?

If there are equivocal findings of peritoneal violation, further diagnostic evaluation with DPL, CT, or DL is indicated to determine whether injury requiring operative intervention is present.

Diagnostic Peritoneal Lavage

DPL, although invasive, is a rapid, reliable indicator of intra-abdominal injury and need for operative management (14). It is also effective in determining hollow viscus or diaphragmatic injury. The presence of 10 cc of gross blood or lavage fluid with 10,000 red blood cells (RBC) per high power field (HPF) indicates the presence of visceral injury. When low chest wounds are also present, the cutoff is dropped to 5,000 to 10,000 RBC/HBF to pick up potential isolated diaphragmatic or small bowel injury. Of note, bleeding from torso muscles and subcutaneous tissues at the SW site can cause false-positive DPL results.

Computed Tomography

CT is an important diagnostic modality following blunt trauma, as it is excellent for detecting solid visceral injury and hemoperitoneum. Its role in hemodynamically stable patients with penetrating abdominal trauma is expanding, and it can help facilitate nonoperative management for selected injuries. Many centers are now using CT with only intravenous (IV) contrast for hemodynamically stable patients with penetrating abdominal trauma, a protocol that appears to be safe for patients and effective in determining free air, free fluid, hematoma, and other injuries. Nonetheless, most practitioners recommend those patients at high risk for diaphragmatic, bowel, or pancreatic injury with a negative

abdominal CT should have further testing, observation, and serial examinations, because even new high-resolution CT lacks adequate sensitivity in detecting these injuries (15). Triple-contrast CT (IV, oral, and rectal) is generally reserved for low abdominal, flank, and back wounds to detect colorectal injury.

Diagnostic Laparoscopy

DL has been used for direct inspection of the diaphragm, detection of peritoneal violation, and evaluation of solid viscera. However, it remains inadequate for identifying hollow viscus and retroperitoneal injury. In centers experienced with DL, it is usually used for low chest, upper flank, and upper back penetration on the left side where the diaphragm is far more vulnerable to herniation of abdominal contents into the chest.

Selective Nonoperative Management

While many centers proceed to laparotomy for patients found to have peritoneal injury, others employ selective nonoperative management (SNOM) of hemodynamically stable patients with SWs to the abdomen. With this approach, patients typically have serial clinical examinations over 12 to 24 hours along with other diagnostic modalities such as CT, US, or DPL. Although safely employed in selected trauma centers, SNOM requires careful and frequent observation, which may prove to be impractical for some systems. Nevertheless, for patients with stable hemoglobin levels, stable or declining white blood cell counts and nonconcerning PEs, SNOM remains a viable option. In fact, one study which used SNOM managed 18 cases with grade III to V solid organ injuries without a laparotomy (15). This practice has been confirmed by others that found for selected patients with penetrating abdominal injury and a negative ED workup they may be discharged safely from the ED after a period of observation (16).

Stab Wounds to the Flank and Back

The risk of retroperitoneal injury is significantly greater after an SW to the flank and back than to the anterior abdomen. Not surprisingly, the risk of intraperitoneal injury resulting from an SW to the flank or back ranges from just 15% to 40%, markedly lower than the risk from SW to the anterior abdomen. LWE can be very difficult to perform in the flank and back because of the lack of a definite fascial plane of demarcation with the peritoneal cavity and therefore CT in hemodynamically stable patients with flank and back wounds is commonly used to triage patients.

Stab Wounds in Proximity to the Diaphragm

Because missed injuries to the diaphragm can cause substantial morbidity and mortality, some centers recommend mandatory exploration for SWs in close proximity to the diaphragm. Although this protocol is the most sensitive technique to determine injury, it also carries the risk of a high negative laparotomy rate.

As CT can miss diaphragmatic injury from penetrating abdominal trauma, laparoscopy, thoracoscopy, and DPL are commonly employed as adjuncts to diagnose injury. There is evidence showing in asymptomatic hemodynamically stable patients with penetrating thoracoabdominal injury, laparoscopy is sufficient to exclude diaphragmatic injury (17).

Gunshot Wounds

In most institutions, the knowledge or strong suspicion of peritoneal violation is enough to prompt laparotomy. As compared to SWs, GSWs are more frequently associated with multiorgan injury and have a 10-fold higher mortality rate. However, studies have found GSW to the anterior abdomen incur peritoneal violation and resultant intra-abdominal organ injury in only 30% to 74% of patients, far lower than the nearly 90% reported in other papers citing mostly military experience (18). An algorithm for patients with abdominal GSWs can be predicated on three sequential questions (Fig. 34.2).

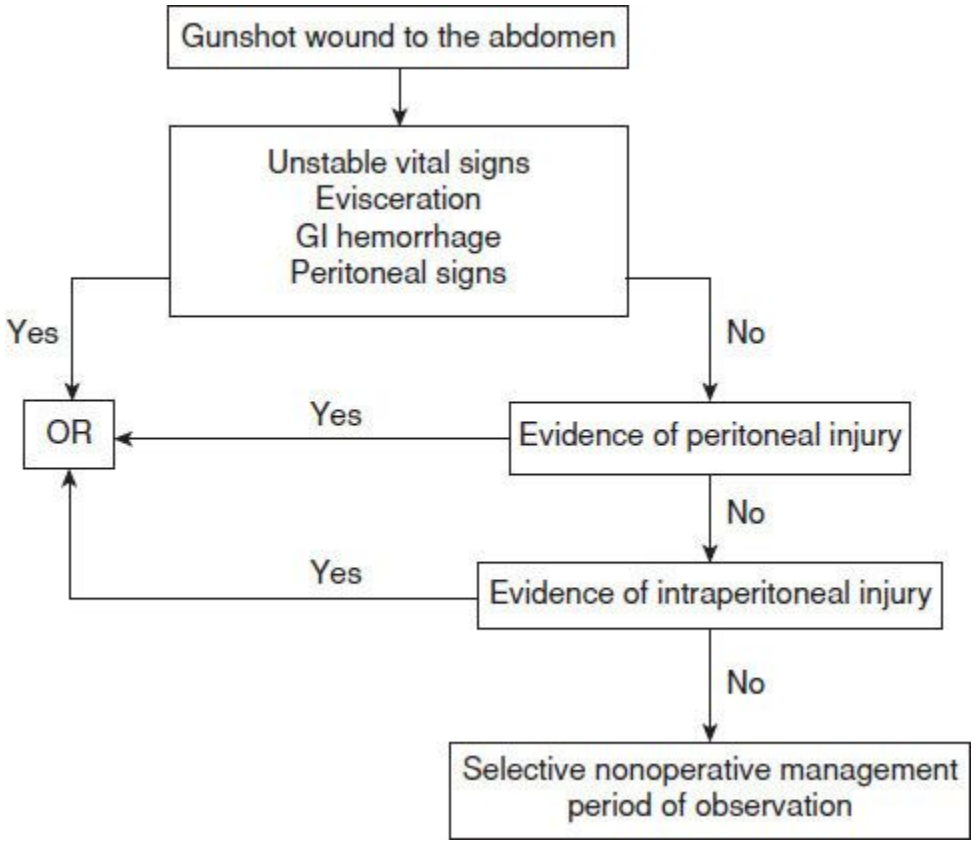

FIGURE 34.2 Algorithm for the management of patients with gunshot wounds to the abdomen.

Are There Indications for Immediate Laparotomy?

As with abdominal SWs, GSWs to the abdomen have accepted criteria for immediate surgical consultation and operation. In a recent study, 74.3% of US trauma surgeons practice SNOM of abdominal GSWs, regarding peritonitis, bowel evisceration, and hemodynamic instability after resuscitation as indications to proceed to the OR (19), but there are marked differences in the acceptance of this practice, ranging from 30% of Canadian trauma surgeons to 100% of South African trauma surgeons (20). One study delineated acidosis (base deficit ≥ 8), blood loss $>1{,}500$ mL, temperature $<35^{\circ}$C, and New Injury Severity Score $>$ 35 as indications for early damage-control resuscitation (21).

Unstable Vital Signs

Any victim of a GSW with unstable vital signs requires immediate surgical consultation as it may be presumed that an injury to a major vessel or solid organ is present. Hemopneumothorax, hemopericardium, or both may be causal or contributory to the clinical situation and should be ruled out.

Peritoneal Signs

As with SWs, there is a well-documented lack of specificity of peritoneal signs with GSWs, but patients with initial diffuse abdominal tenderness or exhibiting signs of peritonitis after a GSW to the abdomen often require surgical exploration (18).

Gastrointestinal Hemorrhage

As is true for patients with SWs, GI bleeding in association with a GSW to the abdomen, flank, or back mandates surgical exploration for potential intestinal injury.

Evisceration

Because of the great amount of energy transference and cavitation that occurs with GSWs to the abdomen, evisceration warrants surgical exploration.

Is There Evidence of Peritoneal Penetration by the Missile?

The following methods can determine if the missile has penetrated the peritoneum. In many centers, this is enough to prompt laparotomy.

Plain Films

If performed in two planes, radiographs can help determine the trajectory of the missile. However, plain films are not helpful when the missile has already left the body. Furthermore, multiple missiles and a ricocheting effect of bones make interpretation of plain films more difficult.

Local Wound Exploration

LWE is more difficult for GSWs than SWs because there is more tissue destruction and difficulty in visualizing the entire tract. It is best used for low-velocity missiles with superficial wounds.

Ultrasound

As with SWs, US may be used to detect the presence of hemoperitoneum and pericardial fluid in patients with GSWs to the abdomen. However, a negative FAST does not rule out the presence of intra-abdominal injury, particularly to hollow viscera and the diaphragm.

Diagnostic Laparoscopy

DL may help identify the presence of peritoneal violation and diaphragmatic injury, but it is inadequate to evaluate for hollow viscus injury. However, DL is an invasive procedure that can increase risk and cost to the patient and therefore its role in the evaluation of patients with abdominal GSWs is still evolving.

High-velocity GSWs transmit tremendous energy and oftentimes cause serious intraperitoneal damage. If no peritoneal violation is initially determined, these patients should be observed for 12 to 24 hours unless their injury was of low velocity with a superficial missile path. If peritoneal penetration is discovered or if it is suspected, then most centers proceed with laparotomy. However, a SNOM approach in a setting that employs the opportunity for close serial PE and additional diagnostic testing, such as DPL, CT, and DL, is now being adopted by some trauma centers (18).

Is There Evidence of Intraperitoneal Injury?

In those centers not proceeding to laparotomy when peritoneal violation is found or strongly indicated, several diagnostic techniques have been utilized to include or exclude intraperitoneal injury following GSWs to the abdomen. Of these, DPL and CT have received the most attention, with a smaller number of studies evaluating DL.

Diagnostic Peritoneal Lavage

DPL, with a RBC threshold lowered to 5,000 to 10,000 RBC/HPF, coupled with clinical examination, can help guide the need for laparotomy. One study found DPL had a sensitivity of 87.5% and specificity of 95.8% in predicting intra-abdominal injuries from SGWs (22).

Computed Tomography Scan

In patients with torso injuries, CT has been used to determine peritoneal violation and avoid nontherapeutic invasive procedures, including laparotomy, in selected hemodynamically stable patients with penetrating trauma to the abdomen, flank, or pelvis (23). In patients with wounds concerning for colon or rectal injury based on location or other associated PE findings such as rectal bleeding, triple-contrast CT (oral, IV, and rectal) should be performed. In a study of 75 consecutive patients with penetrating torso trauma, triple-contrast CT accurately predicted whether laparotomy was necessary in 96% of patients (24). In another study of 200 patients, triple-contrast CT was 97% sensitive and 98% specific in determining peritoneal violation for hemodynamically stable patients with penetrating torso trauma (25). With the advent of high-resolution CT, some centers utilize CT with only IV contrast in stable patients with nontangential abdominal GSWs and a reliable PE.

Diagnostic Laparoscopy

DL is best used in those patients with tangential GSWs to the abdomen who do not have a clear indication for laparotomy or in those with GSWs to the left low chest without indication for thoracotomy or laparotomy.

CRITICAL INTERVENTIONS

- Completely undress and carefully examine all patients with suspected penetrating trauma to the abdomen.
- Obtain early surgical consultation for patients with penetrating abdominal trauma.

- Perform LWE as an initial screening test in stable patients with anterior abdominal SWs to determine the potential for peritoneal penetration.
- For patients with left low chest or upper abdominal SWs, perform a workup for diaphragmatic injury (laparoscopy, thoracoscopy, or DPL).

DISPOSITION

In most centers, patients who undergo a negative DPL, CT, or DL are observed for 12 to 24 hours to ensure absence of injury, an approach that has been shown to have a wide margin of safety.

Ideally, all patients with an SW or a GSW to the torso are triaged from the point of injury directly to a level I or level II trauma center. When this does not occur, transfer to such a center at the earliest opportunity is recommended. Only lifesaving maneuvers such as endotracheal intubation, tube thoracostomy, pericardial aspiration, fluid resuscitation, and emergent surgical stabilization are indicated before initiating transfer.

Common Pitfalls

- Failure to recognize an SW or GSW.
- Minimizing the injury. The presence of peritoneal injury should be assumed.
- Delaying transport to the OR for patients with indications for laparotomy.
- Blind probing of wound tracts with digits or instruments; this is inaccurate and potentially dangerous.
- Relying on a negative PE or abdominal US to rule out injury after penetrating abdominal trauma.
- Failure to observe and admit the patient with penetrating abdominal trauma for repeat examinations after a negative DPL or CT.
- Failure to obtain early consultation with the trauma team.
- Failure to observe and properly monitor trauma patients who are undergoing diagnostic procedures outside of the ED (e.g., CT

scan in the radiology suite).

CHAPTER 35

Genitourinary Trauma

Carrie D. Tibbles

The genitourinary (GU) system is involved in approximately 10% of acutely injured patients (1). The presentation of GU trauma may be occult and is often overshadowed by more dramatic and immediate life-threatening injuries. However, if these injuries are not identified and properly treated, the patient may experience delayed complications and significant long-term morbidity. Clues to suggest the possibility of GU trauma lie in the mechanism of injury, a constellation of associated injuries, and physical examination findings identified during the secondary survey. For diagnosis and management, GU trauma is generally divided into upper tract injuries (kidney and ureter) and lower tract injuries (bladder, urethra, and external genitalia). A systematic approach and thorough understanding of the appropriate diagnostic modalities are necessary for emergency physicians to effectively manage these injuries.

CLINICAL PRESENTATION

Upper Tract Injury

The kidneys and ureters lie securely in the retroperitoneum, beneath the lower ribs and musculature of the back. Therefore, injuries to the upper urinary tract typically occur in the setting of high-energy, multisystem trauma. Blunt force to the back, flank, or abdomen; falls from height; or, less commonly, rapid deceleration may result in injuries to the kidneys or ureters (2). Upper tract injuries may occur in isolation. However, more commonly, trauma that results in renal injuries produces associated bony, vascular, and visceral injuries that

directly contribute to the observed morbidity and mortality (1). Penetrating injury, which accounts for 6% to 11% of renal injuries, is suggested by transaxial wounds or wounds in anatomic proximity to the kidneys and ureter. Although nearly all significant blunt renal injuries will present with either gross or microscopic hematuria, about 25% to 30% of ureteral injuries will not have associated hematuria. The presence of hematuria is a less reliable indicator of upper tract injury with penetrating trauma and the location of the wound is used to guide subsequent management decisions (3). A vascular pedicle injury may present as refractory hypotension following severe blunt trauma; this injury usually results from a deceleration mechanism.

The American Association for the Surgery of Trauma (AAST) has established a classification system for renal injuries based on anatomic location and severity (Table 35.1; Fig. 35.1) (4). Grade I and grade II injuries consist of contusions and lacerations confined to the cortex respectively and are considered minor injuries. Eighty-five percent of renal injuries are classified as minor injuries. Grade III injuries are deeper lacerations that extend into the corticomedullary junction. Lacerations into the collecting system or those involving segmental arteries are grade IV injuries. The most severe injuries are classified as grade V and include a shattered kidney, thrombosis of the main renal artery, or avulsion of the renal hilum. A review of the National Trauma Data Bank found that the AAST injury scale predicts the need for nephrectomy in both blunt and penetrating trauma and mortality in blunt trauma patients (5). Recently investigators from Parkland recommended a substratification of grade IV injuries into high risk and low risk based on three predictors of needing operative intervention, specifically, intravascular contrast extravasation, hematoma size greater than 3.5 cm, and a medial renal laceration site (6,7).

TABLE 35.1
Grading System for Renal Injuries

Minor Injuries

Grade I: Contusions and contained subcapsular hematomas

Grade II: Nonexpanding perirenal hematomas and cortical lacerations

Major Injuries

Grade III: Parenchymal lacerations into the corticomedullary junction and thrombosis of a segmental artery without an associated parenchymal laceration

Grade IV: Renal lacerations involving segmental renal vessels, lacerations violating the collecting system, and contained injuries to the renal vessels

Grade V: Avulsion of the renal hilum, thrombosis of the main renal artery, shattered kidney

American Association for the Surgery of Trauma grading system.

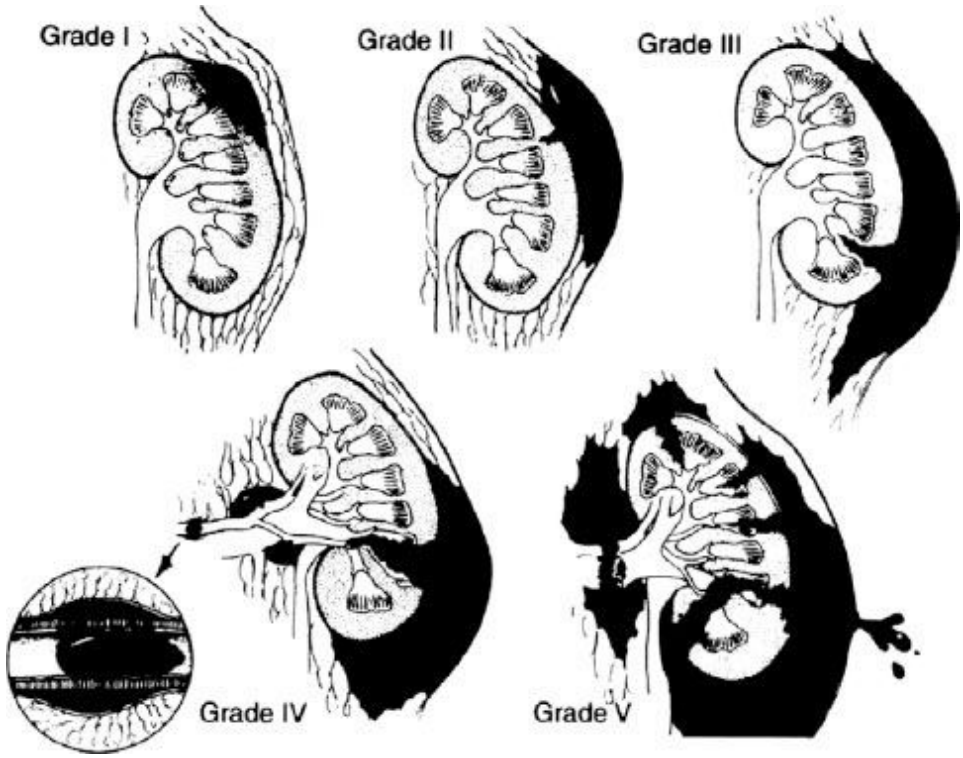

FIGURE 35.1 Grading system of renal injuries. (From Santucci RA, McAninch JW, Safir M, et al. Validation of the American Association for the Surgery of Trauma organ injury severity scale for the kidney. J Trauma. 2001;50:195–200, with permission.)

Lower Tract Injuries

Blunt trauma to the lower urinary tract (bladder and urethra) is usually associated with pelvic rami fractures and symphyseal

diastasis. *Anterior urethral injuries* (penile and bulbous urethra, below the urogenital diaphragm) are associated with self-instrumentation, falls, and straddle injuries. *Posterior urethral injuries* (membranous and prostatic urethra, above the urogenital diaphragm) commonly accompany pelvic fractures (Fig. 35.2). As the urinary continence mechanism and autonomic innervation responsible for erection are contained in the posterior urethra, posterior urethral injuries may result in permanent incontinence and erectile dysfunction. Signs of anterior urethral injury depend on the integrity of Buck fascia. If this fascial layer is torn, blood and urine may pass into the penis, scrotum, and abdominal wall. Clinical signs of urethral injury are blood at the urethral meatus, high-riding prostate, scrotal or perineal hematoma, and difficulty voiding. However, these signs can be absent in some patients with urethral injury.

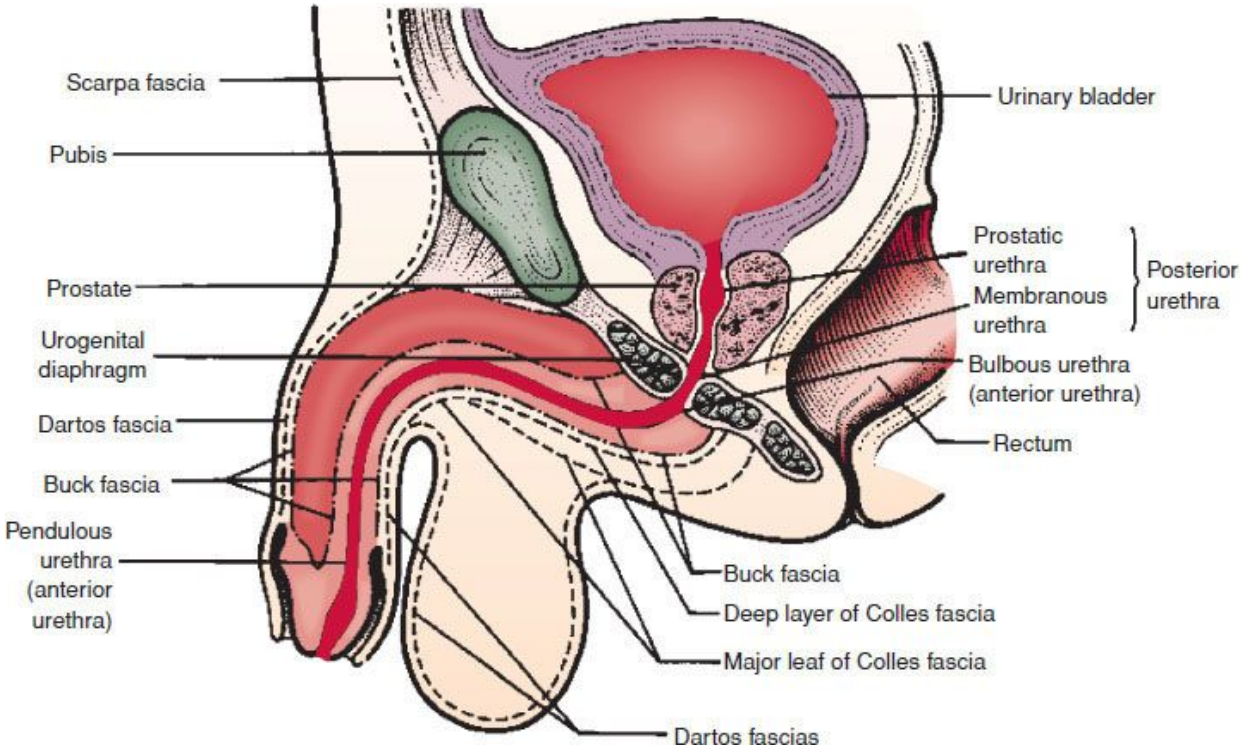

FIGURE 35.2 Normal anatomy of the male urethra. (From Schneider RE. Genitourinary system. In: Marx JA, Hockberger RS, Walls RM, eds. Rosen's Emergency Medicine Concepts and Clinical Practice. 5th ed. St. Louis, MO: Mosby; 2002:438, with permission.)

Bladder rupture is classified as *extraperitoneal* or *intraperitoneal*. *Extraperitoneal* bladder injuries are most commonly associated with pelvic fractures and bladder laceration by bony fragments. There is leakage of urine into the perivesicular space. *Intraperitoneal* bladder injuries result from compressive forces in the presence of a full bladder, and rupture occurs at the dome of the bladder through the peritoneum into the abdominal cavity. The presence of a pelvic fracture and gross hematuria is virtually diagnostic of bladder rupture. Bladder injury is more likely in pelvic fractures with a widened pubic symphysis and sacroiliac disruption (8). Ninety-eight percent of patients with bladder rupture will have gross hematuria. Other signs of bladder injury are suprapubic or lower abdominal pain and tenderness, inability to void, and blood at the urethral meatus.

As with penetrating trauma to the upper GU tract, penetrating injuries to the lower tract are suggested by location of wounds. Any penetration of the lower abdominal wall in the region of the pelvis raises the possibility of urinary tract injury. Given the variability of the projectile tract, any gunshot wound in the region should include consideration of GU tract injury.

External Genitalia Trauma

Testicular injuries are often the result of a fall or direct trauma. They include lacerations, contusions, dislocations, or fractures. Symptoms include pain, nausea, lightheadedness, and acute urinary retention. A swollen, tender testicle or a hematoma may be seen on physical examination. Penile injuries range from small lacerations and contusions to complete amputations. Penile fracture, which involves rupture of the tunica albuginea, most commonly occurs during overzealous vaginal intercourse, although several other mechanisms have been reported (9). Any constricting object placed around the penis can result in marked edema and eventual incarceration and necrosis distal to the constriction. Entrapment of the penis in a zipper occurs most often in uncircumcised young boys.

Vaginal injuries are frequently complications of pelvic fractures but may also be seen following sexual assault or other penetrating injuries. The majority of patients present with vaginal bleeding. A

careful vaginal examination is required in any female patient suspected of having a pelvic fracture. According to one series, up to one-third of patients with vaginal trauma unrelated to childbirth will have concurrent urethral injuries (10).

ED EVALUATION

Upper Tract Injury

The emergency department (ED) evaluation of a multitrauma patient begins with the standard advanced trauma life support assessment and resuscitation. In this manner, immediately life-threatening injuries are identified and treated. In the unstable patient requiring emergency laparotomy for other reasons, gross hematuria and signs of a pelvic fracture should be noted during the secondary survey. Definitive evaluation of the GU tract can be performed once the patient has been stabilized. In the stable patient, the emergency physician determines the necessity of further evaluation and diagnostic imaging.

The first task is to identify those patients at risk for significant renal injuries. Mee et al. published the classic article establishing criteria for the evaluation of blunt renal trauma. This 10-year prospective study of 1,007 consecutive blunt trauma patients established markers associated with increased risk of major renal lacerations. Gross hematuria, microscopic hematuria (>5 red blood cells [RBCs]/high power field [HPF]) with shock either in the prehospital setting or in the ED, or, less commonly, a history of significant deceleration, are associated with renal injuries. The authors concluded that if radiographic evaluation were limited to those patients, no significant renal injuries would be missed (11). These guidelines have been supported by subsequent studies and have become the criteria defining the population of patients who require further radiographic evaluation (2,3,12). While children are more prone to renal injuries than adults because the pediatric kidney is proportionally larger and has less protection from surrounding tissues, the same criteria screening used to image adult patients may be appropriately applied to pediatric patients (13,14). Most authors

advocate radiologic imaging in the setting of penetrating trauma to evaluate for upper urinary tract injuries, as a substantial percentage of patients may have significant injury in the absence of hematuria (2,3).

Computed tomography (CT) scanning is the preferred diagnostic modality for evaluating the hemodynamically stable patient with blunt or penetrating trauma. CT clearly defines parenchymal lacerations, hematomas, and the presence of urinary extravasation; may identify renal vascular injuries; and can identify associated injuries (Fig. 35.3). Significant findings on CT scan include a devitalized renal segment, a nonfunctioning kidney, actively expanding hematoma, or extravasation of urine. Nonfunction suggests extensive trauma to the kidney, renal artery thrombosis, or a severely shattered kidney. Extravasation of contrast material implies trauma involving the capsule, parenchyma, or collecting system.

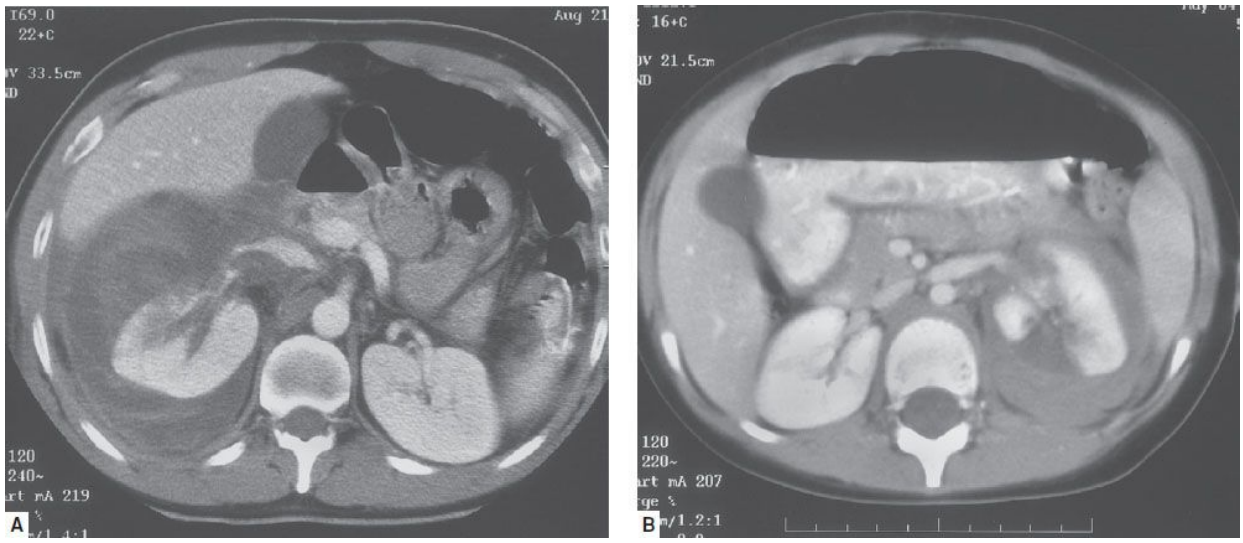

FIGURE 35.3 Renal lacerations with perirenal hematoma.

Arteriography has a very limited role in the evaluation of renal injuries and is reserved for stable patients requiring further clarification of pedicle injuries. Arteriography may demonstrate intimal tears and complete or partial disruption of the renal vasculature. CT findings requiring further evaluation by

arteriography include large perirenal hematomas, major renal fractures, or segmental areas of nonenhancement. Nonenhancement of the kidney on CT scan is diagnostic of renal artery thrombosis and is sufficient indication for surgery without additional studies (15).

Ureteral injury remains a diagnostic challenge. Approximately one-third of ureteral injuries are not identified on initial evaluation. If a ureteral injury is suspected, a contrast enhanced helical CT with delayed images should be obtained. Extravasation of contrast visualized on the delayed images may be the only sign of ureteral injury (Fig. 35.4).

FIGURE 35.4 Delayed CT image demonstrating extravasation of contrast diagnostic of ureteral disruption following blunt trauma.

Lower Tract Injury and External Genitalia Injury

Lower tract GU injuries should be evaluated in a retrograde fashion. Once the potential for injury has been identified based on mechanism of injury, physical findings (i.e., scrotal hematoma, blood at the urethral meatus, or a high-riding prostate), or radiographic

evidence of associated high-risk injuries (i.e., pelvic fracture), the urethra should be evaluated first. The presence of urethral injury should be ruled out prior to Foley catheter placement, because catheter placement may potentially convert a partial urethral tear to a complete urethral disruption. A retrograde urethrogram (RUG) is the diagnostic modality for evaluating the urethra. However, many trauma patients may require urgent CT scan for the evaluation of multiple injuries. The performance of the RUG and subsequent Foley catheter placement can often be delayed until after more urgent CT scans are performed. High resolution CT scan may demonstrate signs of urethral trauma, typically extravasation of urinary contrast material, but is not adequately sensitive to rule out a urethral injury or to fully evaluate or characterize specific injuries.

A RUG is performed with the patient supine. An initial KUB (kidneys, urethers, bladder) is obtained for comparison. A Foley catheter is then passed approximately 1 to 2 cm to the fossa navicularis, and the balloon is inflated with 1 to 2 mL of saline. Alternatively a 60-cc Toomey syringe with a Christmas tree or Cooke adapter may be gently inserted until snug. Lateral traction is applied to the penis, and 60 mL of water-soluble contrast material is injected over 30 to 60 seconds. The radiograph is exposed as the last 10 mL of contrast material is injected. Extravasation of contrast material or failure of contrast material to reach the bladder is diagnostic of urethral injury, mandates urologic consultation, and precludes the passage of a urethral catheter by the emergency physician (Fig. 35.5).

FIGURE 35.5 Retrograde urethrogram with partial tear of membranous urethra.

If a team member inadvertently places a urinary catheter prior to adequate evaluation for urethral injury, *it should not be removed.* It is not necessary to remove the catheter to perform a RUG. Instead, the presence or absence of urethral injury should be determined by passing a small feeding tube beside the catheter and performing a modified RUG.

A diagnostic workup for bladder injury is indicated for patients with gross hematuria, inability to void, or a pelvic ring fracture in association with microscopic hematuria. After exclusion of urethral injury and placement of catheter, a CT cystogram may be performed. Importantly, while a routine CT scan of the abdomen and pelvis may demonstrate evidence of a bladder injury, it is not sufficient to fully exclude these injuries. A CT cystogram is performed after retrograde instillation of 400 mL of dye through a Foley catheter into the bladder to cause bladder distension. CT cystogram is 95% sensitive and 100% specific for the detection of bladder rupture (16).

Clinical examination of the scrotum after blunt trauma is often difficult because of severe pain and swelling. If there is a clinical suspicion of a testicular injury, further evaluation with a CT scan should be performed. Any patient with significant external genitalia trauma with hematuria, urinary retention, or pain with urination should have a RUG to evaluate for a urethral tear.

KEY TESTING

- Hemodynamically stable patients with any of the following require a contrast enhanced CT scan for upper tract injury:
  - Penetrating trauma
  - Blunt trauma with gross hematuria
  - Blunt trauma with microscopic hematuria and hemodynamic instability (hypotension or tachycardia)
  - High-energy deceleration mechanism or suspected associated intra-abdominal injuries
- Patients with any of the following signs require imaging to assess for a lower tract injury:
  - Indications for a RUG:
    - High-riding prostate
    - Gross hematuria
    - Blood at the meatus
    - Trauma to the external genitalia
  - Indications for a CT cystogram:
    - Gross hematuria
    - Inability to void

Pelvic ring fracture
Lower abdominal pain following significant trauma

ED MANAGEMENT

Upper Tract Injury

The principles of care for the patient with multisystem trauma apply to the patient with trauma to the upper GU tract. Hemodynamic stabilization with crystalloid and blood products is the initial priority. Once immediately life-threatening injuries are addressed, evaluation of the GU tract and associated injuries can occur as outlined in the previous section.

In a review of more than 2,500 trauma patients, Santucci et al. (17) demonstrated a very strong correlation between AAST renal injury grade and the subsequent need for surgical intervention. In general, the majority of blunt renal trauma may be successfully managed nonoperatively. Expectant management of grade I, II, and III renal injuries is widespread. In many centers, hemodynamically stable patients with grade IV and potentially grade V injuries are also initially managed with a trial of expectant management. Overall injury severity, renal grade, hemodynamic instability, and transfusion requirements are predictors of subsequent nephrectomy (18). CT scan findings that predict need for operative intervention include extravasation of contract, a perirenal hematoma greater than 3.5 cm, and a medial location of the renal laceration (6). Delayed interventions may be necessary in a subset of patients managed nonoperatively who develop complications, including persistent bleeding, formation of urinoma, or persistent urine leak. As expected, these complications are more common in patients with higher grade injuries. Patients with the combination of a devitalized renal segment and extravasation of urine on the initial CT scan are particularly at risk. Most complications can be managed by either endoscopic or percutaneous techniques (19). Following traumatic nephrectomy or conservative management of high grade lesions, the majority of patients will have full recovery of their renal function and a normalization of their creatinine (20).

The management of penetrating upper tract trauma has evolved in recent years. There is a lower threshold for operative exploration and intervention after penetrating trauma, but many of these injuries are now managed nonoperatively as well. According to the EAST Practice Guidelines, nonoperative treatment of penetrating renal lacerations is appropriate in hemodynamically stable patients without associated injuries who have been staged completely with CT scan (12). Expectant management of stab wounds is more widely accepted, although small series of successful nonoperative management of renal gunshot wounds have also been published. Delayed bleeding can be seen in up to 20% of patients following nonoperative management of renal stab wounds, particularly when the patient increases activity. This bleeding may be managed by therapeutic angiography and rarely requires intervention (19). Figure 35.6 outlines a potential algorithm for the conservative management of renal injuries. Ureteral injuries and injuries to the renal pelvis are repaired surgically or stented. Renovascular injuries are typically managed with an immediate nephrectomy or they are repaired primarily.

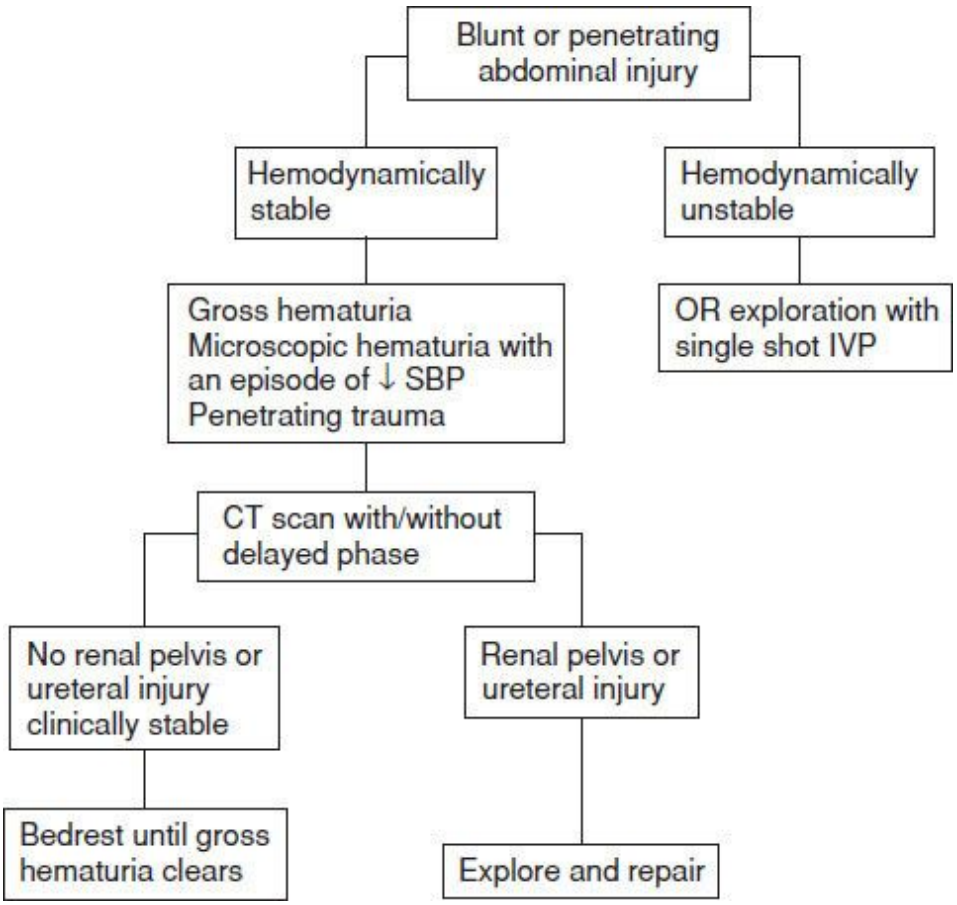

FIGURE 35.6 Algorithm for the management of renal parenchymal injuries. (Adapted from Santucci RA, Fisher MB. The literature increasingly supports expectant (conservative) management of renal trauma—a systematic review. J Trauma. 2005;59: 493–503.)

Lower Tract Injuries

If a urethral disruption is identified, urologic consultation should be obtained and a suprapubic tube should be placed to allow drainage of the bladder. This may be performed in the resuscitation bay if the patient is stable. If the patient is unstable and requires operative intervention for associated injuries, it can be performed in the operating room. If a catheter was placed prior to identifying the injury, it should be left in place. Occasionally, a catheter may be placed through a partial urethral tear. Once the partial disruption is

identified, however, any gentle and limited attempts at urethral catheterization should be done by a urologist.

The acute management of bladder rupture is bladder drainage via Foley catheter. Patients with intraperitoneal bladder rupture undergo primary surgical repair. Those patients with extraperitoneal bladder rupture are typically managed nonoperatively, with simple urinary drainage by Foley catheter or a suprapubic catheter. In general, in the absence of urethral injury, a transurethral catheter is preferred over a suprapubic catheter as it is associated with fewer complications and days of catheterization (12).

External Genitalia Injury

Diagnosis of testicular rupture or dislocation should prompt urgent urologic consultation, as surgical repair within 72 hours dramatically improves the salvage rate.

There have been several reported cases of microvascular reimplantation following amputation of the penis. Successful repair depends on the condition of the severed part and the ischemia time. In the prehospital and emergency setting, the amputated penis should be preserved in a manner similar to that for other amputated parts. Prompt urologic and microvascular consultation is imperative for successful reimplantation (21). Penetrating trauma to the external genitalia mandates early surgical exploration and conservative debridement; this is followed by primary repair in most cases (22). Some authors have also advocated operative repair of penile fractures, proposing that it decreases the incidence of erectile deformity and may speed recovery (9). For patients with penile zipper entrapment, Nolan and associates described the successful atraumatic removal by cutting the median bar of the zipper with bone cutters. The upper and lower shields of the zipper device separate, releasing the skin with minimal injury (23). Penile incarceration may be managed by the string technique, similar to that described for removal of rings from fingers.

CRITICAL INTERVENTIONS

- Address immediately life-threatening injuries first. If the patient is hemodynamically unstable, evaluation of the GU system can be performed after operative intervention for other injuries (e.g., intraperitoneal injuries).
- Rule out a urethral injury by clinical examination, and RUG if necessary, before placement of a Foley catheter.
- Obtain an urgent urology consultation if testicular disruption is diagnosed.

DISPOSITION

The majority of patients with blunt renal injuries require admission to the hospital. Selected patients with microscopic hematuria in the absence of any hemodynamic instability, and no associated injuries, may be discharged with a follow-up repeat urinalysis in 1 week to ensure resolution. All patients with penetrating renal or ureteral trauma require admission or transfer to a facility capable of providing definitive diagnostic and therapeutic care. Disposition following trauma to the external genitalia depends on the complexity and severity of the injury as well as any associated injuries. Many of these patients will require a urology consultation in the ED or close outpatient urology follow-up.

Common Pitfalls

- Failing to consider upper tract injury in the absence of hematuria. Patients with renal pedicle injury resulting from a deceleration mechanism, or ureteral injury resulting from penetrating trauma, may not have hematuria.
- Delaying an urgent laparotomy to perform further diagnostic imaging of the GU tract.
- Ruling out significant injury following penetrating trauma to the flank based on a suboptimal local wound exploration. If the wound is in anatomic proximity to the GU tract, the patient requires further diagnostic evaluation.
- Failure to obtain a RUG prior to attempting to place a Foley catheter in the presence of a potential urethral injury.

- Attempting to rule out bladder injury with routine abdominal CT without adequate distension of the bladder (i.e., instillation of 400 mL of contrast).

CHAPTER 36

Peripheral Vascular Injuries

Maria E. Moreira and Peter T. Pons

Prompt recognition and management of peripheral vascular injuries is crucial to limb salvage and preservation of function. A vascular injury should be suspected in any patient with a penetrating injury or a major fracture or dislocation secondary to blunt trauma. Penetrating trauma accounts for approximately 85% of vascular injuries in the United States; blunt trauma and iatrogenic causes are responsible for the rest.

Blunt trauma can cause spasm, external compression, mural contusion, intimal tear, thrombosis, or aneurysm formation. A high index of suspicion is necessary in these cases as injury can be very subtle in presentation. Stretching, tearing, or shearing forces can damage a vessel while leaving very little external injuries. The classic example is dislocation of the knee with associated popliteal artery injury in which there are very few visual clues to indicate vascular injury.

In penetrating trauma, the penetrating object can directly injure vascular structures when traversing the path of a vessel. Injuries can include partial or complete vessel transection, contusion, laceration, or arteriovenous fistula. The most commonly involved vessels are the brachial and axillary arteries in the upper extremity and the femoral and popliteal arteries in the lower extremity.

The emergency physician must obtain a complete history, perform a careful physical examination, and be aware of the mechanics that

produce vascular injury, even if there are minimal or absent physical findings that suggest vessel damage.

CLINICAL PRESENTATION

Evaluation of extremity pulses distal to the injury is essential to the identification of vascular injuries. The following pulse findings are indicative of a vascular injury: diminished or absent pulses, thrill or bruit suggestive of an arteriovenous fistula, a pulsatile mass or rapidly expanding hematoma. Other etiologies for the pulse difference, such as shock should also be considered. Pulse differences due to shock should correct with resuscitation. The examiner must consider that the presence of a pulse does not completely exclude a vascular injury. Collateral circulation or transmitted pressure waves through a small clot or intimal flap can produce a distal pulse.

A Doppler can be used to further assess quality of pulses. The three levels of Doppler signal are monophasic, biphasic, and triphasic. Triphasic is the normal signal in an intact vessel. Changes in the signal can provide an indication of vascular compromise. When a triphasic signal changes to a monophasic signal the provider needs to consider loss of flow. This signal is evaluated in conjunction with other physical examination evidence of perfusion (1).

Determining the arterial pressure index (API) is an important adjunct to the physical examination. A Doppler is used to determine the systolic blood pressure distal to the penetrating injury. The systolic pressure is then measured in the same location in the contralateral uninjured extremity. The ratio of the injured to the uninjured extremity is the API. A normal API is greater than or equal to 0.9. A ratio of less than 0.9 is indicative of a vascular injury and necessitates further evaluation (1–3). The sensitivity and specificity of API of less than 0.9 is 87% and 97%, respectively. In one study when insignificant injuries were excluded the sensitivity of API less than 0.9 increased to 95% (4).

Ankle-brachial index (ABI) is often considered synonymous with API. The ABI is calculated as follows: systolic blood pressure at dorsalis pedis or posterior tibialis divided by the brachial systolic blood pressure. An ABI less than 0.9 is considered abnormal.

Typically, ABI has been used in the diagnosis of peripheral vascular disease, although it is not uncommonly used for trauma patients as well. In a patient with underlying peripheral vascular disease obtaining both an ABI and an API may be useful in identifying a new injury due to trauma.

The other "P"s of arterial compromise leading to ischemia include pallor, pain, poikilothermia, paresthesias, and paralysis. Additional findings may include tenseness of the extremity, coolness to touch, and delayed capillary refill (>3 seconds). Unfortunately, some of these signs require a patient who can relate these complaints, and many multiply injured patients cannot. In addition, concomitant neurologic injury of the extremity may present with similar findings. Careful examination is necessary to differentiate the paresthesias of vascular insufficiency from those of neurologic injury. As many as 70% of upper- and 30% of lower-extremity vascular injuries have associated nerve damage, of which 40% to 45% result in permanent deficit.

Many vascular injuries appear relatively innocuous at first glance. Penetrating wounds of an extremity can present with a small entrance site that harbors significant underlying vascular damage. Blunt injury may be quite misleading because of minimal obvious external signs. Thus, repeat examination of the patient is important to look for evolving signs of vascular injury.

Finally, the structural integrity of the skeletal system must be evaluated. About 18% of patients with peripheral vascular injuries have an associated fracture from either blunt or penetrating trauma.

ED EVALUATION

Initial physical examination findings will dictate further evaluation. Patients with hard signs of vascular injury (Fig. 36.1) require immediate intervention. Hard signs include absent pulses, active hemorrhage, rapidly expanding hematoma, and palpable thrill/bruit. In such cases, operative intervention should not be delayed for other diagnostic studies or radiographic imaging, unless the location of the vessel injury cannot be determined clinically (5). In the absence of hard signs in a hemodynamically stable patient, further evaluation

can be undertaken. Patients with an API <0.9 require further testing. Those with soft signs of injury (diminished pulses, large nonexpanding hematoma, peripheral nerve injury, or delayed capillary refill) and proximity wounds can be followed with serial physical examinations, tracking the API (3,6–9). Color-flow duplex Doppler ultrasonography can also be used to assess patients with soft signs (10–12). Color-flow duplex Doppler ultrasonography interprets the sound of blood flow and shows it as red and blue colors based on the speed and direction of the flow relative to the ultrasound probe. This sonographic technique will easily demonstrate absence of arterial flow but is less valuable for more subtle injuries such as intimal flaps or pseudoaneurysms that may not interrupt blood flow in the damaged vessel (10).

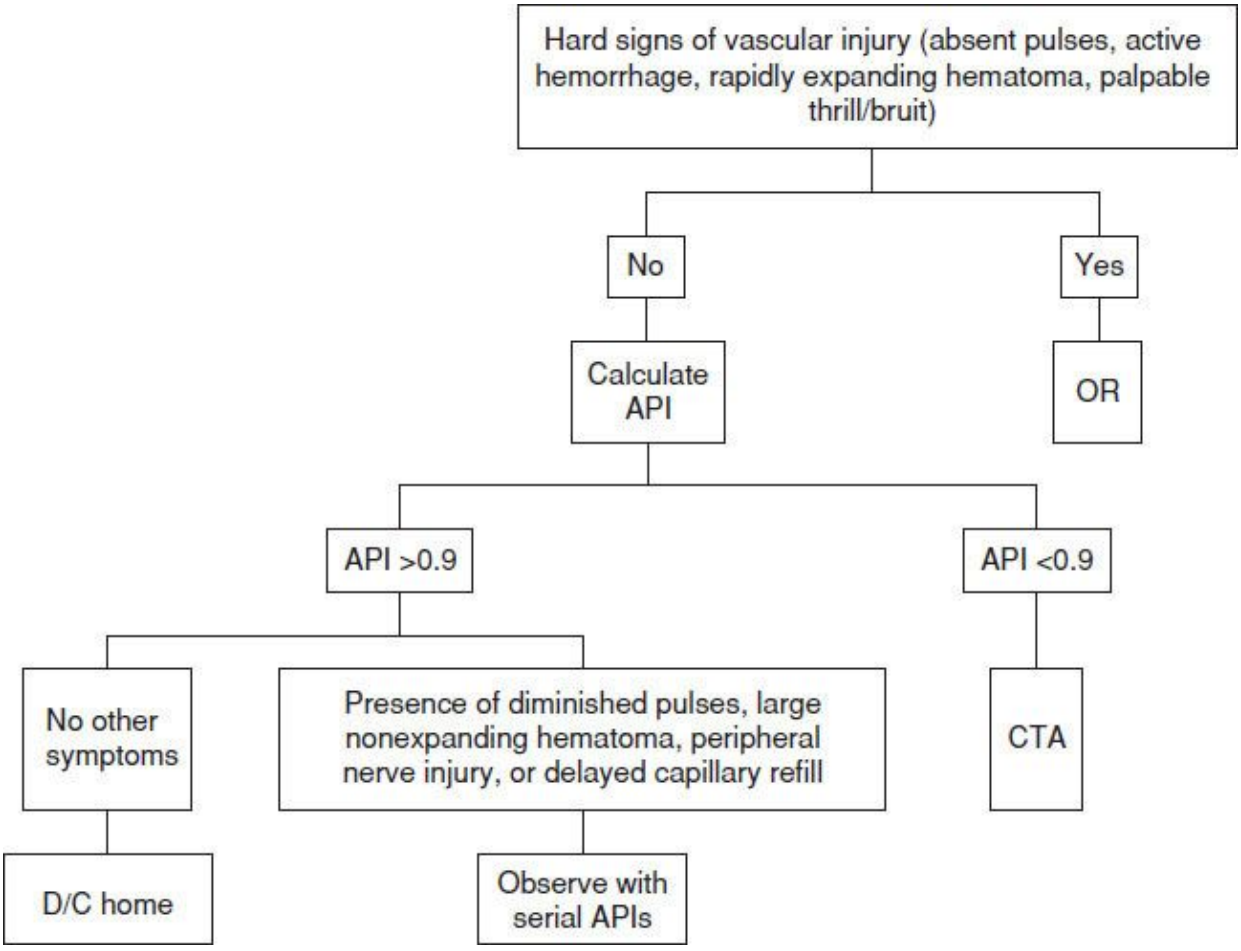

FIGURE 36.1 Peripheral vascular injury clinical algorithm.

The mainstay of evaluation and diagnosis has been contrast arteriography, with a sensitivity of 97% to 99% for detecting arterial injury. Magnetic resonance angiography (MRA) and spiral computed tomographic angiography are other options for evaluating vascular injuries (13–18). CTA is currently the preferred study for initial evaluation of the vasculature due to its ready availability and use of only intravenous contrast. Several studies demonstrated CTA to have a 100% sensitivity and specificity for detecting clinically significant arterial injuries (4,19,20).

Shotgun wounds to an extremity have a much higher incidence of vascular injury owing to the nature of the weapon (i.e., multiple missiles and multiple trajectories) (12). In addition, victims of blast injury, high-velocity weapons, and military munitions have a higher incidence of vascular injury (21). Therefore, angiography is indicated in these patients unless the physical examination, including API, suggests that the potential for vascular injury is remote. If angiography is not performed, a period of observation is warranted.

Each institution should determine in advance how it plans to evaluate patients with potential peripheral vascular trauma by having protocols in place agreed upon by the emergency medicine, surgery, and radiology departments.

KEY TESTING

- Determine the arterial pressure index (API)
- CTA should be performed in patients with API <0.9
- Patients with soft signs can be followed by serial examinations monitoring the API

ED MANAGEMENT

Prehospital and emergency department (ED) management priorities include control of hemorrhage, fluid resuscitation, and assessment and management of other life threats (9).

Hemorrhage should be controlled by direct pressure over the bleeding site. Blind clamping of bleeding vessels deep in a wound is to be condemned, as adjacent structures such as nerves and tendons

may be crushed in the attempt to stop hemorrhage. If a bleeding vessel can be identified and isolated, it may be clamped using a noncrushing vascular clamp. Recent work in animals and experience in the conflicts in Iraq and Afghanistan suggest that hemostatic agents may be of benefit in controlling exsanguinating hemorrhage secondary to proximal vascular injury such as femoral artery or vein injury in the groin (22). If compression or hemostatic agents are unsuccessful at stopping the bleeding, tourniquets can be used as a temporizing method (3). The key is to minimize the tourniquet time.

Fluid restoration is accomplished by initiating one or more intravenous lines (as the trauma mechanism and vital signs dictate) and infusing crystalloid. After bleeding is controlled and resuscitation started, a careful examination for other life-threatening injuries is performed. As with all trauma patients, a patent airway and adequate ventilation must be ensured while circulation is being addressed. Vascular injuries are treated after other potential life threats have been assessed and managed.

Angulated fractures associated with pulse deficits should be anatomically repositioned and splinted. This may restore perfusion to an ischemic extremity by alleviating kinking of the blood vessel.

Blood for type and crossmatch should be sent to the laboratory and appropriate preparations made for transfusion if blood loss or anticipated surgical needs indicate. Unless indications for immediate surgery are present, complete evaluation for possible vascular injury should follow.

Tetanus immunization status should be ascertained and the patient immunized, if necessary. Prophylactic antibiotics are indicated when operative repair or vascular grafts are to be undertaken and if there is an open fracture. Anticoagulants should generally not be given until surgical consultation has been obtained, the absence of other major injuries has been determined, and the patient is ready to undergo arterial repair.

CRITICAL INTERVENTIONS

- Control hemorrhage by using direct pressure over the bleeding site.

- Resuscitate with crystalloid infusion and blood when indicated.
- After bleeding is controlled, perform a general examination for other life-threatening injuries.
- Measure the arterial pressure index in all patients with penetrating extremity trauma.
- Reduce angulated fractures associated with pulse deficits immediately.

DISPOSITION

Surgical consultation must be obtained as early as possible, as the amount of time elapsed from injury until operative repair is a crucial determinant of successful repair and decreased morbidity in the ischemic extremity. Endovascular embolization may be an option for treatment of nonessential vessels in select situations. Endovascular stent placement is an alternative to surgery for the treatment of vascular injuries and is gaining increasing acceptance and use (23). Observation for a period of 12 to 24 hours is appropriate for vascular proximity wounds in patients without obvious signs of vessel injury and a normal API. In fact, one study suggests that asymptomatic patients with an API ≥ 1 may be safely discharged from the ED (24). In addition, clinically occult arterial injuries have been shown to have a benign course. Therefore, patients meeting the following criteria are candidates for observation: <5-mm intimal disruption, adherent intimal flaps, intact distal circulation, and no active hemorrhage (6,9). The medical team taking care of the patient will need to make the assessment of whether operative repair versus amputation is the optimum treatment for the patient given other potential injuries (25).

Common Pitfalls

- Failure to realize that vascular injuries may be subtle in origin and misleading on physical examination.
- Failure to appreciate injury mechanics or vessel proximity to a penetrating wound.

- Failure to recognize that delays in diagnosis of vascular compromise may lead to permanent deficit or loss of the limb.
- Blind clamping of bleeding vessels deep in a wound.

PART 3 • ORTHOPAEDIC TRAUMA

CHAPTER 37

Approach to Musculoskeletal Injuries

Andrew D. Perron and Carl A. Germann

Musculoskeletal injury has been cited as the second most common reason for emergency department (ED) visits in the United States (1). In addition, missed fracture has been cited as a common reason for medical malpractice lawsuits against emergency physicians (2). A coherent and systematic approach to the assessment and management of patients with orthopedic injuries and other musculoskeletal complaints is essential (3). Musculoskeletal injuries range from minor (tendinosis, sprains, strains, and contusions) to potentially life- and limb-threatening trauma (pelvis fracture, femur fracture, knee dislocation). Most of the time, acute trauma is responsible for the presenting complaints, and usually the primary impairment is an inability to move a part of the body owing to pain or discomfort. The mechanisms of trauma include sports injuries, assaults, motor vehicle collisions, falls in the home, and industrial catastrophes. When acute trauma is absent, overuse syndromes or repetitive movements are often the culprits.

The immediate tasks of the emergency physician evaluating a patient with a musculoskeletal complaint include the following:

- Accurately determining those injuries that need only symptomatic care and distinguishing them from ones that require more complex, timely specialist intervention.
- Differentiating injuries that can be handled solely by an emergency physician (the vast majority of musculoskeletal injuries) from those that require emergent consultation or

timely referral to an orthopedic surgeon (e.g., open fractures, compartment syndrome, growth plate injuries, and flexor tendon injuries).

- Formulating a logical, cost-effective algorithm for the diagnosis and management of each patient.
- Realizing the limitations of diagnostic modalities and the potential for "missed" injuries.
- Aggressively managing the pain associated with these injuries early and effectively, recognizing that "a mere sprain or contusion" can be the source of exquisite pain. Also paying particular attention to analgesia in those patients at the extremes of age (very young and very old), where it has been shown that oligoanalgesia is the rule, rather than the exception.
- Recognizing that care for many musculoskeletal injuries is not complete when emergency care has been delivered. Successful management of the patient is complete only when appropriate follow-up has been arranged, as a large percentage of acute musculoskeletal injuries require reevaluation and ongoing care (e.g., physical therapy and rehabilitation) for optimal recovery.

CLINICAL PRESENTATION

Sprains

A sprain is a ligamentous injury. Ligaments link bone to bone. Damage to the fibers of the ligament ranges from microscopic damage to complete disruption. A sprain can result from an abnormal (nonbiomechanical) force vector applied to a joint, an excessive force applied along a normal vector, or a combination of the two mechanisms. It is possible to sustain a sprain that is significantly more severe than an analogous fracture. For example, a complete lateral ankle ligament rupture and a transverse avulsion fracture of the distal fibula cause the same pattern of instability. However, because bone regenerates without scarring, the outcome for the latter injury can be significantly better.

The grading of sprains is based on the severity of the damage, recognizing that with an acute injury there may be too much pain

and spasm to accurately determine the grade of the sprain.

Grade I Sprain

A grade I sprain (in older terminology, “first-degree”) represents microscopic tears of the ligament, which lead to localized hemorrhage and inflammation as the healing process evolves. Active range of motion is usually preserved but painful. Abnormal movement of the joint stabilized by the sprained ligament is not elicited by stress maneuvers, but these maneuvers may produce focal pain, and the area overlying the sprained ligament is tender to palpation.

Grade II Sprain

In a grade II sprain (“second-degree”) or partial tear, the overall macroarchitecture of the ligament is preserved, with the majority of fibers still in continuity, but clearly some of them have been completely ruptured. Hemorrhage is more extensive, and swelling is often pronounced. Loss of function secondary to decreased and painful range of motion is the hallmark. When the joint that the ligament stabilizes is stressed, there may be some gapping of the joint or abnormal motion. However, with a grade II sprain, any abnormal laxity is limited, and frank instability does not occur.

Grade III Sprain

A grade III sprain (“third-degree”) denotes a complete tear of the ligament and is synonymous with a complete rupture. Hemorrhage is more extensive, and healing involves the formation of scar tissue in the area between the torn fragments of the ligament. Stressing the joint reveals greater gapping than in the case of a grade II sprain, and frank instability without a well-defined end point may be elicited. This frank instability can be summed up by the examiner’s thought, “I should stop stressing this joint, as it isn’t going to resist my efforts.” This is tempered by the knowledge that with acute injury, the physical examination may be severely limited owing to acute pain and muscular spasm.

Common ligament sprains seen in the ED include lateral ankle sprains, injuries to the anterior cruciate and collateral ligaments of

the knee, and ligamentous injuries of the shoulder, associated with either glenohumeral dislocations or acromioclavicular separations.

The clinical signs of a sprain typically include point tenderness to palpation, swelling, painful or decreased range of motion, and ecchymosis. With a complete (grade III) sprain, with no fibers in continuity, the joint may be completely pain free when stressed. Often, athletes will continue to play after a grade III sprain of the medial collateral ligament of the knee, but it is rare that they continue activities after a grade II sprain. In fact, pain may be inversely proportional to the severity of the injury. A grade I sprain is extremely painful when stressed, as there are many intact but damaged and inflamed fibers that will be stretched, triggering the discharge of pain fibers as the ligament is loaded with force. With a grade III sprain, the same maneuver does not cause any stretching of the ligament, as it cannot be loaded by force, and the only pain fibers triggered by the stress maneuver will lie in surrounding soft tissue. Bone can be injured at the same time as a ligament is damaged. For example, grade III sprains of the medial, deltoid ligament of the ankle are often accompanied by fibula fractures. Bony evidence of sprains on x-ray may include small avulsion fractures at the point of insertion of the ligament into the bone, impaction injuries, or joint space widening.

Strains

Tendons connect muscles to bone. A strain is an injury to this musculotendinous unit, which can range from mild “pulled muscles” to complete tendon ruptures. The mechanisms of injury are twofold: (a) Stretching a muscle beyond its normal range of motion by forced extension (“overstretching injury”) and (b) tearing of muscle or tendon fibers by a violent, uncontrolled contraction or repetitive, prolonged contractions, often in attempted compensation for an unexpected change in direction of movement, unanticipated variations in terrain, or a sudden force applied to the antagonist muscle group.

Strains are graded from first-degree to third-degree, reflecting the severity of damage:

- In a first-degree strain, microscopic damage occurs to the musculotendinous unit, with associated localized hemorrhage, inflammation, and tenderness to palpation. Active range of motion is often unrestricted, but pain can be elicited by resisted contraction or forced extension of the muscle group.
- A second-degree strain involves more severe damage, with rupture of some fibers of the muscle or tendon. Hemorrhage is usually visible, swelling more severe, and range of motion limited by pain.
- In a third-degree strain, the muscle or tendon is completely ruptured. The rupture can occur in the muscle belly, at the musculotendinous junction, within the tendon itself, or at the point of insertion of the tendon into bone.

Common strains seen in the ED include those to the quadriceps, hamstring, rotator cuff, thigh adductor (groin), and Achilles tendons.

The clinical signs of a strain include pain, ecchymosis, edema, and decreased or painful range of motion. With complete disruption of the muscle or tendon, a palpable defect is often present. Physical examination should include inspection of the injured area, observation of active and passive range of motion, palpation of the affected area, and provocative maneuvers (either resisted contraction or passive stretching) to elicit the location and extent of injury. In addition, with certain suspected injuries, specific tests should be performed. For example, if an Achilles tendon rupture is suspected, then a Thompson test is performed. While the patient lies prone with the knee flexed at 90 degrees, the examiner squeezes the calf on the affected side and observes whether the foot plantar flexes. The presence of plantar flexion indicates an Achilles tendon that is at least partially intact. Absent plantar flexion often represents complete Achilles tendon rupture.

Contusions

A contusion is a bruise caused by a direct blow to a body part. Contusions can occur to bone, with significant pain from periosteal bruising and bone edema, or, more commonly, to soft tissue, especially fat and muscle. In these crush injuries, the degree of injury is proportional to the force of the blow and the surface area of impact. Tissue damage occurs as the energy transmitted by the impact dissipates into or is absorbed by surrounding structures.

The diagnosis of contusion is one of exclusion, with fracture, dislocation, sprain, and strain being the most important diagnoses that must be ruled out. Common contusions seen in the ED include bruised quadriceps muscles, rib cage contusions, contusions of the ulnar aspect of the forearm in "defensive maneuvers" during an assault, and direct blows to the anterior tibia.

Either the blow itself or the body's reaction to it causes signs and symptoms that prompt the patient to seek emergency care. Typically, they include pain, swelling, ecchymosis, and decreased range of motion of the affected part.

Usually, the entities that are ruled out (e.g., fracture, dislocation, sprain, and strain) are potentially more serious than the diagnosis of contusion itself. However, the clinician must remember that contusions can lead to serious complications, including severe pain, rhabdomyolysis, compartment syndrome, and *myositis ossificans.*

One of the most common reasons that patients seek reevaluation in an emergency room is inadequate analgesia following a soft tissue injury. Initial attention to adequate analgesia ensures patient comfort and decreases the need for reevaluation. A number of studies have confirmed that physicians notoriously undertreat painful conditions (4–6). This is particularly true in both the pediatric and geriatric patient populations.

Severe muscle breakdown can occur after strenuous exercise without an acute, isolated injury or after a significant contusion to a muscle body. *Rhabdomyolysis* results from the destruction of myocyte cell membrane integrity. The subsequent release of intracellular contents, including potassium, myoglobin, uric acid, phosphate, and the enzyme creatine kinase, into the bloodstream can result in a number of systemic complications, including

metabolic abnormalities and acute renal failure. The emergency physician must assess the extent of tissue involvement, the degree of tissue destruction, and the potential for systemic complications. If rhabdomyolysis is suspected, urinalysis should be performed to look for evidence of myoglobinuria (dipstick positive for blood without microscopic evidence of erythrocytes), and the serum creatine kinase level should be checked (see Chapter 213, "Rhabdomyolysis" for details).

Compartment syndrome occurs when pressure within soft tissues in a fixed body compartment increases to the point at which it compromises venous blood flow and limits capillary perfusion. This leads to muscle ischemia and necrosis. Most commonly associated with long bone fractures, it can occur in the setting of severe contusion, crush injury, or excessive exertion and must be considered in any patient with pain out of proportion to physical findings or with swelling causing obvious tautness in a nonexpansible compartment, such as the anterior tibial compartment. When this diagnosis is considered, it must be objectively ruled out by manometry (see Chapter 48, "Acute Compartment Syndrome," for details).

Severe hemorrhage into a muscle can initiate a cascade of "healing," which can lead to the formation of ectopic bone within the muscle, or *myositis ossificans.* A large number of these cases have occurred in athletes treated with early, aggressive nonsteroidal anti-inflammatory drugs (NSAIDs), heat, massage, and physical therapy in the hope of facilitating early return to athletic competition.

This is of concern to the emergency physician for a number of reasons. If severe quadriceps tear and resultant hemorrhage and ecchymosis are suspected, the initial management should include ice, a brief period (24 hours) of immobilization in a stretched position (knee flexed to 120 degrees for severe quadriceps contusion), and acetaminophen, instead of NSAIDs, for pain control (7). This regimen limits the ongoing bleeding and inflammation in the area. These patients must be referred for appropriate long-term follow-up care. In addition, a decreased range of motion, ongoing pain, and a mass or firmness in soft tissue weeks to months after

sustaining a contusion should suggest the possibility of *myositis ossificans,* as noted above. A soft tissue x-ray is the best way to evaluate for heterotopic bony formation. If heterotopic bone is present, the patient should be referred to an orthopedic surgeon for close follow-up care and potential resection of the bone when it has matured (usually at 9 to 12 months).

Fractures

Most fractures require urgent medical attention. Without appropriate emergency care, many will not heal properly or healing will be accompanied by unnecessary complications. A *fracture* is defined as a partial or complete break in a bone. Bone is unique in that it is the only tissue in the human body, other than the liver, that heals by regeneration, not by scarring (8–10). For regeneration to occur, however, the bone must be immobilized to allow uninterrupted formation of new bone. Ensuring appropriate immobilization is one of the fundamental tasks of the emergency physician when dealing with musculoskeletal problems.

The process of new bone formation begins with hematoma bridging the realigned fracture fragments. Hematopoietic cells in the hematoma secrete growth factors, which stimulate the formation of granulation tissue at the fracture ends, resulting in slow resorption of the hematoma. Over the next several weeks, a primary callus is formed, beginning as a soft callus and progressing to a hard callus. The final phase of healing is remodeling, during which the bone reassumes its original architecture as it is exposed to the normal stresses of weight bearing and movement (9,10).

Fractures also require immediate attention for several other reasons. Virtually all fractures are painful. The vast majority of fractures result from high-energy trauma (relative to sprains, strains, and contusions) and, because of force vectors, are accompanied by well-known associated injuries (e.g., 15% of calcaneal fractures sustained in a fall from height have associated lumbar vertebral fractures). In addition, many fractures place the patient at risk for specific complications (e.g., compartment syndrome in long bone

fractures, blood loss in pelvic fractures, avascular necrosis [AVN] in scaphoid fractures of the hand, fat embolism with femur fracture).

A working knowledge of the nomenclature of fractures is essential to the successful management of fractures in the ED and to ensure clear communication with radiologists and consulting orthopedic surgeons. Adequate description of a fracture includes the bone(s) involved, whether it is open or closed, the location and direction of the fracture within the bone, the number of fragments, the alignment of the fracture fragments, the displacement of the fragments, and notation of associated complications (e.g., compartment syndrome, neurologic or vascular deficits).

The description of the injury should include the side of the body, the specific bone, and the location within the bone. By convention, long bones are divided into proximal, middle, and distal thirds, and these divisions are used to describe the fracture location. Alternatively, long bone injuries can be described as diaphyseal (shaft), metaphyseal (flared ends), or epiphyseal (rounded ends). If the fracture lies at the junction of any two-thirds of the bone, it should be described as such. Fractures in children deserve special mention. In this group, fractures occur frequently through the physis (growth plate), as this is the weakest point in the bone or investing soft tissue. Fractures to the physis can disrupt future bone growth if not recognized and adequately treated. These injuries are described with the Salter–Harris classification system (Fig. 37.1).

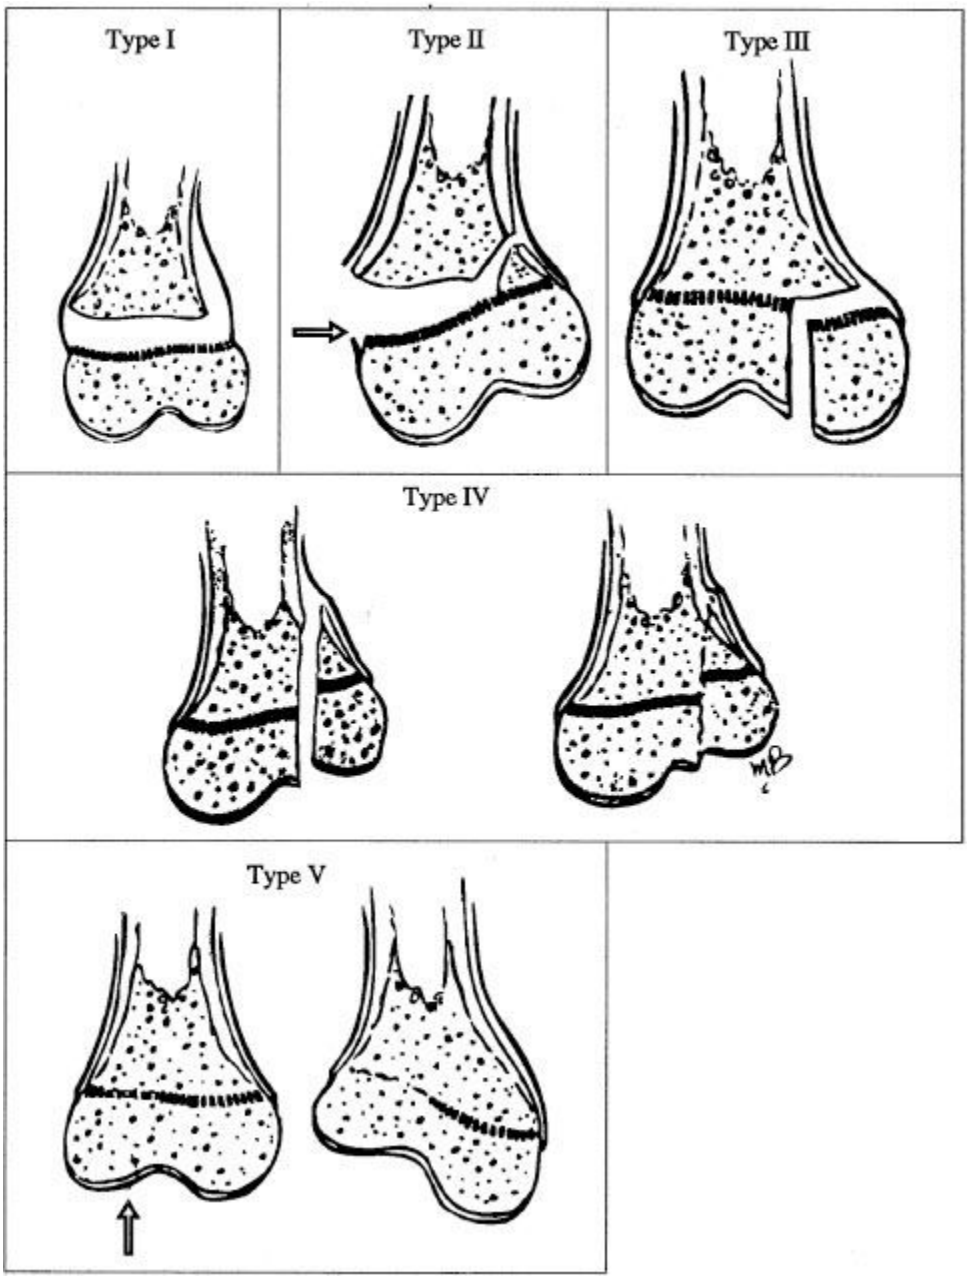

FIGURE 37.1 Salter–Harris fracture classification. (From Rang M. The growth plate and its diseases. In: Rockwood CA Jr, Wilkins KE, King RE, eds. Fractures in Children. 3rd ed. Philadelphia, PA: Lippincott-Raven Publishers; 1991:128, with permission.)

Closed Versus Open Fractures

The old terminology of *simple* (closed) and *compound* (open) fractures should be abandoned, as "simple" linear fractures may be open, and comminuted fractures may be closed. In a closed fracture,

the skin and soft tissue overlying the fracture have not been violated. Therefore, no communication exists between the outside environment and the fracture fragments. Any break in the skin overlying a fracture must be considered an open fracture until proven otherwise. It is frequently difficult to tell whether there has been actual communication between the bone and the environment or whether the patient has simply sustained an abrasion to the skin overlying the fracture.

Open fractures are traditionally classified into three types based on the size of the wound and the amount of soft tissue injury. *Type I* wounds are <1 cm long, the energy dissipated by the mechanism of injury is low, and there is minimal soft tissue trauma. *Type II* wounds are <10 cm long, the mechanism of injury has dissipated a low or moderate amount of energy, and there is moderate soft tissue trauma but no gross contamination of the wound, major crush injury, or soft tissue defects or flaps. *Type III* wounds are >10 cm long. These include high-velocity gunshot wounds, close-range shotgun wounds, open fractures with major vascular injuries, fractures more than 8 hours old, or open fractures sustained in environments where exposure to fecal contents is a concern (e.g., open pelvic fractures with perineal exposure), or extensive soft tissue or periosteal stripping of bone, or evidence of gross contamination or significant crush injury (11).

Open fractures are orthopedic emergencies. These injuries frequently require immediate control of hemorrhage, which can usually be accomplished with appropriate splinting. In addition, open fractures may require emergent reduction if neurovascular compromise exists. Principles of care include irrigation, early administration of sufficient analgesia and appropriate antibiotics, tetanus prophylaxis, and emergent consultation with orthopedic surgery for definitive irrigation, debridement, reduction, and fracture repair in the operating room. Appropriate early intervention is the best way to prevent future complications, as the incidence of infection following open fracture is directly proportional to the time from injury to definitive irrigation and debridement.

Direction and Description of Fractures

The *direction* of a fracture refers to the configuration of the fracture—the way the fracture disrupts the bone. By convention, this descriptive modifier communicates the direction of the fracture in relation to the long axis of the involved bone (Fig. 37.2). A *transverse* fracture disrupts the bone perpendicular to its long axis; an *oblique* fracture lies at an angle to the long axis of the bone; a *spiral* fracture results from a rotational force and spirals around the center of the long axis of the bone. Given the relative flexibility of their bones, children may present with a *greenstick* fracture, or a partial fracture of the cortex with deformity of the intact bone.

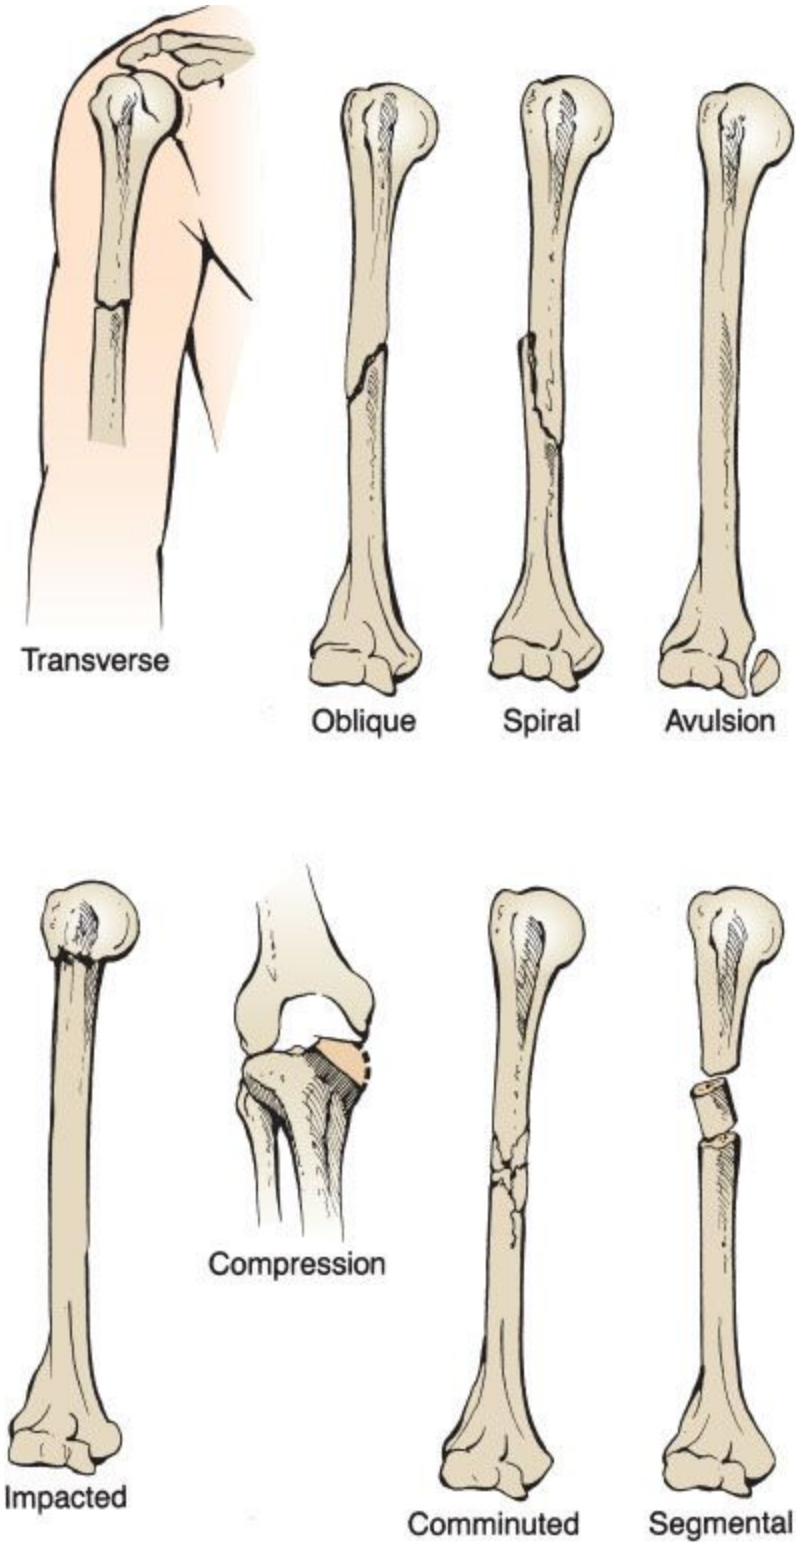

FIGURE 37.2 Fracture configuration.

Additional terms are used to describe the configuration of a fracture. A c*omminuted* fracture has three or more fragments. *Segmental* refers to the presence of two or more fractures in a bone, creating at least one segment of bone that is not connected to either end of the bone. An *avulsion fracture* occurs when a piece of bone is pulled off at the site of insertion of a tendon or ligament. Avulsion fractures are usually the result of traction injuries. Their presence indicates potential instability at the joint, which is caused by the loss of stabilization normally provided by the avulsed ligament or tendon. An *impacted* fracture occurs when the fractured surfaces of the bone are forced into each other, foreshortening the bone. On computed tomography (CT) scan, impacted fractures are often comminuted with numerous small fragments wedging across the main fracture line. *Compression* refers to a fracture in which the trabeculae of the bone are compressed, decreasing the overall volume of the affected part of the bone.

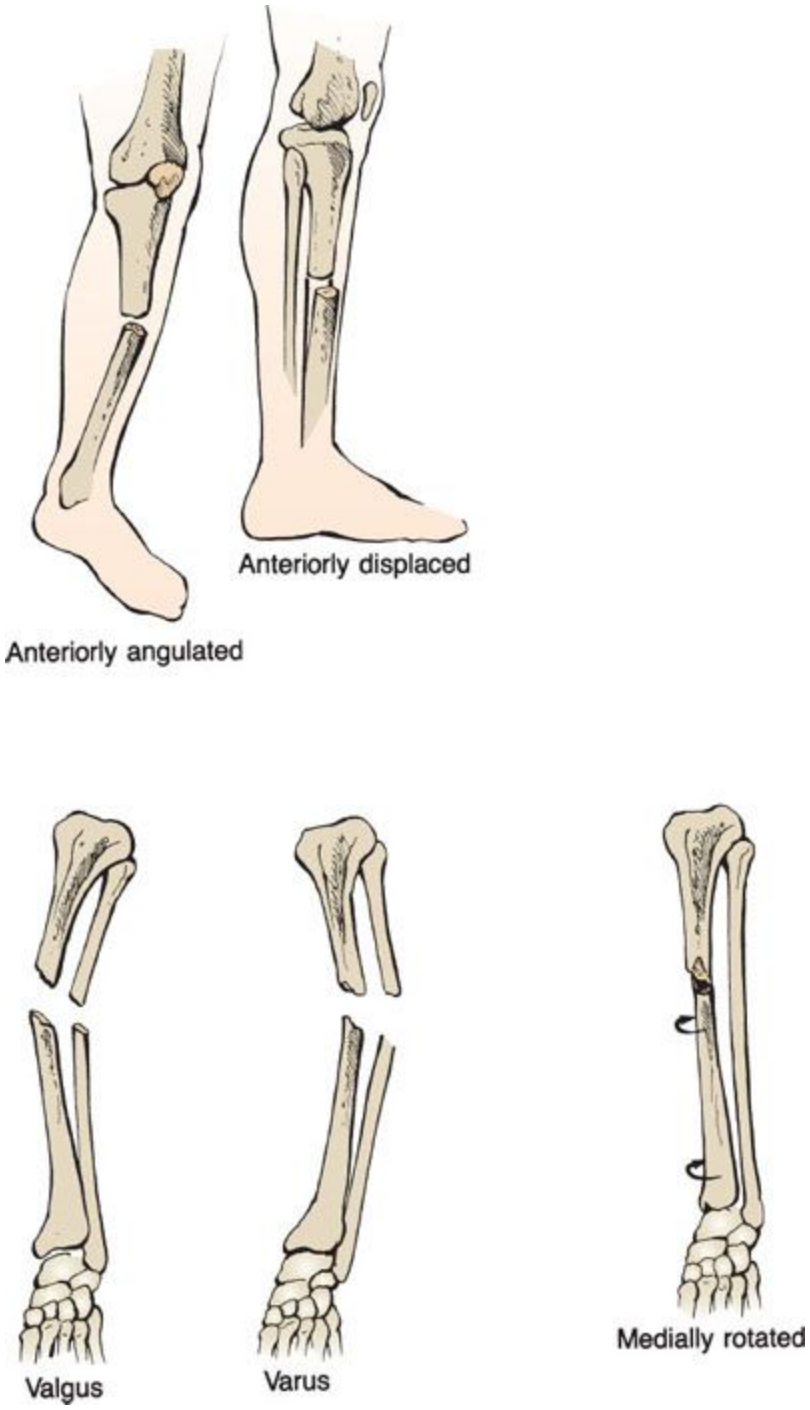
Fracture Alignment

A fracture is also described in terms of its alignment—the relationship of the fracture fragments to each other. The fracture may be *displaced, angulated,* or *rotated.*

A fracture is *displaced* if the fragments are offset in a transverse or longitudinal plane. The position of the distal fragment in relation to the proximal fragment is described. The distal fragment may be displaced in an anterior, posterior, medial, lateral, radial, ulnar, proximal, or distal direction. The amount of displacement is commonly measured in terms of the width of the fractured shaft, using fractions of the width in the description.

A fracture is *angulated* if there is a deviation from the normal relationship of the bony fragments along the longitudinal axis of the bone (eFig. 37.1). The direction of angulation may be expressed in two ways. It may be described in terms of the direction of the apex of the angle formed at the fracture site by the two main fracture fragments. The apex may point in an anterior, posterior, lateral, or medial direction. The direction of the apex may also be described by other adjectives, including ulnar, radial, dorsal, or volar, depending

on the involved bones. A second way to describe the angulation of the fracture is in terms of the relation of the distal fragment to the proximal fragment. If the distal fragment is angled away from the midline of the body, there is *valgus* angulation (the fracture is in valgus). If the distal fragment angles toward the midline, there is *varus* angulation to the distal fragment (the fracture is in varus).



eFIGURE 37.1 Fracture alignment.

Rotation refers to twisting of the distal fragment in relation to the proximal fragment around the center of the long axis of the fractured bone. When viewed along the long axis of the bone from the most distal point on the bone, if the distal fracture fragment has

rotated toward the midline in relation to the proximal fragment, it is *medially rotated;* if it has rotated away from the midline, it is *laterally rotated.*

Other Descriptive Modifiers

An *incomplete* fracture involves only one cortex of the bone; a *complete* fracture disrupts both cortices. A *pathologic* fracture occurs in an area of abnormal bone, weakened by disease or prior trauma, and is often the result of apparently trivial trauma or a biomechanically routine force applied along a natural vector. Pathologic fractures may occur at sites of old fractures, through primary osteosarcomas, at sites of tumor metastases, near cysts, and in bone weakened by Paget disease, rickets, osteomalacia, tuberculosis, osteomyelitis, chronic steroid therapy, obesity, anorexia, and many other disease processes. A *stress* fracture is the result of the bony cortex becoming fatigued by repeated low-level loading rather than disrupted by one acute episode of trauma. The repeated stress to the cortex causes bone resorption and may result in overt fracture if adequate healing is not allowed. Clinically, patients have pain with activity and tenderness to palpation over the affected bone. Eating disorders and amenorrhea predispose to stress fractures in female athletes. Stress fractures are most common in the proximal tibia but have also been described in the spine, pelvis, femur, ribs, tarsal navicular, and metatarsal bones, among other sites (12).

COMPLICATIONS OF FRACTURES

No assessment and description of a fracture is complete without a thorough assessment for, and identification of, possible associated complications (eTable 37.1). Well-recognized complications of fractures are suggested by the site of the fracture and the mechanism of injury.

Cast-induced injuries posttraumatic arthritis
DVT
Fat embolism
Complex regional pain syndrome

DVT, deep vein thrombosis.

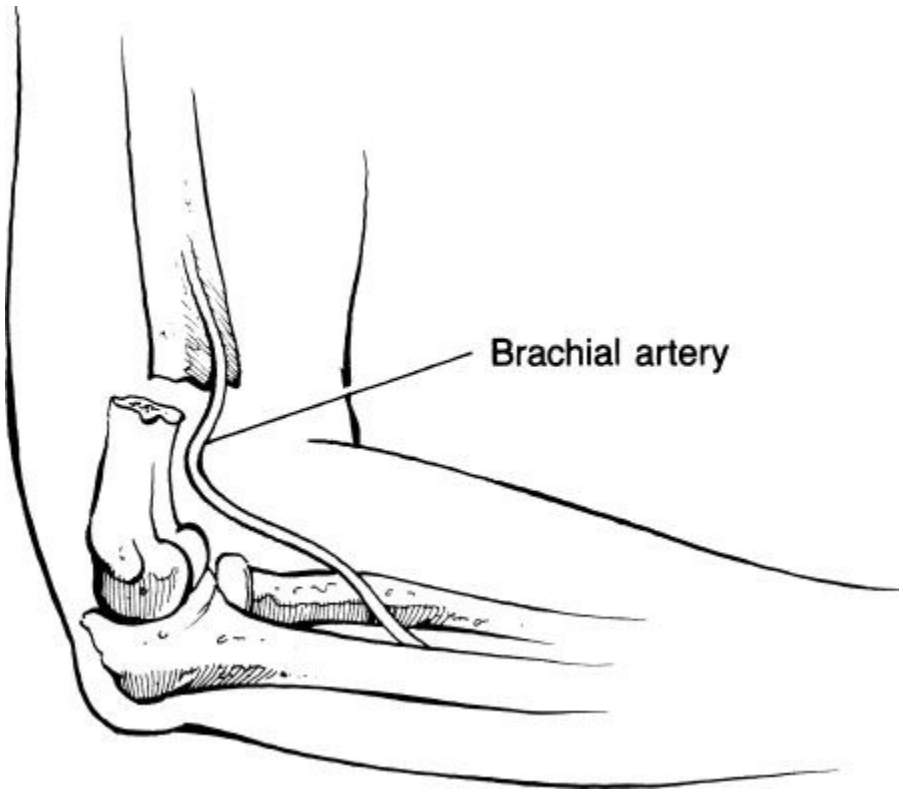
Blood Loss and Shock

Bone has a generous blood supply, and fractures can disrupt the blood vessels, causing localized bleeding. If this bleeding results in the loss of a significant percentage of the patient's blood volume, hypovolemic shock can result. Rarely, exsanguination occurs. An isolated long bone fracture is rarely the cause of shock, with a unilateral tibia and fibula fracture typically resulting in loss of approximately 500 mL of blood. Certain femur fractures can result in the loss of 3 or 4 units of blood into the thigh, with subsequent development of shock. Hemorrhagic shock can occur with pelvic fractures, in which typical blood loss is between 1,500 and 3,000 mL (10). If a bleeding disorder such as hemophilia A, thrombocytopenia, or marked anemia is present, a fracture that typically results in modest blood loss may be the source of life-

threatening hemorrhage. This is also true in patients on anticoagulation therapy. In these patients, isolated long bone fractures may require administration of vitamin K, fresh frozen plasma, and transfusion of packed red blood cells.

Vascular Injuries

Vascular injuries occur most commonly in open fractures, widely displaced fractures, or fracture-dislocations and at sites where the vessels lie close to the bone or are held in a relatively fixed position. Vulnerable sites include the popliteal artery at the knee, which may be injured in supracondylar fractures of the distal femur or in fracture-dislocations of the knee; the axillary artery at the shoulder, injured in fractures of the proximal humerus and humeral head; and the brachial artery at the elbow, which is at risk in supracondylar fractures of the distal humerus (eFig. 37.2). Even at the most vulnerable sites, these injuries are rare, but if they are not diagnosed in a timely fashion, the consequences can be devastating.



eFIGURE 37.2 Fracture-associated vascular injury.

The classic signs of vascular injury are the "Five *P*s": Pain, pallor, pulselessness (or diminished pulse), paresthesia, and paralysis. The Five *P*s are present only in a complete injury to the vessel. A partial injury can have subtle clinical signs and symptoms or be completely asymptomatic. In addition, collateral circulation may maintain distal flow around a vascular injury. Vascular compromise may also be delayed, as in the case of an initial vascular intimal injury leading to progressive thrombosis. Therefore, the location of the fracture and the mechanism of injury determine the need to assess for a potential vascular injury in the asymptomatic patient. Initial evaluation should involve assessment of pulses, evaluation with a Doppler stethoscope if palpable pulses are diminished or absent, observation of the color of the distal extremity, and assessment of capillary refill. With extremity injuries, this assessment should be compared to that of the opposite limb. The ankle-brachial index may be assessed to help evaluate patients where there is concern after the foregoing examination. The systolic pulse is assessed in the brachial artery and in the dorsalis pedis artery in the foot with a Doppler stethoscope. The ratio of the pressure in the ankle is then compared to that in the arm. A ratio of >0.9 is reassuring, although it does not completely rule out partial arterial injury (13,14).

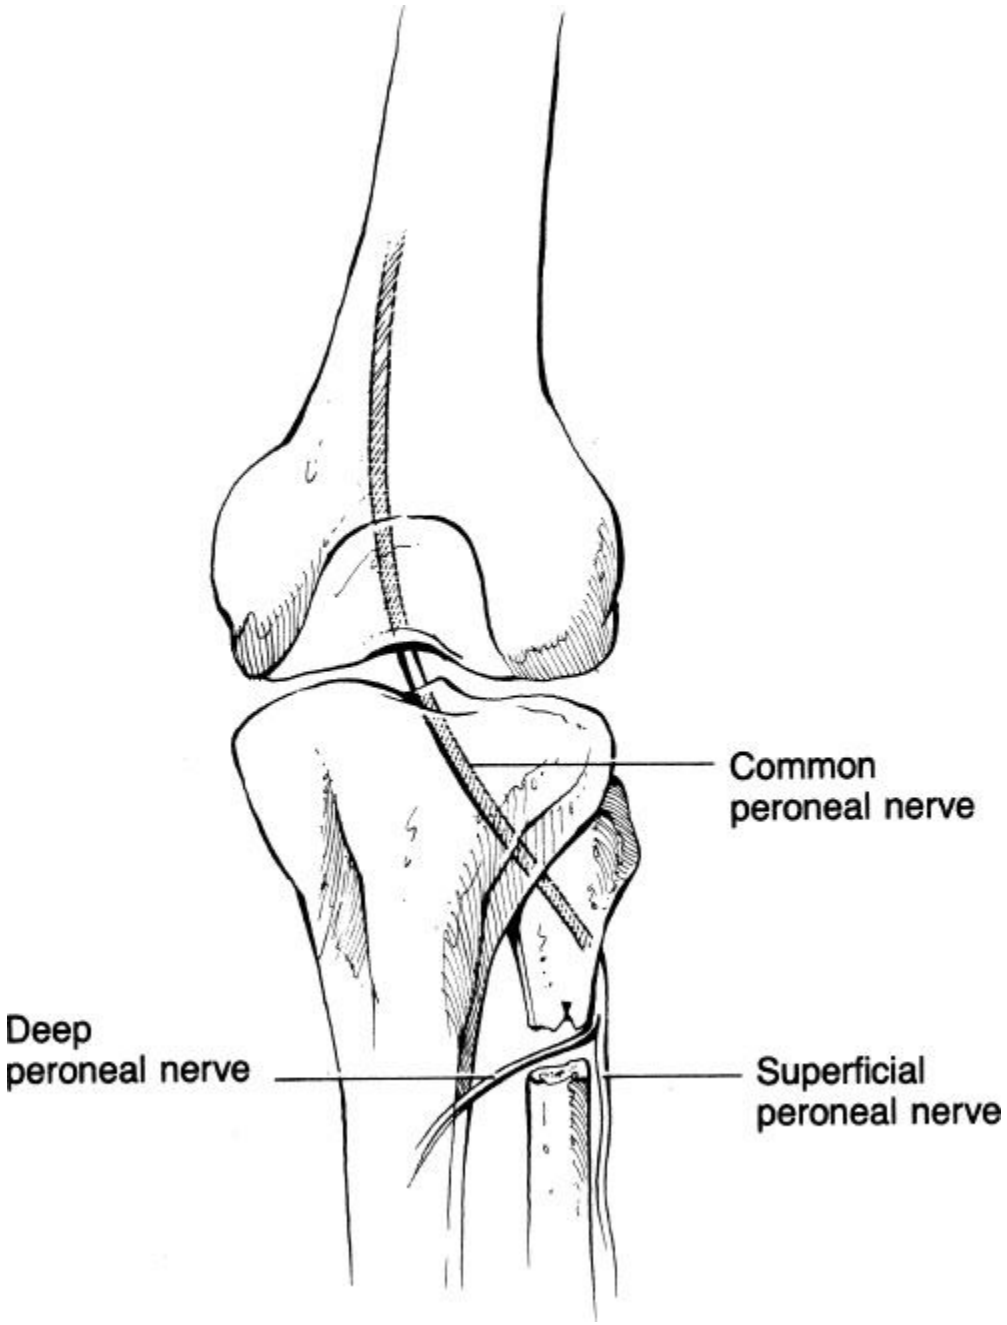
If vascular injury is suspected, further evaluation with angiogram, CT angiogram, color-flow Doppler ultrasound, magnetic resonance angiography, or surgical exploration is usually warranted. Complications of fracture-associated vascular injuries include in situ thrombosis, false aneurysms, true aneurysms, compartment syndrome, arteriovenous fistulas, and distal limb ischemia with mechanical dysfunction.

Nerve Injuries

Nerves are more frequently injured than vessels in association with fractures. They can be damaged by blunt trauma, along the trajectory of penetrating trauma causing an associated fracture, or by the fracture fragments themselves. Nerves are at increased risk of

injury when they are superficial, lie close to the bone, or span the joint, making them susceptible to stretch injury.

The most frequently injured nerves in association with specific fractures include the axillary and musculocutaneous nerves in shoulder fracture-dislocations; the radial nerve in fractures of the distal third of the humerus; the radial, median, and ulnar nerves in supracondylar elbow fractures; the median nerve in fracture-dislocations about the wrist; the peroneal and tibial nerves in knee fracture-dislocations; and the peroneal nerve in fractures of the fibular head or proximal fibula (eFig. 37.3).



eFIGURE 37.3 Peroneal injury associated with a knee fracture.

Nerve injuries are classified based on the amount of damage to the nerve according to Seddon staging system:

- *Neuropraxia:* The least severe injury, neuropraxia involves a contusion to the nerve, with minor injury to the myelin sheath. Sensory loss and transient paralysis may occur, but spontaneous

and complete recovery occurs over a period of several days to weeks (occasionally, a few months).

- *Axonotmesis:* In axonotmesis, more severe crush injury to the nerve occurs with axonal breakdown followed by distal wallerian degeneration. The epineurium and the continuity of Schwann tubes are maintained. Prolonged paresthesias and muscle weakness are the clinical hallmarks. Recovery can be complete but takes months to years. The axon has to regenerate proximally to distally and, for functional conduction to occur, the myelin sheath must be fully repaired. Recovery is often incomplete.
- *Neurotmesis:* The most severe form of nerve damage is neurotmesis disruption of the axon, epineurium, and Schwann cell sheath (complete severance of the nerve). When complete disruption occurs, all functions controlled by the injured nerve are interrupted.

The emergency evaluation of a nerve injury should involve assessment of motor strength, deep tendon reflexes, light touch, and two-point discrimination. Formal testing can be performed using electromyogram; however, this is not necessary in the ED.

Compartment Syndrome

Compartment syndrome (fully discussed in Chapter 48) should be suspected in long bone fractures and fractures associated with significant vascular injuries or pronounced swelling, especially when the patient has pain out of proportion to physical examination findings or paresthesias. Manometry should be performed if compartment syndrome is suspected, as the clinical signs are variable and may be delayed. Compartment syndrome is a surgical emergency and requires prompt decompression to prevent or minimize the associated morbidity.

Infection

Infections occur primarily in open fractures, especially in those in which there is a delay in treatment. The general rule in open

fractures is that they need “urgent” irrigation and debridement in the OR. Though 6 hours was historically cited as the cutoff time for this urgent procedure, recent literature has questioned this time frame. Although the exact amount of time is debated, most authors agree that “sooner is better” for this procedure (15). Infection can also occur with extensive hematoma or after open reduction internal fixation repair. It may also occur without a fracture in cases of osteomyelitis, septic arthritis, and abscesses eroding to bone. Septic arthritis should be suspected in the patient with monoarticular arthritis and ruled out in those who present with a swollen, erythematous, hot joint. If the diagnosis is in question, aspiration for crystal analysis, Gram stain, cell count, and culture should be performed. Most orthopedic surgeons recommend aggressive arthroscopic lavage to prevent destruction of the joint space by bacteria and inflammatory-mediated damage.

Casts and Splints

Immobilization devices have the potential to cause postinjury problems. They may become too tight as swelling increases during the first 24 to 48 hours after injury and cause pain and impair circulation. Pressure sores may occur on the skin in areas where a cast or external fixation device exerts localized excessive pressure (e.g., over the heel in a patient with a bimalleolar fracture). Immediate steps should be taken to correct the problem. A cast that is too tight can be split lengthwise; the underlying padding can then be cut and the cast spread open. A cast that is pressing on a particular site can have a window cutout. The window may be replaced more loosely with plaster or covered with soft dressing. An ill-fitting splint can be trimmed. The clinician should take great care in the selection of the appropriate splint (type and material), its placement (to make sure that it has adequate padding and effectively immobilizes the intended joint), and perform a postsplinting examination to ensure neurovascular integrity.

Fat Emboli Syndrome

Single or multiple long bone fractures in the young and hip fractures in the elderly predispose to fat emboli. Twenty percent of patients with pelvic or long bone fractures have detectable fat droplets in their blood. However, the clinical significance of this is not clear, as the vast majority of these patients remain asymptomatic. Fat emboli syndrome is the most common form of nonthrombotic embolism and has a characteristic clinical course. Its etiology is unclear, but three main hypotheses have been postulated: (a) After fat droplets enter the bloodstream, the liberation of free fatty acids from marrow fat by circulating lipase causes a toxic vasculitis and capillary leak syndrome; (b) it is the end result of extensive platelet–fibrin thrombosis; and (c) it results from direct obstruction of distal vascular lumen by fat emboli. After the injury, the patient often remains asymptomatic for 12 to 36 hours before suddenly and unexpectedly developing a life-threatening syndrome that is characterized by rapid cardiopulmonary and neurologic deterioration. Patients develop agitation, hallucinations, delirium, coma, hypoxia, dyspnea, tachypnea, tachycardia, and a petechial rash. If this deterioration is not quickly reversed, refractory hypotension, anemia, thrombocytopenia, disseminated intravascular coagulopathy, and adult respiratory distress syndrome often ensue, with an associated high morbidity and mortality.

Ischemic or Avascular Necrosis

Ischemic or AVN is characterized by bone death that occurs following the interruption of blood supply to bone. AVN is most frequently associated with carpal scaphoid fractures, lunate dislocations, hip dislocations, femoral neck fractures, and complex fractures of the talus. The time required for an injury to result in AVN is extremely variable and is location and patient specific.

Delayed Complications

Other complications of fractures may occur some time after the initial injury. Many fractures require reduction of the displaced fracture fragments in the ED or the operating room. The goal in

reduction is always to reestablish anatomic position; eliminate displacement, angulation, and other forms of malalignment; and immobilize the broken bone in the reestablished anatomic position to promote healing. Sometimes, this ideal condition is not achieved, and the systematic progression from hematoma to callus formation to bony union is delayed or interrupted. *Delayed unions* are fractures that take longer than usual to heal; *malunions* are fractures that heal in a faulty position; and *nonunions* occur when the process of fracture healing stops before the fracture is united.

Joint stiffness, posttraumatic arthritis, and *complex regional pain syndrome* (CRPS)—type I (formerly known as reflex sympathetic dystrophy [RSD])—may also occur as delayed complications of extremity trauma. Any intra-articular fracture of a weight-bearing joint predisposes the patient to early degenerative changes. The patient may present to the ED years after a fracture, complaining of *perceived* sudden onset of joint pain and decreased range of motion. Radiographs typically demonstrate extensive *osteoarthritis.*

CRPS is a three-stage, posttraumatic syndrome of unclear etiology, the development of which has no known correlation to the severity of the initial injury (16). CRPS remains a clinical diagnosis with symptoms that are often difficult to differentiate from normal posttraumatic characteristics. The first, or early, stage characterized by continuous burning and aching in the posttraumatic extremity, is exacerbated by weightbearing and by movement. After a variable period of time, the middle, or dystrophic, stage ensues, characterized by the development of shiny, cool skin over the affected extremity and a progressively decreased range of motion. In the final, or atrophic, stage, the skin atrophies, the muscles atrophy, and flexion contractures develop.

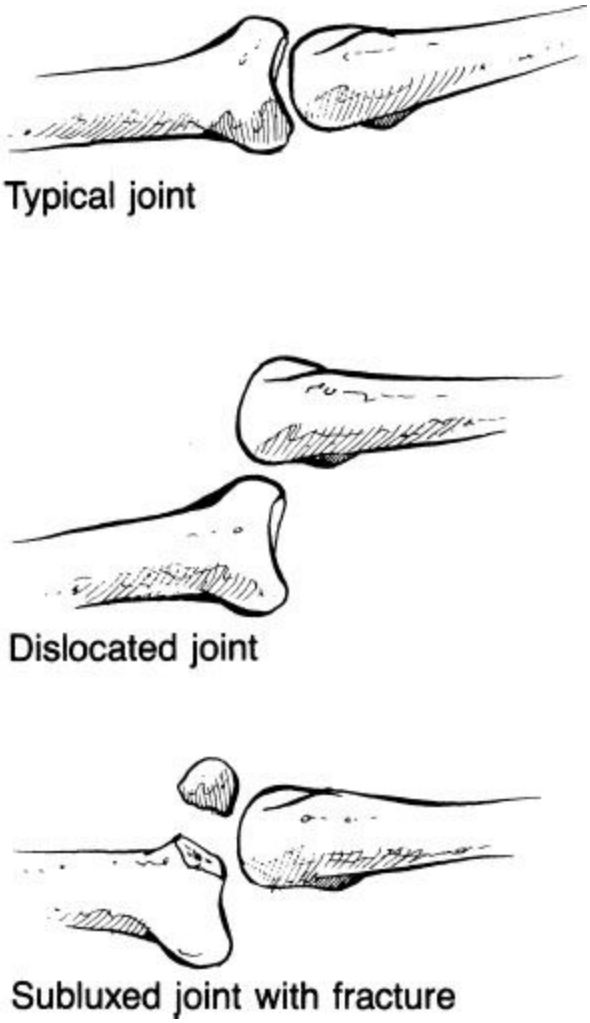
In 1992, Gibbons and Wilson, in the *Clinical Journal of Pain,* developed an RSD score that was proposed as a strict system for the clinical diagnosis of RSD. The scoring system consists of nine criteria and has more than academic interest. Early diagnosis and subsequent early treatment may potentially improve outcome, interrupting the progression from burning to dystrophy to atrophy. The nine criteria are (a) allodynia—the phenomenon whereby pain

is increased by stimuli that activate the involved nerve, such as a breeze blowing on the area, temperature changes, or emotional outbursts (hyperpathia); (b) burning pain; (c) edema; (d) change in color or hair growth in the affected area; (e) change in sweating; (f) change in temperature; (g) demineralization of bone in the involved limb, as documented in radiographs; (h) quantitative measurements of vasomotor disturbances; and (i) a triple-phase bone scan consistent with RSD. A score of five points qualifies as a clinical diagnosis of RSD; one point is given for each positive criterion, zero points for each negative criterion, and one-half point for each equivocal criterion. Application of heat or cold, exercises, early sympathetic blockade, or sympathectomy to the affected limb can halt the progression to atrophy. A minority of patients have been helped by a short course of high-dose prednisone (a 3-week taper) in conjunction with heat, cold, and exercise therapy (17).

Subluxations and Dislocations

Acute or chronic ligamentous laxity or tearing can result in subluxation or dislocation of a joint. Chronic ligamentous laxity is usually the result of an overuse syndrome, in which repetitive microtrauma leads to an attenuation of the static restraints of the joint. Acute ligamentous tears are the result of excessive or abnormal forces applied to the joint. The classic example is subluxation or dislocation of the glenohumeral joint. *Subluxation* occurs when one bone becomes partially disarticulated from the other bone that forms the joint. The articular surfaces forming the joint remain partially intact. *Dislocation* occurs when the bones are completely disarticulated and no parts of their articular surfaces are in contact. Dislocations can occur in isolation or with an associated fracture (eFig. 37.4). Often, the fracture is anatomic evidence of the direction of the pathologic force vector resulting in the dislocation. For example, 90% to 95% of shoulder dislocations occur anteriorly, disrupting the continuity of the anterior capsule and the labrum. Sometimes, these structures resist the forces producing dislocation

to the point that a fracture occurs, avulsing a piece of bone from the anterior glenoid rim, known as a *Bankart lesion.*



eFIGURE 37.4 Joint subluxation and dislocation.

The nomenclature of subluxations and dislocations is straightforward. Most subluxations and dislocations occur at a joint formed by two bones, and the subluxation or dislocation is named after the affected joint (e.g., posterior dislocation of the distal interphalangeal [DIP] joint of the fourth finger of the right hand). If a joint is formed by three bones, and the two major bones are disarticulated, the subluxation or dislocation is named after the joint involved (e.g., posterior dislocation of the knee). If the joint is formed by three bones, and the minor bone is subluxed or

dislocated, the abnormality is named after the minor bone (e.g., lateral dislocation of the patella). As for fractures, direction is assigned with reference to the distal segment.

Specific subluxations and dislocations are frequently seen in the ED and should be skillfully and efficiently reduced, with restoration of anatomic position, by the emergency physician. These include anterior and posterior dislocations of the shoulder joint; anterior and posterior dislocations of the sternoclavicular joint; posterior dislocations of the elbow joint; posterior dislocations of the proximal interphalangeal and DIP joints, often with accompanying avulsion fractures; posterior dislocations of the hip joint; posterior dislocations of the knee joint; lateral dislocations of the patella; and fracture-dislocations of the ankle.

The hallmarks of subluxations and dislocations are pain, deformity, and decreased range of motion. Certain dislocations are associated with specific complications, and these must be ruled out in the evaluation and treatment of the injury. For example, the aorta and trachea are at risk in posterior dislocations of the sternoclavicular joint, and injury to them can lead to rapid respiratory compromise or intrathoracic hemorrhage. The axillary nerve and, less commonly, the musculocutaneous nerve are at risk in anterior shoulder dislocations. Their function must be clearly assessed prior to any attempted reduction and then reassessed after the reduction is complete. The popliteal artery can be stretched, torn, or completely disrupted in a posterior dislocation of the knee. Radiographs are often obtained prior to attempts at reduction and after the reduction has been achieved to document the position of the bones, restoration of anatomic position, and the presence of associated fractures. The need for pre- and postreduction radiographs for all types of dislocations, however, has been challenged in the literature (18,19).

Techniques for the reduction of specific joints are discussed in the chapters dedicated to those joints, but certain principles hold true for all subluxations and dislocations. The length of time between injury and relocation corresponds proportionally to the severity of spasm and swelling that will occur and the difficulty involved in

reducing the joint. Adequate pain control and muscle relaxation can facilitate smooth reduction; excess force applied during the reduction may result in fractures, nerve damage, and vascular injury. The technique used to reduce the dislocation should initially replicate the mechanism of injury to release the dislocated bone from the anatomic structure that is keeping it dislocated. In certain dislocations, the incidence of delayed complications is directly proportional to the time from injury to relocation. For example, AVN of the femoral head occurs in 10% to 20% of hip dislocations. The rate is directly proportional to the total time from injury to successful reduction. Similarly, myositis ossificans is a well-recognized complication of posterior dislocation of the elbow. The incidence of myositis ossificans is directly related to three variables: The number of attempts at reduction, the length of time from injury to successful reduction, and whether the joint is adequately immobilized after reduction.

Tendinosis

Tendinosis is a subset of strain since it is an injury to the musculotendinous unit, but it is more appropriately considered a separate entity. In the past, tendinosis was felt to represent inflammation to the musculotendinous unit, and was hence termed "*tendinitis.*" Recent work has indicated that a more correct term is *tendinosis,* as there is no significant inflammatory response by the body in these conditions (20). Instead, there is a degeneration of the collagen portion of the tendon in the absence of inflammatory cells. Tendinosis differs from strain in that the pathologic changes are *isolated* to the tendon and *involve the insertion of the tendon into the bone,* which occurs via a transitional, calcified fibrocartilage known as Sharpey fibers. Tendinopathy can result from chronic use or from one acute episode of overuse. In acute tendinopathy, the tendon is irritated, and an acute response occurs. Microscopically, there is loss of collagen continuity with an associated increase in ground substance, vascularity, and cellularity. The cellularity results from the presence of fibroblasts and myofibroblasts, not inflammatory

cells. If this cycle is not interrupted, permanent changes in the architecture of Sharpey fibers and atrophy of the tendon fibers occur.

Common tendons involved in acute or chronic tendinosis presenting to the ED include patellar, quadriceps, rotator cuff, and the Achilles tendons.

Clinically, tendinosis presents with pain during active range of motion, loss of function, point tenderness over the affected tendon near its insertion into bone and, often, localized edema and erythema. Forced contraction of the affected muscle against resistance elicits pain, which is exacerbated by pressure over the point of insertion. Pain may also be elicited by forced extension of the tendon, stretching the injured fibers.

Calcific tendinitis is an entirely different entity, representing a truly inflammatory response by the body. It is usually associated with chronic inflammation and consists of calcium deposition within the body of the tendon. It is often an indication of tendinous degeneration altering the macrostructure of the tendon. Calcific tendinitis has a characteristic radiographic appearance, revealing the calcium depositions within the tendon. For example, a band of calcification can be seen passing over the bicipital groove in calcific biceps tendinitis at the shoulder.

Muscle Spasms

Muscle spasms are a poorly understood phenomenon in which a voluntary muscle undergoes sustained involuntary contraction, leading to depletion of stored glycogen, localized buildup of lactic acid, and severe pain. The causes of muscle spasm are not known, but hypotheses include localized alterations in blood flow, regional or systemic electrolyte imbalances (especially sodium and calcium; less often, potassium), and postural abnormalities that place a bone in a nonanatomically neutral position, causing attached musculature to fire continuously. For example, overdevelopment of the muscles on one side of the body in a racquet sports athlete can cause latissimus dorsi spasm, as the proprioceptors present in the

latissimus sense that the arm is out of the neutral position, resulting in repetitive muscle contraction in attempted compensation.

Muscle spasms typically seen in the ED include spasms of the gastrocnemius, levator scapulae, trapezii, rhomboids, and latissimus dorsi. Rectus abdominus muscle spasm can mimic an acute abdomen.

Treatment may be frustrating for both the patient and the clinician, as complete relief is difficult to achieve. The treatments are not perfect, and many are controversial. Treatment options include freezing the muscle belly with fluoromethane spray, followed by passive, gentle, forced range of motion to "break the spasm"; massage; treatment with muscle relaxants, including diazepam and other benzodiazepines; and pain control with acetaminophen, NSAIDs, or opioid analgesics. Recent research indicates that treatment with muscle relaxants for these conditions may not be as good as basic analgesia (21).

ED EVALUATION

The ED evaluation of any injured patient begins with the basic ABCs: Airway, breathing, and circulation. If the patient is reliable, not intoxicated, and has an isolated injury and the mechanism of injury does not suggest other possible injuries, then evaluation and treatment are limited to the injured joint along with the joints immediately proximal and distal to the injury. The contralateral side of the injured joint or limb should be examined for comparison of range of motion, anatomy, laxity, and neurovascular findings.

In patients with multiple injuries, head trauma, amnesia, intoxication, or medical illnesses resulting in their musculoskeletal injury (e.g., a distal radial fracture after syncope), a complete physical evaluation is mandatory and should follow basic trauma guidelines. This should begin with a primary survey and assessment of the ABCs; evaluation of neurologic disability and Glasgow Coma Scale; then continue with complete exposure of the patient and a search for any accompanying injuries. Once this is complete, the emergency physician should systematically evaluate the underlying

medical problem that could have produced the trauma. If a problem is identified, it should be addressed before moving on to the next step in the systematic evaluation. For example, the motorcyclist thrown from the cycle, who presents with an open fracture of the tibia and fibula and flail chest, needs breathing stabilized before the leg is further evaluated. In extremity wounds, hemorrhage can often be rapidly but temporarily controlled with a direct-pressure dressing, ensuring continued circulatory stability until the source of bleeding can be systematically evaluated. After the primary survey, each joint should be palpated and ranged systematically, and the integrity of long bones assessed by inspection, palpation, and range of motion.

As alluded to previously, certain extremity injuries are true orthopedic emergencies, meriting expeditious evaluation and management. These include vascular injuries, compartment syndromes, open fractures and dislocations, and certain dislocated joints (Table 37.1). They should be addressed immediately after the ABCs have been evaluated, stabilized, and recorded on a trauma flow sheet. If vascular compromise is suspected, immediate consultation with an orthopedic or vascular surgeon is advised. When vascular insufficiency is caused by stretching of the vessel across the site of a dislocation or displaced fracture, reduction of the fracture or dislocation may correct the problem. Pulses should be documented after the reduction. If an injury to the vessel itself is suspected, arteriography, color Doppler ultrasound, magnetic resonance angiography, or surgical exploration may be indicated. Color Doppler ultrasound evaluation, followed by close observation with serial neurovascular examinations, is a relatively newer option and is still being validated as a modality. These decisions are usually made in consultation with a surgeon. Blood flow to an ischemic extremity should, ideally, be reestablished within 6 to 8 hours to prevent permanent injuries, including ischemia and necrosis.

Similarly, if compartment syndrome is suspected, it should be ruled out by manometry. This is usually accomplished through emergent consultation with an orthopedic surgeon. If compartment pressures are elevated, emergent fasciotomy is mandatory.

After all life- and limb-threatening injuries have been addressed, attention can be directed toward the identification of individual injuries—fractures, dislocations, sprains, strains, tendinosis, and spasm. This evaluation begins with a *thorough history* to ascertain the mechanism of injury, timing of the injury, previous injury to the limb, handedness where applicable, and medical problems potentially contributory to current disability. The history should include questions about associated symptoms of pain, paresthesia, weakness, signs of pallor, or deformity.

On physical examination, the emergency physician should note the appearance of the injury, looking for deformity, swelling, erythema, ecchymosis, and exposed bone. Other physical findings include the presence of purulent fluid drainage from the wound, abrasions, or lacerations over the injured area.

The emergency physician should palpate for deformity, local or diffuse tenderness, edema, warmth, and induration. Palpation should include a careful assessment of neurovascular integrity. Patients with vascular compromise will have dusky or mottled skin, diminished distal pulses, and delayed capillary refill. Sensation to light touch may be decreased, and hypesthesia often occurs over an area of acute injury. Active range of motion should be tested. In the majority of acute injuries, the patient is not enthusiastic about actively ranging the joint and passive range of motion, and provocative maneuvers are of limited utility due to pain.

Radiographs are the cornerstone of further evaluation and management of most musculoskeletal complaints. Many fractures can be diagnosed clinically. However, in the vast majority of cases, the diagnosis should be supported radiographically. Radiographs frequently determine the need for operative reduction, the length of time the fracture needs to be immobilized, and potential complications during the rehabilitation process. Criteria for obtaining radiographs of specific injuries are formalized but constantly evolving and are beyond the scope of this chapter. They are addressed in the chapters on injuries to specific joints. The goals of objective criteria for obtaining radiographs include reduction in unnecessary imaging, increased efficiency of patient flow in the ED,

decreased exposure to radiation, and containment of healthcare costs. For example, the Ottawa Ankle Rules are objective criteria for obtaining an ankle series after an ankle injury. They state that ankle films are required in patients older than 18 years if pain in the malleolar area is accompanied by inability to bear weight (defined as walking four steps) immediately after the injury and in the ED or by bony tenderness over the posterior aspect of the distal 6 cm of the medial or lateral malleolus. Strict implementation of the Ottawa Ankle Rules has been shown to reduce the number of ankle films ordered by 28%, increase ED efficiency, and decrease ED costs without increasing the percentage of missed fractures (22).

When the decision is made to obtain roentgenograms, the correct views must be obtained, they need to be of sufficient quality to competently evaluate for fracture, and they need to be read thoroughly, in a systematic fashion. Poor-quality films should not be accepted. Many fractures have been missed because of technically inadequate films. In addition, thorough examination of the soft tissue and every bone in the x-ray is essential to avoid missing subtle findings that may indicate fracture or dislocation. For example, the fat pad sign on an elbow x-ray may be the sole indication of a radial head fracture.

Other pitfalls in radiographic interpretation include the following:

- A nutrient foramen, housing a nutrient artery, may be misinterpreted as a fracture. A nutrient foramen will appear less radiolucent than a fracture (very smooth-edged) and will angle obliquely from the edge of the bone through the cortex, and then terminate without involving the cortex on the other side of the marrow.
- Sesamoid bones or accessory ossicles may be confused with fractures. These anatomic variants usually have smooth edges and are well corticated, and no defect in the adjacent bone will be noted. In some instances, a comparison view of the unaffected side can help clarify the structure in question. For example, the patient with pain over the patella following a dashboard injury, who is found to have a two-part patella on x-

ray, may have bipartite patella, which is confirmed by its presence on an x-ray of the unaffected knee.

- Fat and clothing folds, casts, or splints may be misinterpreted as fractures, and jewelry or body piercings may be misinterpreted as foreign bodies.

Every x-ray series should include a minimum of two views that are *taken at right angles to each other.* If the plane of the fracture is at 90 degrees (perpendicular) to the plane of the x-ray beam, the fracture may not be evident on that view but would be readily visible on an x-ray taken in a plane parallel to the plane of the fracture line.

Fractures in the shaft of long bones are often accompanied by additional fractures in that bone proximal or distal to the main fracture site or by dislocations at the joints at either end of the bone. Therefore, all long bone shaft fractures require imaging of the entire length of the bone, including adequate views of its joints. For example, a midshaft femur fracture requires x-rays of the entire shaft, a two-plane knee series, and a two-plane hip series.

Fractures to paired long bones, such as the radius and ulna or the tibia and fibula, may present with different associated fractures. In other words, a fracture to one bone is sometimes accompanied by a distant fracture to the other bone in the pair. For example, medial malleolar ankle fractures resulting from a lateral twisting mechanism sometimes have an associated proximal fibular or fibular head fracture or dislocation. The mechanism of injury explains this association: The twisting force that breaks the medial malleolus is transmitted up the shafts of the tibia and fibula and is dissipated at the weakest point, the proximal fibula, resulting in either fracture or dislocation. Thus, more complex ankle fractures require imaging of the entire shafts of the fibula and tibia and a two-way series of the knee. Certain forearm fractures are commonly associated with a fracture-dislocation of the other bone of the forearm, such as a radial shaft fracture and distal radioulnar joint dislocation, known as a Galeazzi fracture (eFig. 37.5).

eFIGURE 37.5 Galeazzi fracture dislocation.

Additional views are sometimes helpful. A dedicated scaphoid view can aid in the detection of a subtle scaphoid fracture. An axial view of the calcaneus can reveal a fracture missed on standard ankle and foot series. Many posterior dislocations of the shoulder are not evident, except on an axillary view of the glenohumeral joint, clearly depicting the relationship between the humeral head and the glenoid fossa. In certain instances, comparison views to the patient's

other side are helpful. For example, in *distal clavicle osteolysis,* characterized by pain and osteolysis of the distal clavicle, bilateral clavicle views help confirm the diagnosis when a larger separation is seen at the affected acromioclavicular joint compared with the unaffected side. Distal clavicle osteolysis occurs in power lifters and in contact with sports who suffer significant blunt trauma to the point (acromion) of the shoulder.

Adequate films, correctly interpreted, are not 100% sensitive for fractures. Growth plate injuries (also known as Salter–Harris injuries) may appear entirely normal on plain radiographs. The diagnosis may not become evident until there has been new bone deposition or resorption at the site of injury. Similarly, nondisplaced, hairline fractures often become visible, or radiolucent, only on radiographs 7 to 10 days after injury, as bone resorption widens the fracture line, hematoma develops, and new bone formation proceeds. If there is potential morbidity associated with a missed fracture on plain x-rays, a clinically fractured bone should be treated as a fracture, or more sophisticated imaging studies should be obtained. A patient with a story and examination consistent with a femoral neck fracture, which has normal plain radiographs and remains nonweight bearing in the ED, should be treated as having a nondisplaced hip fracture. Assessment of a patient's ability to ambulate is essential prior to discharge, and the inability to ambulate can further confirm the presence of an occult lower extremity fracture. These patients should be kept nonweight bearing, and magnetic resonance imaging should be performed to demonstrate the fracture; a bone scan may also be diagnostic.

Similarly, tenderness in the snuff box (the space on the radial side of the wrist between the extensor pollicis longus tendon and the paired extensor pollicis brevis and adductor pollicis longus tendons) after a *fall on an outstretched hand* should be treated as a scaphoid fracture, *even if the radiographs are normal.* If the radiographs show no fracture, immobilization in a thumb spica with follow-up examination and repeat radiographs in 10 days is mandatory (23).

KEY TESTING

Plain radiographs for skeletal injuries must

- Include the appropriate bone/joint injured.
- Have at least two views at right angles to each other.
- For long bone injuries, include the whole length of the bone and the joint above and below

CT Imaging

- Provides greater osseous detail and can do so in multiple planes (axial, coronal, sagittal)
- Consider when the relationship of fracture fragments is complex or will impact down-stream care (e.g., calcaneal fractures, tibial plateau fractures)
- Can be combined with angiographic contrast (CT-A) to identify injuries to major blood vessels

MR Imaging

- Provides greatest soft tissue detail (tendons, ligaments, disc)
- Can also provide imaging in multiple planes (axial, coronal)
- Consider when there is a potential soft tissue injury that will impact care (e.g., spinous ligaments)
- Can be combined with angiographic contrast (MR-A) to identify injuries to major blood vessels

Ultrasound

- An imaging modality being used by some practitioners in the bedside diagnosis of musculoskeletal injuries.
- In trained hands can identify fractures, dislocations, and some soft tissue injuries (e.g., tendon tears).

ED MANAGEMENT

In general, the initial management of musculoskeletal injuries includes immobilization of the affected extremity and administration of pain medication. As previously mentioned, pain related to musculoskeletal injuries is often undertreated in the ED. Once a fracture or dislocation is identified, appropriate analgesia should be provided, and reduction should be performed as needed; this is determined by the location of the injury and the amount of

distraction or angulation. The management of specific injuries is discussed in subsequent chapters.

The initial management of open fractures and joints should be directed toward reducing the chances of infection. Gross particulate debris in the wound should be removed. Exposed bone *should not be replaced in the wound,* because this may further introduce contamination. A sterile dressing should be applied. The extremity is splinted to prevent further tissue and neurovascular injury. Intravenous antibiotic therapy, usually with a first- or second-generation cephalosporin, is instituted (if not contraindicated by drug allergies), and tetanus prophylaxis (sometimes including tetanus immune globulin) is given when indicated. A macrolide antibiotic or trimethoprim–sulfamethoxazole is a good choice for the penicillin-allergic patient. An aminoglycoside such as gentamicin is frequently added to the cephalosporin when there is heavy contamination of the wound. After these initial management steps have been taken, orthopedic consultation should be obtained. Most open fractures and dislocations require formal debridement in the operating room, which should be performed as soon as patient stability will allow (15). The incidence of infection is directly proportional to the length of time from injury until irrigation and formal debridement occurs.

Certain dislocations require expeditious reduction. Dislocated hips are at risk for development of ischemic necrosis, and dislocated elbows are at risk for development of Volkmann ischemic contracture (compartment syndrome, decreased blood flow, necrosis, and contracture after a dislocation). AVN of the hip is thought to be caused by damage to the vessels supplying the femoral head. In general, these vessels are not completely torn in the dislocation; rather, they are stretched, and blood flow through them is compromised. Therefore, the incidence of AVN is directly related to the length of time from injury to adequate relocation of the hip. Similar principles apply to the development of Volkmann ischemic contracture after elbow dislocation. Therefore, reduction should be accomplished as soon as is feasible.

CRITICAL INTERVENTIONS

- Once the patient has stabilized, palpate every bone and put every joint through a range of motion to search for occult injury.
- Relocate or realign any fractures or dislocations that result in neurovascular compromise in an attempt to alleviate the neurovascular deficit as expeditiously as possible.
- Splint fractures as quickly as is possible to minimize pain, prevent injury to adjacent structures, and reduce blood loss associated with these injuries.
- Perform manometry and obtain early consultation for patients with suspected compartment syndrome.
- Administer intravenous antibiotics (first- or second-generation cephalosporin and gentamicin) early for patients with open fractures.

DISPOSITION

ED care is not complete when the diagnosis is made. Appropriate immobilization should be instituted and instructions for immediate care and follow-up given. These should be tailored to the specific injury but, in general, involve rest, ice, and elevation. These simple, cost-effective steps are often overlooked in the rush to discharge patients from the ED and can, in some cases, affect more than the patient's comfort. For example, the simple application of ice to a lateral ankle sprain during the first 24 hours after injury has been shown to decrease time to return of full function by 50% (24). Conversely, inadequate treatment can lead to decreased mobility, chronic pain, and joint instability.

Depending on the injury, the patient may be instructed to remain nonweight bearing or keep the injured joint immobilized. In other cases, activity as tolerated is appropriate and may speed recovery (e.g., low-back strain). Pain control must be achieved in the ED, and the pain medications given for the outpatient setting should be commensurate with the injury. For example, the patient who requires morphine in the ED for a rib cage contusion should not be discharged with instructions to take acetaminophen as needed for

pain. Adequate postinjury pain control improves outcome and decreases repeat visits to the ED.

Patients should be instructed to return to the ED if they experience any signs or symptoms of neurovascular compromise, excessive pain, coldness, erythema, fevers, chills, cough, pleuritic chest pain, or a cast or splint that feels too tight or causes pain. Appropriate follow-up depends on the nature and extent of the injury and can range from a visit to the patient's primary care doctor in 2 weeks, to orthopedic referral in 10 days' time, to being seen by a hand surgeon in the next few days for operative repair of a flexor tendon laceration.

Patient with CRPS should be referred early to a physician with expertise in this area, which is usually in the realm of pain management. Frequently, multimodality treatment is required, and a great deal of care coordination must occur.

Common Pitfalls

- Ordering the wrong x-ray because of an inadequate physical examination
- Not recognizing all injuries because the physician's attention is focused on one specific injury. For example, the patient who falls off a ladder and presents with a grade II lateral ankle sprain may have a calcaneal fracture from the initial impact.
- Relying on poor-quality x-rays or on a single view without obtaining an additional view at 90 degrees to the initial one
- For patients with long bone fractures, failure to include the length of the bone, the joint above and below in adequately exposed radiographs
- Failure to rule out infection or similar condition (olecranon bursitis) in a patient presenting with a swollen joint. It may be a mistake to assume that the swollen joint in the patient with a history of gouty arthritis is another flare of gout if the presentation is atypical or there are other concerning signs.
- Failure to realize that drops of blood or small abrasions on the skin in the area of a fracture are signs of an open fracture

- Failure to access or document a focused neurovascular examination on initial presentation and after reduction of a fracture or dislocation
- Attributing pain to the fracture itself, rather than thoroughly investigating other potential sources of pain, such as a cast problem, neurovascular compromise, or compartment syndrome
- Not evaluating a patient for compartment syndrome with manometry after considering the diagnosis
- Not pursuing additional studies when the plain radiographs are normal in patients with a suspected fracture, especially if they are unable to bear weight
- Undertreating the pain associated with musculoskeletal injuries.

CHAPTER 38

Shoulder Injuries

Scott C. Sherman

The shoulder joint is composed of three bones (humerus, clavicle, and scapula) and three joints (sternoclavicular [SC], acromioclavicular [AC], and glenohumeral). Figure 38.1 demonstrates the essential osseous and ligamentous anatomy of the shoulder. The rotator cuff surrounds the glenohumeral joint and is composed of the teres minor, infraspinatus, and supraspinatus muscles, which insert on the greater tuberosity of the humerus; and the subscapularis muscle, which inserts on the lesser tuberosity of the humerus. Superficial to these muscles is the deltoid muscle.

The proximal humerus articulates with the glenoid, forming the glenohumeral joint. Because the articular surface ends at the anatomic neck, fractures located proximal to this location are considered articular surface fractures. The surgical neck is the narrow portion of the proximal humerus distal to the greater and lesser tuberosities.

The clavicle is anchored to the scapula by the AC and coracoclavicular ligaments. The SC and costoclavicular ligaments anchor the clavicle medially. The scapula lies over ribs 2 through 7 posteriorly. It is covered with thick muscles over its entire body and spine. The scapula is connected to the axial skeleton solely by the AC joint.

The glenohumeral joint and scapulothoracic articulation function as a unit in abducting the humerus. The ratio of scapular to glenohumeral movement is 1:2; therefore, for every 30 degrees of abduction of the arm, the scapula moves 10 degrees and the glenohumeral joint moves 20 degrees. If the glenohumeral joint is

completely immobilized, the scapulothoracic articulation can provide 65 degrees of abduction.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of shoulder injuries includes tendonitis, rotator cuff tears, bursitis, fractures of the clavicle, proximal humerus and scapula, shoulder dislocations, and injuries to the AC and SC joints.

ED EVALUATION

The clinician should ask the patient about the mechanism of injury, as this frequently aids in diagnosis. In atraumatic conditions, inquire about overuse and activities that worsen pain. A history of prior shoulder injury or surgery is also useful. Finally, the clinician should consider the possibility that the source of pain is not due to shoulder pathology and may represent referred pain from a more severe underlying condition (e.g., myocardial ischemia, perforated viscus).

The examination of the shoulder should be systematic to avoid missing injuries. The examiner starts by inspecting and noting how the patient holds the shoulder and also the presence of any gross deformities or ecchymosis. Palpation begins at the SC joint immediately lateral to the suprasternal notch. The examiner then moves laterally along the clavicle, noting any areas of deformity or tenderness. The AC joint is palpated by pushing in a medial direction against the distal end of the clavicle as it protrudes above the flattened acromion process.

Next, the examiner palpates the proximal humerus. The greater tuberosity of the humerus lies lateral to the acromion process and can easily be felt by following the acromion process to its lateral edge and then sliding the fingers inferiorly. Absence of the proximal humerus in its typical location and a squared-off appearance of the shoulder are consistent with an anterior shoulder dislocation. The bicipital groove, which contains the biceps tendon, is located anterior and medial to the greater tuberosity and is bordered laterally by the greater tuberosity and medially by the lesser tuberosity. Tenderness in this location is consistent with bicipital

tendonitis. External rotation places the groove in a more exposed position for palpation and permits the examiner to palpate the greater tuberosity first, then the bicipital groove, and finally the lesser tuberosity by moving from a lateral to a medial position. Lastly, the attachment of the supraspinatus tendon on the greater tuberosity is palpated. Tenderness in this location is seen in patients with supraspinatus tendonitis and subacromial bursitis.

As with any extremity injury, the clinician must consider injury to nerves and blood vessels and perform a thorough neurovascular examination. The subclavian vessels and the brachial plexus lie in close proximity to the clavicle, so displaced clavicle fractures can be associated with injuries to these structures, but this is rare. The brachial plexus, axillary nerve, and axillary artery lie in close proximity to the proximal humerus, and injuries to these structures may accompany proximal humerus fractures.

The examiner should test function of the associated muscles and range of motion of the shoulder joint. Inability to initiate abduction *or* hold the arm in a 90-degree position despite a slight pressure on the distal forearm suggests a significant tear to the rotator cuff muscles. Strength of abduction is proportional to the size of the tear. Inability to externally or internally rotate the shoulder suggests the possibility of a shoulder dislocation.

Radiographs are indicated in most traumatic situations. Routine shoulder radiographs consist of an anteroposterior (AP) view in internal and external rotation as well as a scapular “Y” view. The scapular “Y” view is obtained by placing the radiographic film along the lateral side of the humerus, with the beam projected along the length of the scapula. The “Y” consists of the scapular spine, body, and coracoid process, with the humeral head positioned at the junction of the “Y.” This radiograph is useful to identify dislocations of the glenohumeral joint and scapular fractures. When the location of the humeral head is in question, it is important to obtain an axillary view. The axillary view requires abduction of the shoulder and the beam is projected superiorly through the axilla with the plate on top of the shoulder.

Clavicle radiographs include an AP view of the upper thorax to define the structures. An AP view with the tube directed 45-degree cephalad (apical lordotic) is useful to detect medial-third fractures or SC joint dislocation (1). Multidetector CT will aid in diagnosing occult fractures or better delineate complex proximal humerus fractures, but is not routinely indicated in the ED (2).

KEY TESTING

- Routine shoulder radiographs that include AP views in internal and external rotation and a scapular "Y" view.
- An axillary view should be obtained when a dislocation is suspected on routine views.
- SC joint dislocation will be occult on routine views of the clavicle. Computed tomography (CT) scan or apical lordotic view should be ordered when clinically suspected.

ED MANAGEMENT

Clavicle Fractures

Clavicle fractures account for 5% of all fractures. They are the most common childhood fracture and may be encountered in newborns secondary to birth trauma. Two mechanisms are responsible: (i) Force applied directly to the clavicle and (ii) force applied to the outer end of the clavicle, which can push the shoulder inward toward the chest, causing a shearing force that fractures the clavicle. Most patients have swelling and tenderness over the fracture site. Frequently, the shoulder is held in downward and inward positions due to loss of support.

Middle-third clavicle fractures are most common, occurring in 80% of all clavicle fractures (eFig. 38.1). Nondisplaced middle-third fractures in adults have an intact periosteum. These heal well and require only a sling for support and ice to reduce swelling. For displaced fractures, a figure-of-eight harness can be used for reduction and maintenance of position, but it provides no more benefit in pain control or fracture reduction than a simple sling. Surgical fixation is frequently recommended in adults with displaced

clavicle fractures, necessitating referral to an orthopedist. Complications of middle-third clavicle fractures include malunion; excess callus formation, resulting in cosmetic defect; and neurovascular compromise.

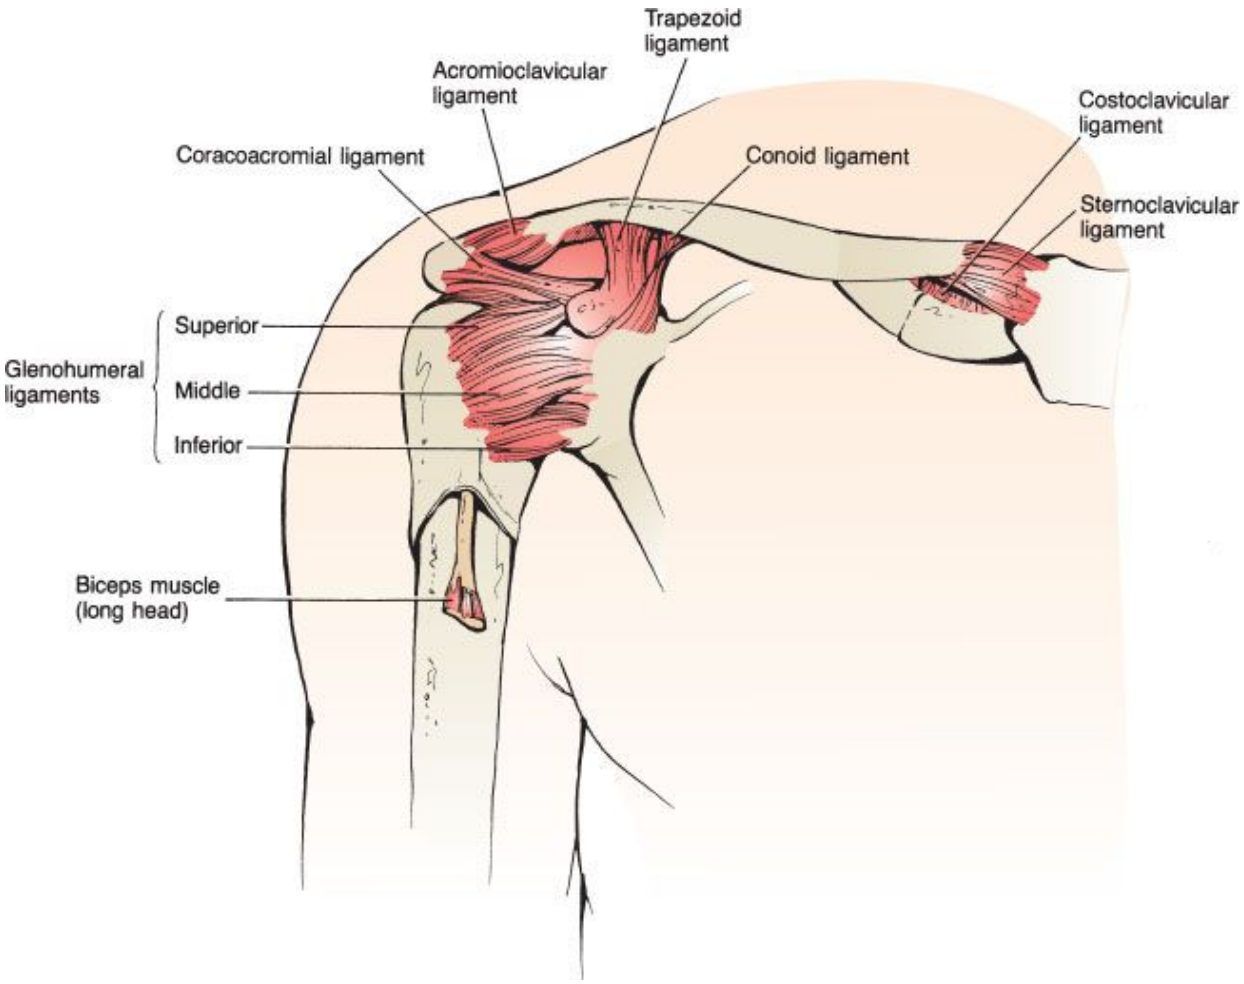

FIGURE 38.1 The ligamentous and bony anatomy of the shoulder.

eFIGURE 38.1 Clavicle fracture. The attachment of the sternocleidomastoid muscles pulls the medial segment superiorly.

Distal-third clavicle fractures account for 15% of all clavicle fractures. Nondisplaced fractures of the distal clavicle are splinted by the surrounding intact ligaments and muscles. They are usually treated symptomatically with ice, analgesics, a sling, and early motion. Displaced fractures of the distal clavicle may require surgical intervention because of rupture of the coracoclavicular ligament (3). Complications of displaced fractures treated conservatively include nonunion. Degenerative arthritis may occur when there is intra-articular involvement.

Medial-third clavicle fractures represent only 5% of all clavicle fractures. Considerable force is required to fracture the medial clavicle, so associated intrathoracic injuries should be considered. Management includes ice, analgesics, and a sling for support. Displaced fractures require orthopedic referral for reduction. Degenerative arthritis frequently complicates these fractures.

Proximal Humerus Fractures

Proximal humeral fractures account for approximately 2% to 3% of upper extremity fractures. They are most common in elderly osteoporotic women. Anatomically, proximal humeral fractures

include all humeral fractures proximal to the surgical neck. Two mechanisms of injury are commonly responsible: (i) a direct blow on the lateral aspect of the arm and (ii) a fall on an outstretched arm. Patients present with pain and swelling over the upper arm and shoulder. Most commonly, the arm is held adducted.

The Neer classification system for proximal humerus fractures is widely used and has both prognostic and therapeutic implications. In this system, the proximal humerus is divided into four segments: greater tuberosity, lesser tuberosity, humeral head, and humeral shaft (4). Depending on the displacement and angulation of fractures of these four components, the injury is divided into one-, two-, three-, and four-part fractures (eFig. 38.2).

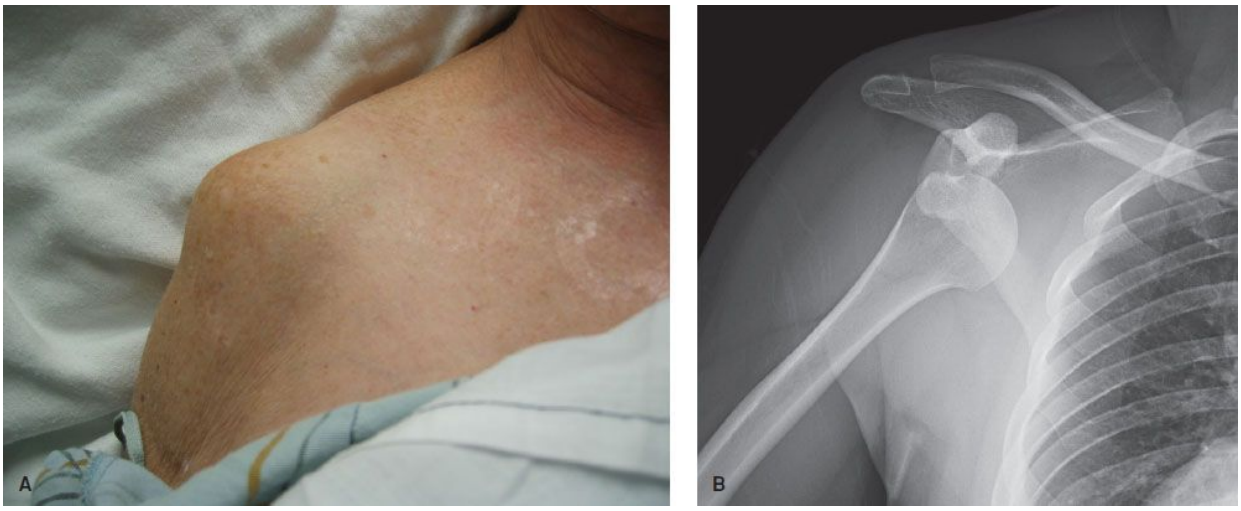

FIGURE 38.2 Anterior shoulder dislocation. A: A “rounded off” appearance of the affected shoulder is typical clinically. B: Characteristic radiographic appearance of a subcoracoid dislocation.

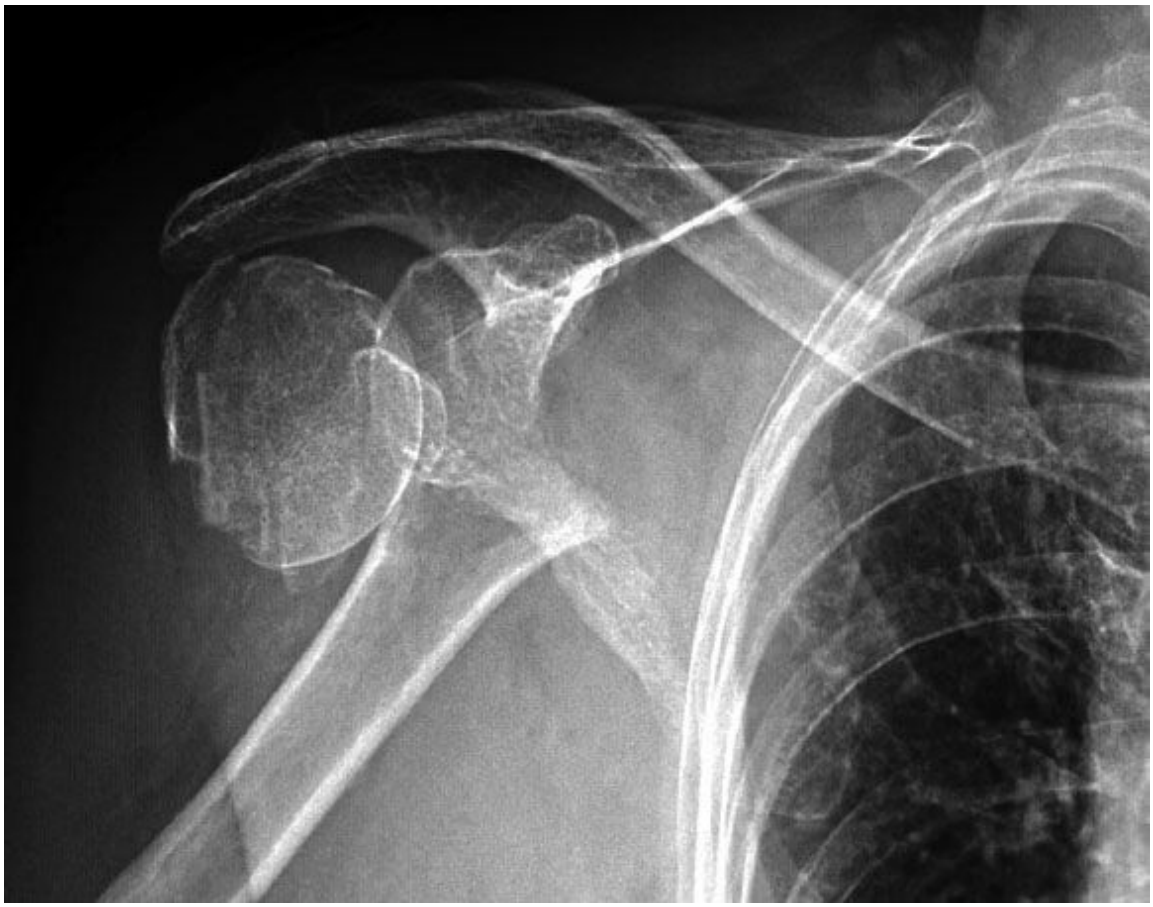

eFIGURE 38.2 Proximal humerus fracture. This image is of a surgical neck fracture with complete displacement. This is an example of a two-part fracture.

One-part fractures are nondisplaced (<1 cm) fractures without significant angulation (<45 degrees). These fractures are the most common type of proximal humerus fracture and represent more than 85% of cases. The humeral fragments are held in place by the periosteum, rotator cuff, and joint capsule. Therapy for one-part fractures includes immobilization in a sling and swathe and orthopedic referral within 4 to 5 days. Circumduction exercises should begin as soon as tolerated, and should be followed by passive exercise of the elbow and shoulder at 2 to 3 weeks. Shoulder motion exercises can usually be started within 3 to 4 weeks.

Two-part fractures have a fragment with more than 1 cm of displacement or over 45 degrees of angulation. These fractures require immobilization with a sling and swathe and orthopedic

referral. Surgery is recommended for two-part fractures of the greater and lesser tuberosity, angulated surgical neck fractures, and in unstable surgical neck fractures in which there is disengagement of the shaft from the humeral head.

Three- and four-part fractures result from severe forces. Three-part fractures involve two fragments that are individually displaced from the humeral head. Four-part fractures involve three fragments individually displaced from the remaining humeral head. These fractures are associated with shoulder dislocations, rotator cuff injuries, and neurovascular compromise. Therapy includes sling immobilization and emergent orthopedic referral or admission. Virtually all of these fractures require surgical repair.

Scapular Fractures

Scapular fractures are rare and represent only 1% of all fractures and 5% of fractures involving the shoulder. Treatment, associated injuries, and complications depend on the portion of the scapula that is fractured.

Body or spine fractures are significant because a great deal of force is usually required to cause these fractures; therefore, they are sometimes associated with other more serious injuries to thoracic structures. Typically, there is little displacement, due to the support of the investing muscles and periosteum. Treatment includes sling and swathe immobilization, early limited exercise, and orthopedic referral.

Acromion fractures result from a direct downward blow to the shoulder. Due to the large amount of force required to produce these fractures, they are often accompanied by brachial plexus injuries, rotator cuff tears, and shoulder dislocations. Nondisplaced fractures are treated with sling immobilization in conjunction with an elastic circular dressing that pushes the elbow up and the lateral clavicle down. Displaced fractures require internal fixation.

Glenoid rim fractures are associated with two mechanisms of injury. A direct blow may result in a stellate fracture. An upward force, secondary to a fall on the flexed elbow, may cause a displaced glenoid rim fracture. Glenoid rim fractures also occur with shoulder

dislocations and are referred to as Bankart lesions. Therapy for fractures with small fragments consists of sling immobilization, ice, and analgesia. Large or widely displaced fragments and stellate fractures require surgical fixation.

Coracoid process fractures occur from a direct blow to the superior part of the shoulder, or from violent contraction of one of the inserting muscles. The patient presents with tenderness to palpation over the coracoid process. Radiographs should include an axillary view for delineation of any displacement of the fragment. Coracoid fractures are usually treated symptomatically with a sling, ice, and analgesics.

Anterior Shoulder Dislocation

Anterior shoulder dislocation is one of the most common dislocations, accounting for half of all dislocations presenting to the ED. This injury occurs when a blow to an abducted, externally rotated arm disrupts the anterior capsule and the glenohumeral ligaments (5). Less commonly, a force to the posterior humerus or a fall on an outstretched arm is the cause.

The patient presents with the affected arm held to the side and resistant to all movements. The patient will be unable to touch the uninjured shoulder with the hand of the dislocated shoulder. In thin individuals, the acromion is prominent, and there is loss of the normal rounded contour of the shoulder (Fig. 38.2A). Upon palpation lateral to the acromion, there is a noticeable gap where the humeral head used to be positioned.

Axillary nerve injury is the most common associated neurologic injury in anterior shoulder dislocations. The axillary nerve is assessed by testing pinprick sensation over the lateral aspect of the deltoid in the “shoulder badge” distribution or deltoid muscle weakness. Unfortunately, sensory loss is not reliably present and an accurate motor examination is impractical in a patient with an acute dislocation. While nerve dysfunction is common, it is seen in up to 42% of patients, most patients recover without intervention.

On AP radiographs, the humeral head is in one of three locations: subclavicular, subcoracoid, or subglenoid (Fig. 38.2B). The physician

should determine the position of the humeral head to ascertain if there are associated injuries. The typical position is subcoracoid. If the humeral head is in a subglenoid or subclavicular position, the patient has either a greater tuberosity fracture or a rotator cuff tear. The scapular Y view, true AP (Grashey view—beam directed at a 45-degree angle from a medial to lateral direction with the plate parallel to the scapular body), and axillary view are used in equivocal cases.

Clinically important fractures are seen in approximately 25% of cases and are more common in patients over age 40, first-time dislocations, and after a traumatic mechanism. In patients with none of these three factors present, a prereduction radiograph is unlikely to be beneficial when the diagnosis is obvious clinically (6,7). The most common associated fracture is an impaction fracture on the posterior lateral portion of the humeral head known as the Hill–Sachs deformity. It is present in 40% of dislocations. Other fractures include Bankart fractures of the anterior glenoid rim (5%) and greater tuberosity fractures (10%). A nondisplaced fracture of the surgical neck is a rare associated injury, but important to note, as attempts at closed reduction of the shoulder dislocation are contraindicated. Attempts at reduction may displace the fracture and worsen the prognosis.

Reduction should begin after obtaining informed consent. Procedural sedation is not necessary in all cases, especially in recurrent dislocators who present promptly. Patient preference should be considered. Reduction without procedural sedation is unlikely to be successful in a patient who is anxious, in pain, and unable to assist in the reduction by relaxing their musculature. Some have used intra-articular lidocaine with good results (8).

There are numerous reduction techniques described, but most techniques use or combine scapular movement, external rotation, shoulder abduction, and traction of the arm. The best technique is one that is quick, simple, associated with few complications, and requires the smallest amount of force. One method that meets these requirements is scapular manipulation with downward traction on the arm by an assistant. Success rates with this maneuver range from 80% to 100% (9–11). This technique is attempted without

procedural sedation in most cases. If this is unsuccessful, the external rotation technique can be used, followed by traction–countertraction, if necessary. Other acceptable alternative techniques include the Milch, Stimson, Spaso, Fares, and Cunningham methods.

Scapular Manipulation Technique

The head of the stretcher is placed at 90 degrees. The patient sits upright with the unaffected shoulder leaning against the head of the stretcher and the legs hanging off the edge (no procedural sedation). The physician stands behind the patient and pushes the tip of the scapula medially and the superior aspect of the scapula laterally (11). This scapular rotation allows the humeral head to disengage from the glenoid. An assistant, standing in front of the patient, gently applies a downward force (Fig. 38.3A) (18).

FIGURE 38.3 Methods of reducing an anterior shoulder dislocation. **A:** Scapular manipulation with downward traction on the arm for

anterior shoulder dislocation. **B:** External rotation technique for anterior shoulder dislocation. **C:** Traction–countertraction technique for reducing anterior shoulder dislocations.

External Rotation Technique

This technique is also simple and may permit the shoulder muscles to reduce the dislocation with minimal analgesia (13). The patient lies supine with the shoulder adducted and elbow flexed to 90 degrees. The patient is encouraged to allow their arm to fall to the side. One of the physician's hands supports the elbow, and the other hand slowly guides the patient's arm (Fig. 38.3B). When pain or spasm is experienced, movement is stopped and the muscles are allowed to relax. Over the course of 5 to 10 minutes, the arm is externally rotated to 90 degrees. The rotation must be performed gradually, and the patient must remain relaxed. After reaching 90 degrees, the shoulder reduces spontaneously with success rates ranging from 80% to 90% (14).

If the shoulder is not reduced, an additional maneuver (Milch technique) can be added. The externally rotated arm is slowly elevated above the patient's head, and slight traction is applied. If the patient is unable to tolerate the external rotation technique because of pain and anxiety, procedural sedation will frequently allow the necessary muscle relaxation to reduce the shoulder.

Traction–Countertraction

With the patient lying in the supine position, an assistant applies countertraction with a folded sheet in the axilla while the examiner applies traction to the arm (Fig. 38.3C). Additional lateral traction may be added with a second sheet applied around the proximal portion of the humerus. To prevent avulsion injuries when using this maneuver, the patient must have good muscle relaxation.

Reduction in the ED is unsuccessful in 5% to 10% of cases. If the dislocation cannot be reduced, general anesthesia should be considered and reduction attempted in the operating room. Irreducible dislocations are usually due to soft tissue interposition.

Upon successful reduction, the arm is immobilized and the patient is sent for radiographs. Postreduction radiographs are not necessary if the prereduction radiographs did not reveal a fracture, the reduction was performed smoothly, and the postreduction physical examination is not suspicious for an unsuccessful reduction.

There is controversy regarding whether the shoulder should be immobilized in internal (sling and swathe or commercially available shoulder immobilizer) or external rotation (15–17). Immobilization in external rotation has been postulated to put the detached labrum in a better position to heal and consequently reduce the rate of recurrent dislocation. Study results are mixed, but immobilization of these patients in internal rotation is recommended until more conclusive evidence becomes available.

The patient is referred to an orthopedic surgeon within 1 week. The older the patient, the earlier mobilization should be instituted to avoid stiffness. For patients younger than 30 years of age, the shoulder is immobilized for 3 weeks, followed by gentle active range-of-motion exercises. The patient should avoid abduction and external rotation for an additional 3 weeks. For patients older than age 30, the shoulder is immobilized for 1 week, followed by active range-of-motion exercises, avoiding abduction and external rotation.

Complications of anterior shoulder dislocations include tears of the rotator cuff, avulsion of the greater tuberosity, axillary nerve injury, and fracture of the humeral head. The most common complication is recurrent dislocation due to labral and ligamentous injury. This complication occurs in 50% to 90% of patients younger than age 20. Prevention of recurrent dislocation is achieved by internal rotation exercises that strengthen the subscapularis muscle. Operative repair is indicated in patients with recurrent dislocations and occasionally in young, first-time dislocators engaged in highly demanding physical activities.

Posterior Shoulder Dislocation

Posterior dislocations are less common and more subtle on examination and radiographs than their anterior counterpart, making delayed and misdiagnosis more likely. The common mechanisms

involved in this injury include violent internal rotational force occurring during a fall on the forward-flexed, internally rotated arm or a violent muscle contraction following a generalized tonic–clonic seizure or electrocution.

On physical examination, the arm is held in adduction and internal rotation, with abduction severely limited. External rotation of the shoulder is blocked, a critical feature of the examination that should raise clinical suspicion. Additional physical examination findings include prominence in the posterior aspect of the shoulder accompanied by flattening of the normal anterior shoulder contour. Neurovascular compromise is uncommon.

Evidence of a posterior shoulder dislocation on a standard AP view is subtle and may be undiagnosed in 50% of cases (18). Some clues to the radiographic diagnosis include the *light bulb, trough line,* and *rim signs* (Fig. 38.4A). The light bulb sign refers to the circular appearance of the humeral head caused by internal rotation that changes the projection of the tuberosities. The trough line sign is a linear appearance within the humeral head that represents the "trough" of the reverse Hill–Sachs impaction fracture. The rim sign is present when the distance between the medial aspect of the humeral head and the anterior glenoid rim is abnormal, usually with additional overlap between the two. Whenever there is a question of a posterior shoulder dislocation on AP views, an axillary view should be obtained (Fig. 38.4B). Isolated fractures of the lesser tuberosity are commonly associated.

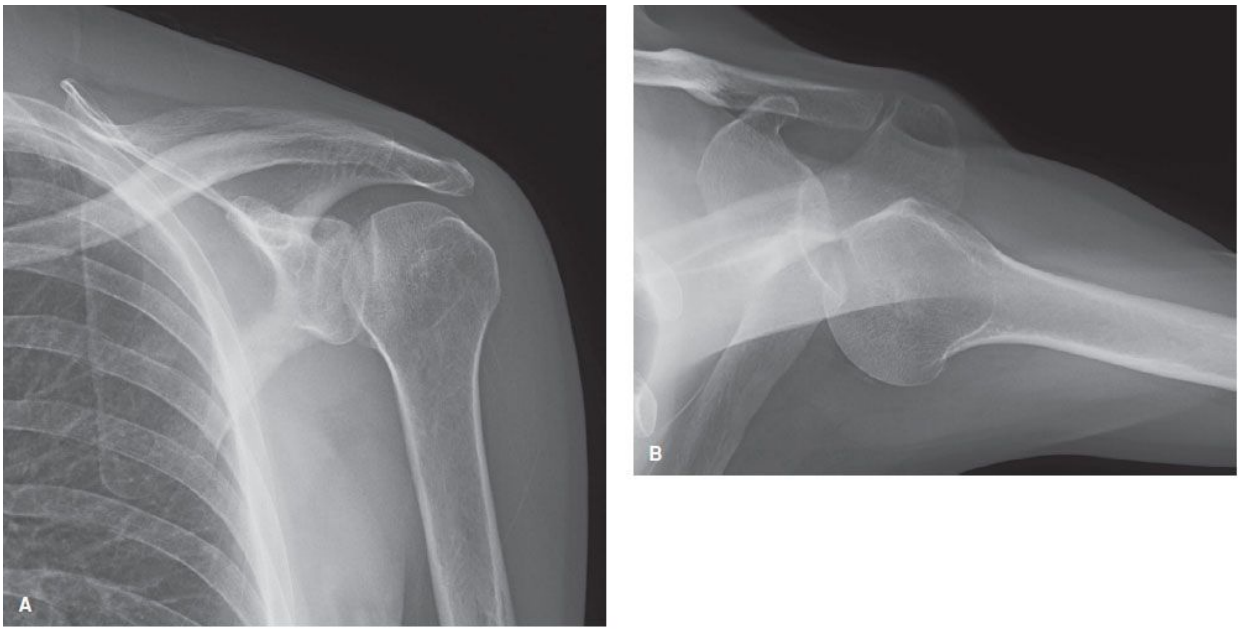

FIGURE 38.4 Posterior shoulder dislocation. A: AP view. Notice there is additional overlap of the glenoid and humeral head (rim sign), a rounded appearance of the humeral head (light bulb sign), and a linear opacity medial within the humeral head (trough line sign). B: Axillary view.

Consultation with an orthopedic surgeon is recommended for posterior shoulder dislocations. Closed reduction is attempted only if the anterior surface defect ("reverse Hill–Sachs deformity") is $<20\%$ of the total humeral head surface and the duration of dislocation is <3 weeks (19). Posterior shoulder dislocations may be reduced by hanging the arm with weights (Stimson method), or other techniques that push the posteriorly displaced humeral head forward. If there is severe pain or muscle spasm, general anesthesia may be necessary. Surgical intervention is needed when the articular surface defect is $>20\%$ of its surface area, when the dislocation is irreducible using closed techniques, or when a lesser tuberosity fracture remains displaced after joint reduction.

Inferior Shoulder Dislocation (Luxatio Erecta)

Inferior dislocations of the shoulder are uncommon, representing approximately 0.5% of all shoulder dislocations. The mechanism of

injury is forceful hyperabduction. Because of its dramatic presentation, this dislocation is rarely missed.

On physical examination, the patient is in severe pain and holds the arm upright, as if asking a question. The humeral head can be palpated along the lateral chest wall. Compression of the axillary artery and brachial plexus may occur as the humeral head tears through the inferior capsule. Vascular injury occurs in approximately 3% of patients, but it is more common with inferior dislocations than with any other form of shoulder dislocation (11,20).

Radiographically, the humeral head is seen beneath the coracoid or glenoid with the humerus abducted. Associated fractures of the acromion, inferior glenoid rim, and greater tuberosity may be present (20).

To reduce the dislocation, the physician applies traction in the longitudinal axis of the humerus while an assistant applies countertraction with a folded sheet wrapped around the supraclavicular region. With traction maintained, the arm is rotated inferiorly in an arc toward a position of complete adduction. Closed reduction is successful in most cases. After reduction, the shoulder is immobilized for 2 to 4 weeks. Rotator cuff tears are frequently present. Occasionally, general anesthesia may be required to reduce the dislocation and repair the torn rotator cuff.

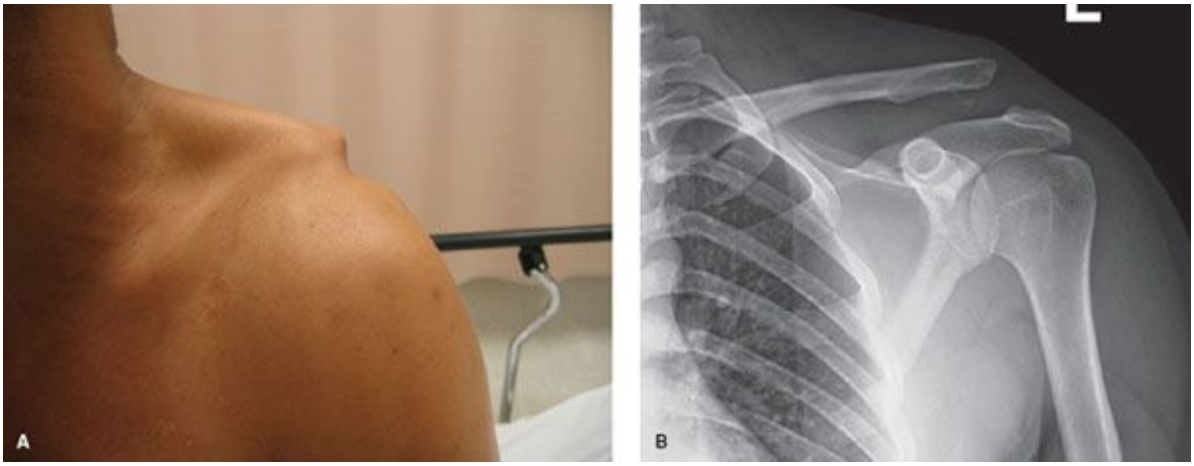
AC Joint Injury

The AC joint functions to elevate and abduct the arm. Stability is provided by two ligaments—the AC and the coracoclavicular. Injury to these ligaments, commonly referred to as a “shoulder separation,” accounts for 10% of all dislocations. Most injuries of the AC joint are caused by a direct force applied to the point of the shoulder. The therapy for AC joint injuries depends on the amount of ligamentous injury—first-, second-, or third-degree injuries (21).

First-degree injuries are a simple sprain of the AC ligament and involve an incomplete tear of that structure. The patient complains of pain and has tenderness over the AC joint. Swelling is minimal, no subluxation is present, and radiographs are normal. Therapy includes rest, ice, and a sling, with early range of motion.

Second-degree injuries involve disruption of the AC ligament, with sprain of the coracoclavicular ligament. There is a partial subluxation of the distal end of the clavicle from the acromion. The patient experiences tenderness to mild palpation and moderate swelling is present. Radiographic findings are subtle and include an increased width of the AC joint of 3 mm or more or greater than a 50% increase compared to the opposite side. The distal clavicle is elevated no more than half its diameter from the acromion. Stress films, previously recommended to help distinguish between second- and third-degree injuries, are no longer routinely recommended because they do not affect treatment decisions (22). Second-degree injuries are treated conservatively with ice, rest, and immobilization in a sling. Commercially available clavicle braces (Kenny-Howard sling) may be used but have not been shown to produce superior long-term function over a sling.

Third-degree injuries result in complete dislocation at the AC joint, with disruption of both the AC and coracoclavicular ligaments. The diagnosis of an AC joint injury is made by examining the patient in the upright position and looking for a deformity at the tip of the shoulder (eFig. 38.3A). On radiographs, the inferior border of the distal clavicle is above the midpoint of the acromion (eFig. 38.3B). Treatment is controversial. In the past, third-degree injuries were treated surgically in young patients. However, conservative treatment has been shown to be equivalent to surgery. Patients with these injuries should be immobilized in a sling and referred to an orthopedist within 1 week (23,24).



eFIGURE 38.3 Acromioclavicular separation—Third degree. A: Clinical picture. B: Radiograph of the same injury.

SC Joint Injuries

The SC joint is stabilized by the SC ligament and the costoclavicular ligament. The most common mechanism of injury to this joint is a force that thrusts the shoulder forward. In the absence of trauma, an infectious process within the joint should be considered. Traumatic injuries are divided into mild and moderate sprains and SC joint dislocation.

Mild SC joint sprain involves incomplete tears of the SC and costoclavicular ligaments. The patient experiences minimal swelling and has tenderness at the joint. Therapy includes ice, analgesics, and a sling for 3 to 4 days.

Moderate SC joint sprain involves subluxation of the clavicle from its manubrial attachment. Complete rupture of the SC ligament and partial rupture of the costoclavicular ligament occur. There is pain on abduction of the arm, and swelling is noted over the joint. Treatment includes 6 weeks of immobilization with a figure-of-eight clavicle strap and a sling to permit ligamentous healing.

SC joint dislocation involves complete rupture of the SC and costoclavicular ligaments, permitting the clavicle to dislocate from its manubrial attachment. Anterior dislocations are much more common, but posterior dislocations have the potential to result in much more serious injuries. Patients experience severe pain, which is

increased by any motion of the shoulder. Posterior dislocations may constitute a true emergency because respiratory embarrassment can occur secondary to tracheal compression, pneumothorax, or venous congestion. These associated injuries may necessitate emergency reduction by the emergency physician, whereas reduction in the operating room is recommended in all other cases (1). Reduction is accomplished by placing a folded sheet between the shoulders, with the patient supine. This serves to separate the clavicle from the manubrium. The arm is abducted and traction is applied. For posterior dislocations, following the instillation of local anesthesia, the clavicle should be grasped near its medial border with a towel clip and pulled out of its posterior position. Unstable SC joint dislocations may require surgical intervention (3).

Complications of anterior SC dislocation are cosmetic, with chronic swelling around the joint. Although it has been reported that up to 25% of posterior dislocations are associated with complications—including pneumothorax, laceration of the superior vena cava, occlusion of the subclavian artery or vein, and rupture or compression of the trachea—this may be an overestimate (1).

Rotator Cuff Injury

Tears of the rotator cuff are more common in the elderly and may occur after minimal trauma. The mechanism of injury following an acute injury, which is more common in younger patients, is typically a sudden forceful elevation of the arm against resistance. The most common area of cuff injury is at the anterosuperior portion, at the attachment of the supraspinatus muscle. The tendon at this point is worn down by the compressive forces between the humeral head and the coracoacromial arch.

Patients complain of pain that radiates to the anterior aspect of the arm and is aggravated by activity. Abduction and external rotation of the arm are painful and weak. Tenderness is present over the insertion at the greater tuberosity. Thirty percent or more of the tendon must be ruptured to produce a significant reduction of strength. The extent of the tear is directly related to the limitation of shoulder abduction.

The *drop arm test* is positive in patients with significant tears. This is performed by horizontally elevating the arm to the 90-degree position and asking the patient to continue to hold the arm in this position. Slight pressure on the distal forearm will cause the patient to drop the arm suddenly. In addition, the patient cannot bring the arm from the abducted position to the side in a slow fashion, but drops it precipitously.

Emergency treatment includes ice, immobilization, and orthopedic referral within 4 to 5 days. Passive range-of-motion exercises should be instituted as soon as possible in elderly patients. Magnetic resonance imaging is diagnostic of full-thickness tears with 100% sensitivity, but is not indicated in the ED (25). Conservative therapy results in a good outcome in 50% of patients. In the young, early surgical repair is indicated for complete tears of the rotator cuff. Anterior tears have the best outcome, while patients with posterior tears are poor candidates for arthroscopy (26). In the elderly patient with a more sedentary life, repair may not be indicated.

CRITICAL INTERVENTIONS

- Evaluate patients with scapular fractures for associated thoracic injuries, with careful physical examination, radiographs, and further testing when indicated.
- In patients who have had a grand mal seizure, check external rotation of both shoulders to evaluate for posterior shoulder dislocation.
- Use the towel clip method to reduce posterior SC dislocations when they are associated with respiratory distress due to tracheal compression.

Common Pitfalls

- Failure to obtain an axillary view when assessing the shoulder for dislocation.
- Failure to remember that lesser tuberosity fractures are often associated with posterior shoulder dislocations.

- Attempting to reduce an anterior shoulder dislocation in a patient with a concomitant surgical neck fracture.

CHAPTER 39

Elbow Injuries

Andrew D. Perron and Carl A. Germann

The elbow is a complex synovial hinge joint consisting of three articulations between the distal humerus, radius, and ulna. Because of the need for a wide variety of articular motions (flexion–extension and pronation–supination), the joint is at risk for instability with injury. The humerus widens distally to form the lateral and medial condyles. The capitellum is a spheroidal cartilaginous structure of the lateral condyle that articulates with the radial head, permitting pronation and supination. The trochlea is a spoon-shaped cartilaginous projection of the medial condyle that articulates with the deep trochlear notch of the ulna, permitting flexion and extension at the elbow. The articulating surfaces of the head of the radius and ulna are held together by the annular ligament. The associated musculature and the anterior capsule combined with the radial and ulnar collateral ligaments provide stability at the elbow joint.

A number of important structures traverse or are located within the elbow. The wrist flexor and pronator muscle groups originate from the medial epicondyle. The wrist extensor and supinator muscles attach to the lateral epicondyle. The brachial artery traverses the elbow and is palpable medial to the biceps tendon in the antecubital space. The median nerve traverses deep in the antecubital fossa medial to the brachial artery. The ulnar nerve courses posteriorly in the cubital tunnel between the medial epicondyle and olecranon process. The radial nerve passes between the heads of the triceps in the posterior humerus and is at risk for injury in humeral shaft fractures.

There are several bursal structures in and around the elbow that help facilitate the wide range of motion possible in the joint. The superficial olecranon bursa lies beneath the skin over the olecranon process and is particularly vulnerable to traumatic and infectious processes. Figure 39.1 illustrates the anatomy of the elbow.

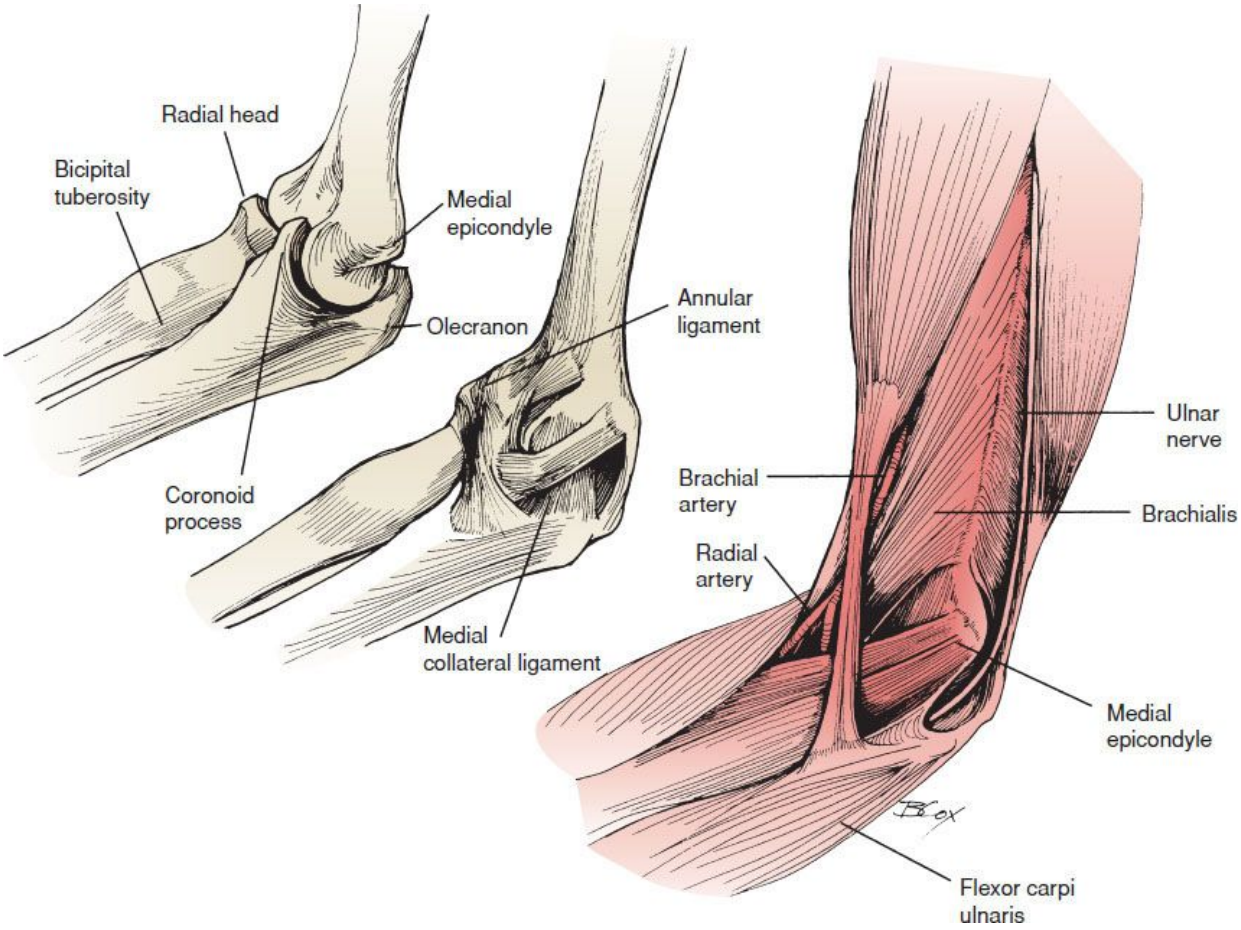

FIGURE 39.1 Elbow anatomy. (From McCue FC III, Sweeney T, Urch S. The elbow, wrist, and hand. In: Perrin DH, ed. The Injured Athlete. 3rd ed. Philadelphia, PA: Lippincott-Raven; 1999, with permission.)

ED EVALUATION

The emergency department (ED) assessment of elbow injuries should include a focused history of the mechanism of injury. The most common complaints are pain, restriction of movement, and swelling. A description of the location and duration of pain, aggravating factors, and presence of paresthesias or loss of movement is

important. Elbow pain may also be referred from injuries to the shoulder, forearm, or wrist. Conversely, injuries to the elbow may refer pain to the wrist. Identification of one injury should not preclude the search for other injuries. An occupational history may provide a clue to the diagnosis in patients presenting with chronic pain.

Inspection of the involved extremity for swelling, open wounds, deformities, effusions, and discoloration is the first step in the physical examination of the patient with elbow pain. In most cases, the involved joint should not be extensively manipulated until radiographs have been obtained to exclude fracture and dislocation. The shoulder, forearm, wrist, and hand should also be carefully examined to look for associated injuries. Laceration over the medial epicondyle should raise suspicion of an ulnar nerve injury, whereas laceration over the antecubital fossa should raise suspicion for injury to the brachial artery or median nerve. Any abnormality noted in the involved extremity should be compared with the contralateral extremity.

An effusion is best palpated over the soft tissue area lateral to the radial head. The bony prominences of the medial and lateral condyles, olecranon, and radial head should be palpated for tenderness. The radial head is best palpated with the thumb of one hand while pronating and supinating the forearm with the examiner's other hand. Limitation of motion, crepitance, or pain should all be noted. With the elbow flexed to 90 degrees, the medial and lateral condyles and the olecranon should form a triangle. In an elbow dislocation, this triangle is disrupted with displacement of the olecranon. A posterior dislocation or extension-type fracture is suggested by a prominent olecranon. Loss of the olecranon prominence suggests an anterior dislocation or supracondylar fracture. The triangular relationship is maintained in supracondylar fracture. Each of the muscle groups should be tested against resistance and the muscle belly palpated during contraction.

Careful neurovascular examination of the structures distal to the elbow is of critical importance. Brachial, radial, and ulnar pulses should be palpated and capillary refill assessed. The brachioradialis,

biceps, and triceps reflexes should be elicited. The radial nerve is best tested by evaluating wrist and finger extension. Wrist drop results from radial nerve injury. Flexion of the wrist and digits and pronation of the forearm are the functions of the median nerve. Inability to flex and abduct the thumb is diagnostic of median nerve injury. Loss of strength of the interossei muscles and adduction of the thumb suggests ulnar nerve injury. The sensory component of the radial nerve innervates the dorsum of the hand and is best tested in the web space between the thumb and index finger. Median nerve sensation is tested over the palmar aspect of the thumb and the digits to the radial one-half of the ring finger; at the volar tip of the index finger, there is no overlap from the radial or median nerves. The ulnar nerve is tested at the volar tip of the small finger. The neurovascular examination of the extremity should be repeated after manipulation and at regular intervals as edema from a fracture may result in neurovascular compromise.

The radiographic examination of the elbow should consist of a minimum of two views at right angles to each other (anteroposterior [AP] and true lateral). Radiographs are most commonly misread because a true lateral view of the elbow is not obtained. In one university ED setting, the incidence of missed elbow fractures was 12% (1). Oblique views may be obtained to provide additional information. Specialized views, such as the radial head–capitellum view, are indicated when a suspicion for particular injury exists.

On the lateral radiograph, a line parallel to the anterior border of the humerus should intersect the anterior portion of the middle third of the capitellum (Fig. 39.2) (2). If this intersection is displaced, usually anterior to the capitellum, a supracondylar fracture should be suspected.

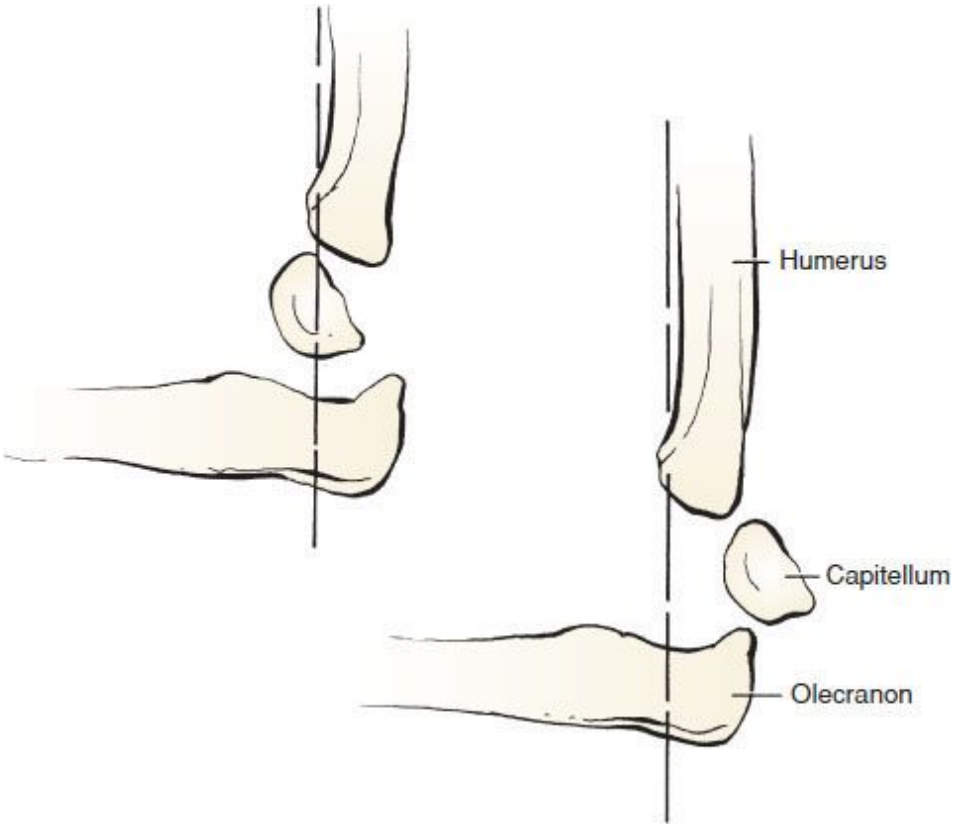

FIGURE 39.2 Anterior humeral line. The anterior humeral line is drawn on the lateral radiograph along the anterior surface of the humerus through the elbow. Normally this line transects the middle of the capitellum (left). With an extension fracture of the supracondylar region, this line will either transect the anterior third of the capitellum or pass entirely anterior to it (right). (Adapted from Simon RR, Koenigsknecht SJ. Emergency Orthopaedics: The Extremities. 2nd ed. Norwalk, CT: Appleton & Lange; 1987, with permission.)

The radiocapitellar line extends from the center of the radius and should intersect the middle third of the capitellum on the lateral view (2). Disruption of this line suggests radial head dislocation or fracture and is most useful in evaluating subtle fractures in children.

Fat pad signs are helpful in diagnosing occult fractures within the joint capsule. The *anterior fat pad* consists of fat in the coronoid and radial fossa. This radiolucent fat overlaps and normally appears as a triangular area anteriorly over the distal humerus on a lateral

radiograph of the elbow. The *posterior fat pad* is located in the olecranon fossa and is normally hidden by the overlying humeral condyles on a lateral radiograph.

When an effusion is present, it distends the joint capsule and displaces the fat pads (Fig. 39.3). The *anterior fat pad* displaces anteriorly and superiorly and appears bowed out as a "ship's sail." The *posterior fat pad* becomes visible on radiography with elbow injury and is highly indicative of intra-articular disease. In the setting of elbow trauma, a visible posterior fat pad or a prominent anterior fat pad in the absence of visible fracture should prompt consideration of occult fracture, most commonly of the radial head.

FIGURE 39.3 Anterior and posterior fat pad signs are indicated by the large white arrows. Small black arrows indicate the radial head fracture that produced the effusion displacing the fat pads.

Positive fat pad signs can also be present with any intra-articular disease process and thus are not strictly pathognomonic for fracture. Fat pad signs may be seen with arthritis, gout, pseudogout, infection, neoplasia, or other disease process causing an intra-articular fluid collection (3). A fat pad sign may not be present with severe injury causing disruption of the joint capsule.

Though usually not necessary in the ED evaluation of these patients, computed tomography (CT) scanning may be useful in delineating complex fractures in adults. Magnetic resonance imaging (MRI) has become the procedure of choice for evaluating soft tissues, cartilaginous surfaces, joint space, and trabecular bone (4).

KEY TESTING

Plain radiographs for skeletal injuries must:

- Include the appropriate bone/joint injured
- Have at least two views at right angles to each other
- Be adequate for diagnosing most elbow fracture and dislocation injuries

CT Imaging:

- Particularly useful to better characterize elbow injury and assist in preoperative planning
- Consider when the relationship of fracture fragments is complex or will impact downstream care (e.g., multifragment radial head fractures, fracture/dislocation injuries)
- Can be combined with angiographic contrast (CT-A) to identify injuries to major blood vessels)

MR Imaging:

- Provides greatest soft tissue detail (tendons, ligaments, disc)
- Can also provide imaging in multiple planes (axial, coronal)
- Consider when there is a potential soft tissue injury that will impact care (e.g., degree of tendon injury)

Ultrasound:

- An imaging modality being used by some practitioners in the bedside diagnosis of musculoskeletal injuries
- Trained hands can identify fractures, dislocations, and some soft tissue injuries (e.g., tendon tears)

ED MANAGEMENT

Supracondylar Fractures

Supracondylar fractures occur in the distal humerus proximal to the epicondyles and are most commonly seen in children. In adults, because of their stronger bones, elbow dislocations from ligamentous disruption are more common. These fractures most commonly result from a fall on the outstretched hand with the elbow in extension.

Twenty-five percent of supracondylar fractures are nondisplaced. Treatment of a *nondisplaced* fracture is a posterior splint from axilla to palm, with the elbow flexed to 90 degrees. These patients should be urgently referred to an orthopedic surgeon for follow-up within 24 to 48 hours. The patient and parents should be carefully counseled regarding warning signs of compartment syndrome. A child with elbow tenderness and swelling should be splinted, even without a demonstrable radiographic fracture, because of the possibility of occult fracture (5).

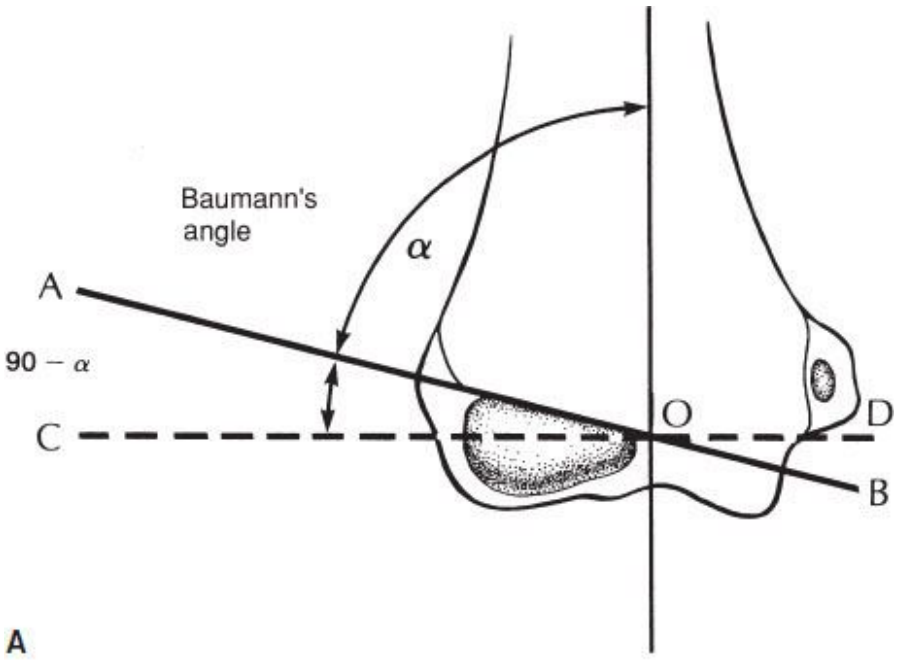
In displaced fractures, the distal fragment is usually displaced posteriorly (extension injury), and an abnormal anterior humeral line will be visualized on the lateral radiograph. Anterior displacement of the distal fragment (flexion injury) occurs less frequently and is caused by a direct blow to the posterior aspect of the flexed elbow.

Assessment of neurovascular function is essential, especially with extension injuries, because occult injury to the brachial artery may occur. A strong pulse does not completely rule out arterial injury, and a vascular study should be performed if injury is clinically suspected. The reported rate of nerve injury in displaced supracondylar fractures is up to 20% (6). Injury to the median and radial nerve can occur from stretching or entrapment on the proximal humeral fragment. The ulnar nerve may also be disrupted and is more frequently damaged in a flexion-type fracture (6). Closed reduction of displaced fractures should be attempted as soon as possible if neurovascular compromise is present.

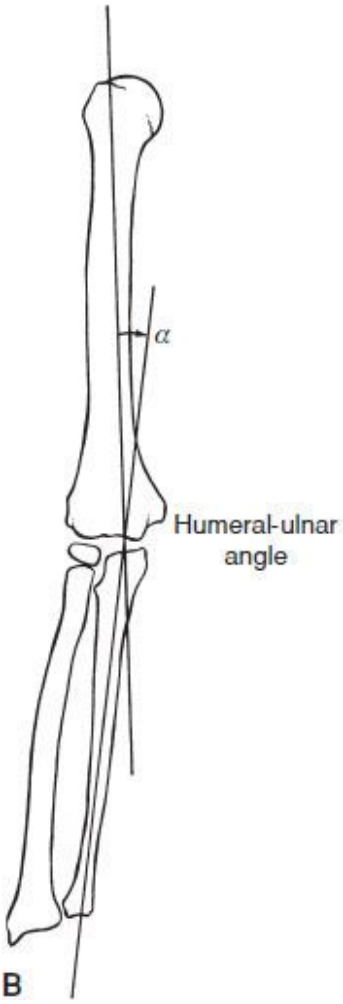
Displaced fractures require internal fixation or percutaneous pinning if good alignment is not maintained with closed reduction.

Patients with displaced fractures should be admitted because of the risk of delayed swelling and neurovascular compromise, including compartment syndrome, and the potential for Volkmann ischemic contracture. Flexion fractures may also require internal fixation and should be splinted in extension.

A common complication of supracondylar fracture is an abnormal carrying angle. The normal carrying angle is 10 to 15 degrees of valgus. Measurement of Baumann's angle, formed by a line perpendicular to the humeral shaft and a line through the lateral humeral condyle, is predictive of an acceptable carrying angle (7). This angle normally measures about 75 degrees. A discrepancy of >5 to 10 degrees, compared with the uninjured extremity, is an unacceptable reduction, as it may impair useful function of the arm (Fig. 39.4).



A



B

FIGURE 39.4 A: Baumann's angle. B: Humeral–ulnar angle. (From O'Brien WR, Eilert RE, Chang FM, et al. The metaphyseal-diaphyseal angle as a guide to treating supracondylar fractures of the humerus in children. Unpublished data, with permission.)

Intercondylar Fractures

Intercondylar fractures usually occur in older patients as a result of direct trauma to the flexed elbow. They usually occur in "T" and "Y" configurations, and treatment is based on the amount of displacement of the humeral condyles from each other and from the proximal humerus. Neurovascular complications are uncommon, and these fractures rarely require manipulation by the emergency physician.

Nondisplaced fractures are treated in a posterior splint for 3 weeks, and then active range of motion is begun. Displaced fractures are treated with internal fixation and early range of motion beginning after 1 week. Severely comminuted fractures may be treated with olecranon traction for 3 to 4 weeks if operative repair is not possible.

Humeral Condyle Fractures

Isolated humeral condyle fractures are caused by a fall on the outstretched hand, by direct trauma, or by avulsion of bone from the pull of the flexor or extensor muscles from the medial and lateral condyles, respectively. Lateral condyle fractures are more common than medial condyle fractures and frequently involve the joint surface.

Nondisplaced lateral condyle fractures are immobilized in a posterior splint, with the elbow flexed to 90 degrees and the forearm in supination with the wrist extended. The forearm should be in pronation and the wrist flexed for medial condyle fractures. Active range of motion is begun as early as 2 to 3 weeks after injury. Operative fixation is required for displaced fractures, owing to instability caused by the pull of the forearm muscles. All of these

patients should be treated in consultation with an orthopedic surgeon.

Epicondyle Fractures

Epicondyle fractures in adults are usually caused by a direct blow. The medial epicondyle is involved more commonly than the lateral epicondyle, and ulnar nerve function should be evaluated, as it is in close proximity to the medial epicondyle at the elbow (Fig. 39.5). There is up to a 50% incidence of associated elbow dislocation with medial epicondyle fracture (8).

FIGURE 39.5 Avulsion fracture of the medial epicondyle. (From Yochum TR, Rowe LJ. Yochum and Rowe's Essentials of Skeletal

Radiology. 3rd ed. Philadephia, PA: Lippincott Williams & Wilkins; 2004.)

Nondisplaced fractures may be treated with immobilization and early range of motion. If more than 10 mm of displacement is present, then surgical fixation may be required. Intra-articular fragments may impede joint mobility and are difficult to visualize radiographically. Entrapment of the ulnar nerve is a possible complication.

Articular Surface Fractures

Fractures of the capitellum and trochlea usually occur as a result of a posterior elbow dislocation. Isolated fractures are rare, and joint stability is maintained because the condyles remain intact, but motion may be impeded.

Nondisplaced fractures with normal anatomic alignment can be treated with immobilization for 2 to 3 weeks. Displaced small fragments may ultimately need excision, whereas larger fragments may require internal fixation with early range of motion. Common complications of capitellar fractures include restriction of motion and, rarely, nonunion and avascular necrosis.

Proximal Ulna Fractures

Olecranon fractures are usually intra-articular and may result from a direct blow or an avulsion injury from the pull of the triceps muscle (Fig. 39.6). On examination, the patient is unable to extend the elbow against resistance. Because of its proximity, the ulnar nerve may be injured, and its function should be assessed.

FIGURE 39.6 Olecranon fracture. (From Chambers H, Jose Fernando DLG, O'Brien E, et al. Fractures of the radius and ulna. In: Rockwood CA, Wilkins KE, Beaty JH, eds. Fractures in Children. 4th ed. Philadelphia, PA: Lippincott-Raven; 1996. Fig 9.217 C, p.633, with permission.)

Treatment of these injuries varies with the amount of displacement and usually requires orthopedic consultation. Nondisplaced fractures may be splinted with the elbow in a semiflexed position and with early range of motion begun at 2 to 3 weeks after injury. Complete healing generally occurs in 6 to 8 weeks. If more than 2 mm of displacement is present, then operative intervention is usually indicated. Treatment options include tension band wiring, olecranon screws, or plates (9). Range-of-motion exercises may be started in 1 week. Management of severely comminuted fractures is controversial and may require removal of the loose fragments.

Fractures of the coronoid process usually occur in combination with a radial head fracture, a dislocation of the elbow, or both. Large

coronoid fractures are often associated with persistent elbow instability even after reduction of the dislocation. Nondisplaced coronoid fractures may be missed on AP and lateral radiographs; thus, CT or MRI should be considered to rule out small fractures (10).

Fractures involving $<50\%$ of the coronoid process are often treated with closed reduction and splinting with flexion. Complicated coronoid fractures or fractures involving $>50\%$ of the coronoid may require internal fixation or a hinged external fixator. Treatment of these injuries should be performed in conjunction with an orthopedic surgeon.

Radial Head Fractures

Radial head fractures are the most common elbow injuries in adults. They usually occur as a result of a fall on the outstretched hand, which drives the radial head into the capitellum. On examination, patients have tenderness to palpation over the radial head and pain with pronation and supination of the forearm.

Fractures are classified as nondisplaced, displaced, or comminuted. Nondisplaced fractures may be difficult to visualize on standard radiographs. Any disruption of the normally smooth, concave cortical contour of the radial head suggests fracture. A positive fat pad sign on a lateral radiograph without evidence of fracture should raise suspicion for an occult radial head fracture. This fracture may be better visualized radiographically with a radial head–capitellum view.

Nondisplaced fractures are treated with a posterior splint or sling, followed by early range of motion after a few days. Aspiration of the hemarthrosis in the ED may provide pain relief and expedite mobilization. Minimally displaced fractures may be treated in a similar manner. Fractures displaced >3 mm or involving more than one-third of the joint surface are often treated with operative fixation (Fig. 39.7). However, the amount of displacement that favors open reduction with internal fixation (ORIF) rather than nonsurgical treatment has not been elucidated (11). These patients should begin early range of motion postoperatively.

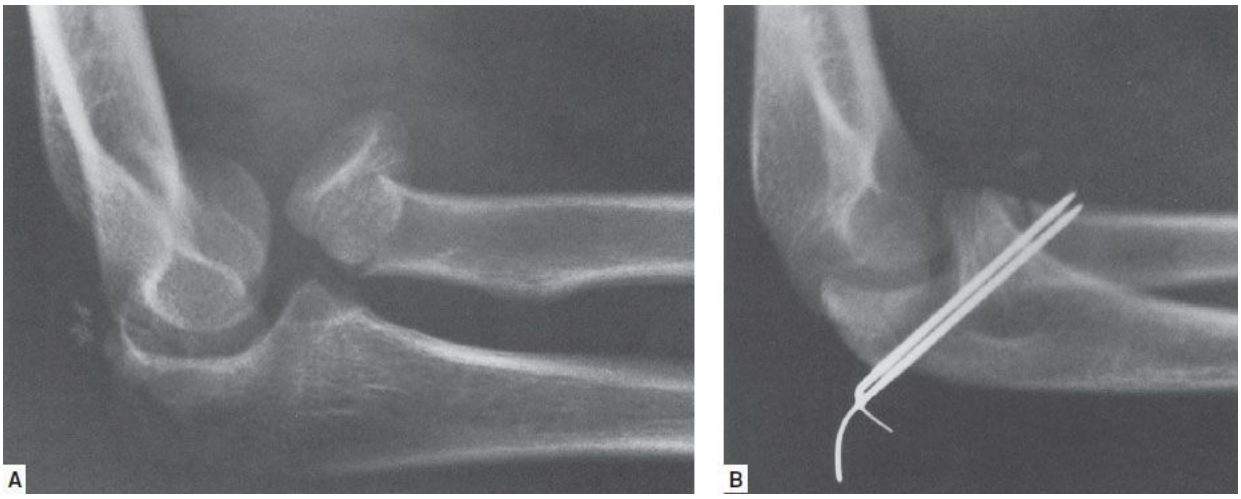


FIGURE 39.7 Displaced radial head fracture. (From Wilkins KE, ed. Operative Management of Upper Extremity Fractures in Children. American Academy of Orthopaedic Surgeons Monograph Series. Rosemont, IL: AAOS; 1994:57.)

Comminuted fractures may be treated with a sling and early range of motion in 1 to 2 weeks. Joint aspiration and injection of a local anesthetic can aid in assessing joint mobility. The treatment of severely comminuted and displaced fractures is controversial and may include excision of fragments or complete radial head excision, with or without prosthetic implants.

Any patient with a radial head fracture should also be examined for wrist tenderness. The *Essex-Lopresti lesion,* a radial head fracture with disruption of the distal radioulnar joint ligaments and forearm interosseous membrane, must be recognized early because internal fixation produces the best results (12).

Aspiration of the radiohumeral joint should be considered to relieve pain, promote early range of motion, and assess joint mobility with radial head fractures. This can be performed in the acute setting, to the great relief of the patient. Elbow joint aspiration is also indicated to diagnose a septic joint. The aspiration should be performed over the lateral elbow in the center of the triangle that connects the radial head, lateral epicondyle, and olecranon process (Fig. 39.8) (13). No neurovascular structures are located in this area, and the joint capsule is present beneath the skin and the thin

anconeus muscle. Using sterile technique, the skin over this area is anesthetized with a local anesthetic. An 18-gauge needle on a 10- to 20-mL syringe is directed into the center of the triangle and perpendicular to the skin. Aspiration of up to 5 mL of blood from the joint and injection of 1 to 2 mL of a long-acting anesthetic provide relief of pain and allow assessment of joint mobility.

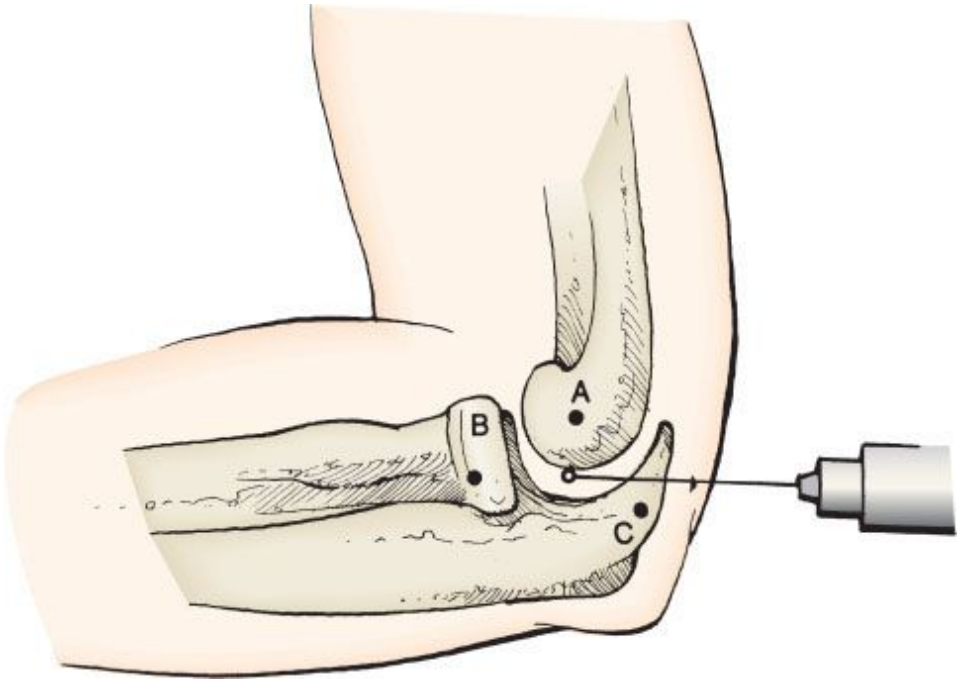

FIGURE 39.8 Elbow aspiration. The safest place to aspirate the elbow is in the center of a triangle produced by connecting (A) the lateral epicondyle of the humerus, (B) the radial head, and (C) the olecranon. (Adapted from Simon RR, Koenigsknecht SJ. Emergency Orthopaedics: The Extremities. 2nd ed. Norwalk, CT: Appleton & Lange; 1987, with permission.)

Nursemaid's Elbow

Subluxation of the radial head is most commonly seen in children 1 to 3 years of age but has been described even into the early teen years. The mechanism of injury is usually a sudden longitudinal pull of the forearm, causing fibers of the annular ligament to become stuck between the capitellum and the radial head. The child is

unwilling to move the arm, and the elbow is held in slight flexion with pronation of the forearm.

When a child presents with the characteristic history for radial head subluxation, radiographs are not necessary. However, the presence of swelling or deformity, or the child's refusal to resume normal use of the arm after reduction, is an indication for a radiograph.

Treatment usually consists of supination and flexion of the forearm in one continuous motion. The examiner's thumb can be used to apply pressure over the radial head. If this reduction maneuver is unsuccessful, pronation with extension is also described as an option (14). With successful reduction of a nursemaid's elbow, the child will resume using the arm normally within several minutes, and no further treatment is necessary.

Monteggia Fracture

Fracture of the proximal one-third of the ulna with dislocation of the radial head is a Monteggia fracture (Fig. 39.9). Based on the position of the radial head, there are four types of Monteggia fractures. The radial head dislocates anteriorly in 60% of cases, with posterolateral, lateral, and posterior dislocations being less common. The mechanism of injury involves direct trauma, forced hyperpronation, or hyperextension. The most commonly associated injury is paralysis of the radial nerve. The usual treatment is ORIF. Any patient found to have an ulnar fracture should be carefully examined for elbow pain or limitation of range of motion. The radiocapitellar line should be closely examined on the lateral elbow radiograph to ensure a normal relationship (15).

FIGURE 39.9 Monteggia fracture. The first component is fracture of the proximal one-third of the ulna; the second component is dislocation of the radial head.

Elbow Dislocation

Dislocation of the elbow accounts for 20% of all joint dislocations and is described by the direction in which the forearm is displaced in relationship to the distal humerus. Posterior and posterolateral dislocations account for 90% of all elbow dislocations. Dislocation may also occur between the radius and ulna. Posterior dislocations are caused by a fall on an extended and abducted arm. Patients present with significant swelling, tenderness, and deformity, with the elbow held in flexion and prominence of the olecranon. Anterior dislocation is the result of a blow to the olecranon while the elbow is held in extension with the forearm supinated and is associated with loss of the olecranon prominence.

Radiographs should be obtained before reduction to exclude associated fractures, which occur in up to 60% of patients with elbow dislocation. Avulsion fractures of the medial or lateral epicondyle, radial head and neck fractures, coronoid fractures, and supracondylar fractures in the younger patient may occur (16). A complete neurovascular examination must be performed on presentation. Neuropraxia is present in 20% of patients, most commonly involving the ulnar and median nerves. As with most nerve injuries associated with dislocations and fractures, these deficits are usually transient (17). Brachial artery injury is most commonly associated with open dislocations and those with concomitant fractures. The incidence of vascular injury is greater with anterior dislocations. Closed dislocations are rarely associated with vascular injury, especially in the absence of accompanying fracture (18).

Analgesia and muscle relaxation are required for closed reduction. Posterior, medial, and lateral dislocations are reduced using the same technique. With the patient lying supine, the area of the wrist and forearm is grasped, and traction is applied along the long axis of the forearm. An assistant provides countertraction to the upper arm. Any medial or lateral displacement is corrected. While forearm traction is continued, the elbow is flexed, and a palpable “clunk” should be felt as the elbow is reduced. Downward pressure over the proximal forearm may aid in disengaging the coronoid from the olecranon fossa (Fig. 39.10). After reduction, the neurovascular examination should be repeated and postreduction films obtained. The elbow should be flexed to 90 degrees as long as good pulses are maintained and then immobilized in a posterior splint. Patients should be assessed serially over 2 to 4 hours after reduction for vascular injury to the brachial artery. Any concern for vascular compromise should prompt consultation with an orthopedic or vascular surgeon. All patients should follow up with an orthopedic surgeon within 1 week to begin early range-of-motion exercises and help prevent contractures.

FIGURE 39.10 Technique for reduction of posterior dislocation of the elbow.

Indications for open reduction include an associated fracture, open dislocation, neurovascular injury, or inability to accomplish a closed reduction. Long-term complications include stiffness, contractures, neurovascular injury, heterotopic bone formation, and ankylosis. Recurrent elbow dislocations are rare.

Epicondylitis

Tennis elbow, or *lateral epicondylitis,* is an "overuse syndrome" characterized by inflammation at the radiohumeral joint or the lateral epicondyle. It is believed to represent a failure (microtearing of the ligament) of the extensor carpi radialis brevis attachment to bone in this region (19). It is most commonly seen in athletes or adults with occupations requiring repeated rotary motion, as in twisting or grasping (e.g., tennis players, pipefitters, and carpenters) (20). The gradual onset of a dull ache appears over the lateral epicondyle and radiates into the forearm. Dorsiflexion of the wrist and supination of the forearm against resistance with the elbow extended will reproduce the pain. Radiographs should be obtained to exclude an associated fracture. In chronic conditions, calcification may be seen over the lateral epicondyle.

The mainstay of treatment is avoidance of the offending activity and immobilization. A posterior splint is applied with the elbow flexed 90 degrees, the forearm supinated, and the wrist slightly dorsiflexed. Moist heat, nonsteroidal anti-inflammatory agents (NSAIDs), and physical therapy may be helpful. Local infiltration of the affected area with 1 to 2 mL of a corticosteroid and anesthetic mixture will give dramatic relief. Although corticosteroid injection is effective in the short term, it does not provide a clear long-term therapeutic benefit. All patients should have an orthopedic or sports medicine referral.

Medial epicondylitis, or "*golfer's elbow,*" is similar to tennis elbow and involves the common flexor origin at the medial epicondyle of the humerus. It is seen in golfers but occurs more frequently in people who routinely perform household chores, manual labor, and other tasks involving repetitive movements. Maximal tenderness is localized over the medial aspect of the elbow and medial epicondyle. Treatment is similar to that for lateral epicondylitis, and routine orthopedic follow-up (in 7 to 10 days) should be arranged. Surgery is often performed if there is no response after 3 to 6 months of conservative treatment (21).

Olecranon Bursitis

Olecranon bursitis is inflammation of the bursa overlying the olecranon process at the proximal aspect of the ulna. The bursa functions to provide a mechanism for the skin to glide freely over the olecranon process, preventing tissue tears. Inflammation of the bursa can be caused by a variety of mechanisms, including acute trauma; chronic friction (due to overuse, also known as "draftsman's bursitis"); crystal deposition (e.g., gout, pseudogout); local infection; and systemic diseases such as rheumatoid arthritis, scleroderma, uremia, and oxalosis. Regardless of the etiology, patients usually present with focal swelling and pain exacerbated by pressure over the posterior aspect of the elbow. Flexion of the elbow may be slightly restricted, due to tightening of the skin over the inflamed bursa. Regardless of etiology, the area may be warm and tender, so this is not a reliable determinant of infectious versus other etiologies. Repetitive trauma can result in a chronic inflammatory process and a thickened, rubbery, and usually painless bursa.

Aspiration of the bursa is essential for both diagnostic and therapeutic purposes if infection is suspected. The aspirated fluid should be analyzed for crystals, Gram stain, cell count, and cultures. The cell count should be interpreted in light of the clinical picture and other synovial fluid results, as there is considerable overlap between expected counts in noninflammatory, inflammatory, and infectious conditions. Cell counts $>$50,000 to 100,000 white blood cells (WBCs) per mm^3 and cell counts with polymorphonuclear cells (PMN) predominance are strongly suspicious for infectious etiologies. However, cell counts can be as low as 5,000 WBC per mm^3 in cases of early infection. In these situations, the Gram stain and culture become critical in the evaluation of the fluid results. The bursa is aspirated utilizing an 18-guage needle from a posterolateral approach so that the ulnar nerve is not inadvertently injured. Care should be taken to avoid aspiration of the bursa through an area of superficial cellulitis, to avoid seeding of a noninfected bursa. Patients suspected of having septic bursitis should be treated with antibiotics while awaiting culture results. *Staphylococcus aureus* is the most commonly identified organism in septic olecranon bursitis, and high resistance to penicillin has been reported (22). Antistaphylococcal

coverage should be provided. Besides antibiotics in cases of suspected infectious bursitis, other measures that can be utilized include analgesia (NSAID and narcotic), moist heat, and splinting for comfort. Occasionally, cases of septic bursitis will require serial aspiration (every 1 to 3 days) to resolve. Rarely, in cases that progress despite drainage and antibiotics, open incision and drainage will be required by an orthopedic or general surgeon.

In simple noninfectious olecranon bursitis, drainage of the bursa should be considered with subsequent compression dressing, NSAIDs, and protective measures to prevent recurrence. Symptoms may be recurrent, and serial drainage may be required. In refractory cases, bursal excision by a surgeon may be performed.

Rupture of the Distal Biceps or Triceps Tendon

Distal rupture of the biceps tendon may be the result of degenerative changes or sudden, forceful flexion of the elbow against resistance. Patients present with a history of a painful snap at the elbow. Flexion of the elbow and supination of the forearm are weakened. On flexion, the belly of the biceps retracts, producing a bulbous swelling in the upper arm. The treatment is surgical if significant motor weakness is present and should occur within 2 weeks after injury (23).

Avulsion of the triceps tendon should be considered in patients with pain, swelling, and weakness with arm extension. A defect is often palpable just proximal to the olecranon. Associated injuries include radial head and neck fractures and wrist fractures. The diagnosis is confirmed radiographically when a bony avulsion is seen on the lateral view of the elbow. Orthopedic consultation in the ED within 24 to 48 hours should be assured, and early surgical treatment is usually recommended.

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a process of avascular necrosis of the subchondral bone and the overlying articular cartilage and is most common in males and adolescents. There is usually a history of

trauma or sports-related activities. Repetitive trauma or overuse is thought to lead to microfracture and compromised circulation on the subchondral bone, followed by separation of the articular surface and formation of loose bodies (24). Patients may complain of the gradual onset of dull, aching pain; limited extension; intermittent swelling; and catching, locking, or clicking of the affected elbow (25). The capitellum is the most common site of involvement, and joint effusion may be present. Diagnosis is made in the ED using plain x-rays of the involved joint. The clinician may either see the lucency of the fracture or an osteochondral fragment free in the joint. MRI is useful for distinguishing normal cartilage and bone formation from edema and OCD irregularities (26). Treatment consists of immobilization with a sling or cast, avoidance of all throwing activities, and NSAIDs. Loose bodies within the joint may restrict movement of the elbow and should be surgically removed. Prognosis is usually good.

CRITICAL INTERVENTIONS

- Assess the radial head for dislocation in patients with a fracture of the proximal ulna. Monteggia fractures require internal fixation, whereas isolated ulna fractures are treated with immobilization.
- In patients with radial head fractures, examine the wrist for the Essex-Lopresti lesion. These patients require internal fixation, whereas radial head fractures are usually treated conservatively.
- Obtain radiographs before reducing an elbow dislocation to exclude associated fractures, except with nursemaid's elbow. Postreduction films should always be obtained (except with nursemaid's elbow).
- Measure the anterior humeral line to aid in diagnosing supracondylar fractures in children. Splint the arm if a significant mechanism of injury or swelling exists, and refer for orthopedic consultation.

DISPOSITION

Disposition of patients with elbow injuries is important, as deformity or loss of motion at the elbow can affect proper function of the forearm, wrist, and hand. Clearly, any patient with an open fracture or neurovascular compromise after elbow injury needs urgent ED consultation. Compartment syndrome, due to the location of the brachial artery, and neurologic entrapment may occur after injuries to this region. All pediatric supracondylar fractures are concerning for complications and future disability, and orthopedic consultation in the ED may be necessary. Occasionally, patients in this group with nondisplaced supracondylar fractures can be splinted and discharged but only if urgent orthopedic follow-up is assured (24 to 48 hours), and the patient and parents are fully cognizant of warning signs that would require return to the ED. Most nondisplaced elbow fractures in adults seen in the ED will require urgent orthopedic follow-up (24 to 48 hours), but this decision should be made in phone consultation with the orthopedist who will be seeing them subsequently.

Common Pitfalls

- Failure to diagnose an occult radial head fracture. This injury should be suspected when a positive fat pad sign is present on radiography without demonstrable fracture. Oblique views of the radial head may demonstrate the fracture.
- Making the assumption that a negative radiograph rules out elbow injury. Injuries to cartilaginous and ligamentous structures, as well as soft tissues, may be present. Splinting of the elbow and orthopedic referral should be considered for patients with a significant mechanism of injury.
- Failure to diagnose neurovascular injury. A careful neurovascular examination should be documented, in addition to interval reexamination.
- Failure to diagnose avulsion of the biceps muscle from the bicipital tuberosity of the radius. The patient will still be able to flex the elbow with the brachialis muscle.

CHAPTER 40 Wrist and Forearm Injuries

James R. Gardner and Carl R. Chudnofsky

Wrist injuries are among the most common emergency department (ED) complaints, are often difficult to accurately diagnose, and may result in decreased use of the associated hand if left undiscovered and untreated. Outcome depends on accurate assessment of the injury, appropriate initial management, and prompt recognition of those injuries that require immediate specialty consultation or outpatient referral.

To adequately diagnosis and treat wrist injuries a basic understanding of the underlying anatomy is crucial. The central portion of the wrist is composed of eight carpal bones connected by over 20 ligaments. With the exception of the pisiform (which is actually a sesamoid bone in the tendon of the flexor carpi ulnaris), the carpal bones lack direct muscular attachments. Instead, they function as a passive "intercalated" joint, whose movement is governed by muscles that originate on the radius and ulna and insert on the metacarpals.

To reduce this anatomic complexity, the wrist may be thought of in a simpler, more functionally oriented fashion. Specifically, the eight carpal bones may be grouped into four primary working units —the *scaphoid,* the *lunate,* the *triquetrum,* and the *distal row* (Fig. 40.1). Though it has important stabilizing functions, the pisiform may be neglected in this model, since it lies outside the plane of the other bones and is less important in defining wrist motion. The four bones of the distal row—the *trapezium, trapezoid, capitate,* and *hamate* —are tightly bound and for conceptual purposes, may be viewed as a single unit with the capitate at the center. The articulations of these

four functional units, with each other and with the forearm, allow the bulk of wrist movement (1,2).

FIGURE 40.1 Key conceptual components of carpal anatomy. T, triquetrum; L, lunate; S, scaphoid; DR, distal row; *, space of Poirier. (Graphic overlay by Dr. Gardner J.R. X-ray from Moore KL and Agur A. Essential Clinical Anatomy. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002. Courtesy of Dr. E.L. Lansdown, Professor of Medical Imaging, University of Toronto, Toronto, Ontario, Canada.)

The lunate and scaphoid bones attach to the radius, whereas the distal row attaches firmly to the metacarpals. The intracarpal ligamentous connections are arranged in an "oval" fashion; the distal row attaches to the scaphoid and triquetrum, which then attach to either side of the lunate. The central junction between the distal row and the lunate has no direct ligamentous attachments. This "space of Poirier" enhances mobility, but also provides a locus of anatomic instability when the wrist is injured (3).

While both the triquetrum and the scaphoid provide connection and rotation between the proximal lunate and the distal row, the scaphoid deserves particular attention. Unlike the relatively compact

triquetrum, the scaphoid is an elongated bone that rotates through a wide arc during wrist movement. In addition, the scaphoid attaches directly to the radius, assuming significant load-bearing responsibilities. The scaphoid's elongated shape and load-bearing function enhance its susceptibility to injury, making it the most frequently fractured carpal bone (4).

The *forearm* consists of the radius and ulna, although only the radius directly articulates with the carpal bones (the lunate and the scaphoid). The distal radius has three articular surfaces: the *radiocarpal joint* (RCJ), the *distal radioulnar joint (DRUJ),* and the *triangular fibrocartilage complex (TFCC)*.

The RCJ is formed by a concavity in the distal radius where the scaphoid and lunate bones are seated. Radiocarpal ligaments originating on the radial styloid and on the edges of the RCJ concavity stabilize the radiocarpal connection. Fractures to these segments of the radius may destabilize the carpal bone complex.

The DRUJ is formed by a shallow concavity on the side of the radius where the ulna rests. The radius rotates about the ulna at this point.

The TFCC is a soft tissue complex located on the distal end of the ulna. It is composed of an articular disc that interposes between the ulna and the carpal bones, as well as ligamentous attachments that tether to the lunate and triquetrum distally and to the radius proximally. The proximal attachments serve to stabilize the DRUJ.

The *interosseous membrane* is a collection of fibrous bands that join the radius and ulna along their entire length. This membrane translates mechanical load from the radius onto the ulna, which in turn translates the load to the upper arm. Because of this tight membranous connection, injury to either forearm bone often results in a fracture of the other or causes a dislocation of either the distal or proximal joints (see Forearm Fracture–Dislocations below) (5).

The *ulnar nerve* and *ulnar artery* enter the *volar* aspect of the wrist next to the pisiform bone, running under the *palmar carpal and pisohamate ligaments* in a tissue space known as *Guyon canal.* The *flexor retinaculum,* which lies beneath the Guyon canal, forms the roof of the *carpal tunnel.* The carpal tunnel is the deepest volar space

of the wrist and contains the *median nerve,* flexor pollicis longus, and all of the digital flexors. On the *dorsal* aspect of the wrist, the *radial artery* dives from its volar position in the forearm to run across the dorsal surface of the scaphoid and trapezium. It then circles back over the first metacarpal to form the *deep palmar arch.* The *superficial branch of the radial nerve* also crosses the dorsoradial aspect of the wrist, but unlike the radial artery it runs much nearer the surface, superficial to the fascial plane.

CLINICAL PRESENTATION

Patients with wrist injuries complain of varying degrees of pain, swelling, and limited range of motion in the wrist or forearm. Fractures of the distal radius or ulna may be confused with, or accompanied by, a carpal injury. The carpal bones in children are primarily cartilaginous; as such, carpal injuries are rare. Children are more likely to injure the weakest part of the wrist complex—the immature radial metaphysis or its epiphyseal growth plate. In contrast, the elderly more commonly injure the distal radius because of osteoporosis.

ED EVALUATION

Important historic information includes hand dominance; occupation and avocation; prior hand injuries and preinjury hand function; past medical history (e.g., diabetes mellitus, immunosuppression), including previous tetanus immunizations; and time, mechanism, and circumstances of injury. Mechanism of injury is particularly important, as the precise position of the hand and wrist during the injury help guide investigation and treatment.

On physical examination, surface anatomy should be used to identify and examine specific structures. The volar wrist crease marks the location of the proximal carpal bones and the flexor retinaculum. The EP should palpate the pisiform bone at the base of the hypothenar muscles just distal to the volar crease and the hook of the hamate in the soft tissue of the palm 1 cm distal and radial to the pisiform. On the dorsal side of the wrist the *anatomic snuff box* (*ASB*) is formed by the *radial styloid* proximally, the extensor pollicis

brevis tendon radially, and the abductor pollicis longus tendon along the ulnar aspect. The scaphoid is palpated in the floor of this space. Moving in an ulnar direction from the radial styloid, a small bony prominence (the *Lister tubercle*), can be palpated on the dorsal radial surface. The *scapholunate joint* lies immediately distal to this prominence. With the hand in the neutral position, a small depression can be palpated midway between the base of the third metacarpal and the Lister tubercle. The capitate lies just distal to this depression. With wrist flexion, the depression disappears, and the lunate can be palpated proximally. The ulnar styloid is the largest bony prominence on the ulnar aspect of the wrist—the TFCC and triquetrum are located just distally (6).

It is important to note that damage to important underlying structures may occur despite innocuous-appearing surface wounds. Consequently, it is essential to explore lacerations and evaluate tendon function through a full range of motion. Neurovascular testing is best performed in the hand and is described in Chapter 41. The EP should always test neurovascular integrity before the instillation of local anesthetics.

Radiographs of the wrist and forearm should be obtained in all but the most trivial of injuries. On an adequately positioned posterior–anterior (PA) view (Fig. 40.2), the distal radius and ulna should not overlap, and the third metacarpal axis should be in line with that of the radius. The radial styloid should project between 9 and 15 mm beyond the DRUJ and should create an ulnar inclination of 15 to 30 degrees. A normal PA radiograph should also demonstrate three arcs outlining the carpal bones. The proximal and distal surfaces of the scaphoid, lunate, and triquetrum make up the two proximal arcs, whereas the distal third is formed by the proximal surfaces of the capitate and hamate in the midcarpal area. The carpal bones should be separated from one another by no more than 2 mm; increased intercarpal spaces imply ligamentous disruption and potential instability.

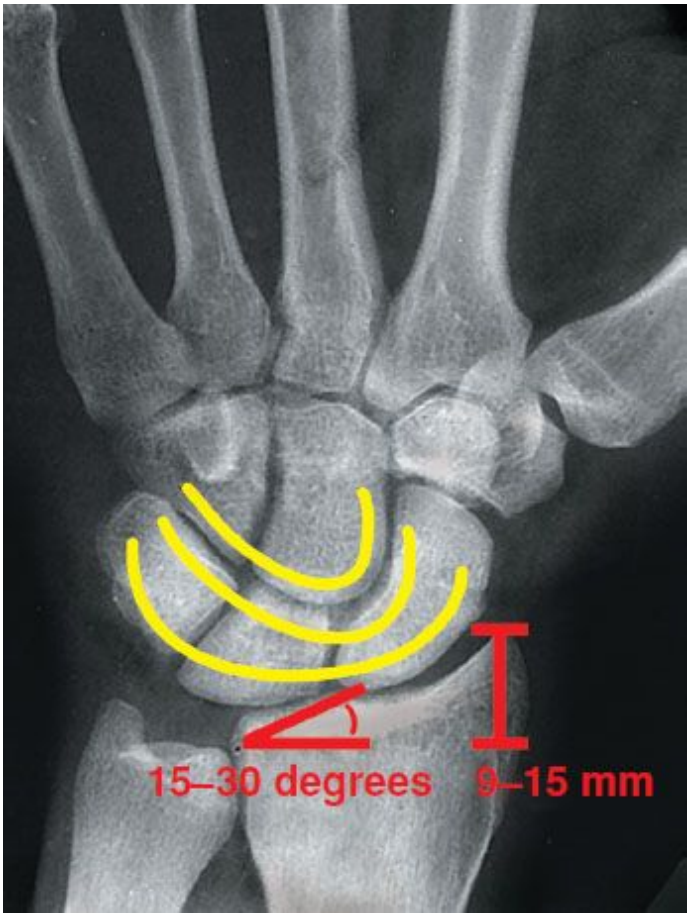

FIGURE 40.2 PA radiograph of wrist. Note 9 to 15 mm of radial styloid projection past the DRUJ, 15 to 30 degrees of ulnar inclination of the distal radius, three smooth arcs outlining the carpal bones, and no more than 2 mm of separation between carpal bones. (Graphic overlay by Dr. J.R. Gardner. X-ray from Moore KL and Agur A. Essential Clinical Anatomy. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002. Courtesy of Dr. E.L. Lansdown, Professor of Medical Imaging, University of Toronto, Toronto, Ontario, Canada.)

On an adequately positioned lateral projection (Fig. 40.3), the palmar edge of the pisiform should lie between the scaphoid and capitate. The normal volar tilt of the radius is between 10 and 15 degrees and the radius, lunate, and capitate are arranged in a straight line (their axes should not vary by more than 10 to 20 degrees). The lunate appears as a “cup in a saucer” articulating with

the distal radius, and the articular surfaces of the three bones create neatly overlapping "C"s. The scaphoid and lunate axes should form an angle of 30 to 60 degrees (the scapholunate angle); an angle of more than 70 degrees is abnormal and suggests scapholunate dissociation (7).

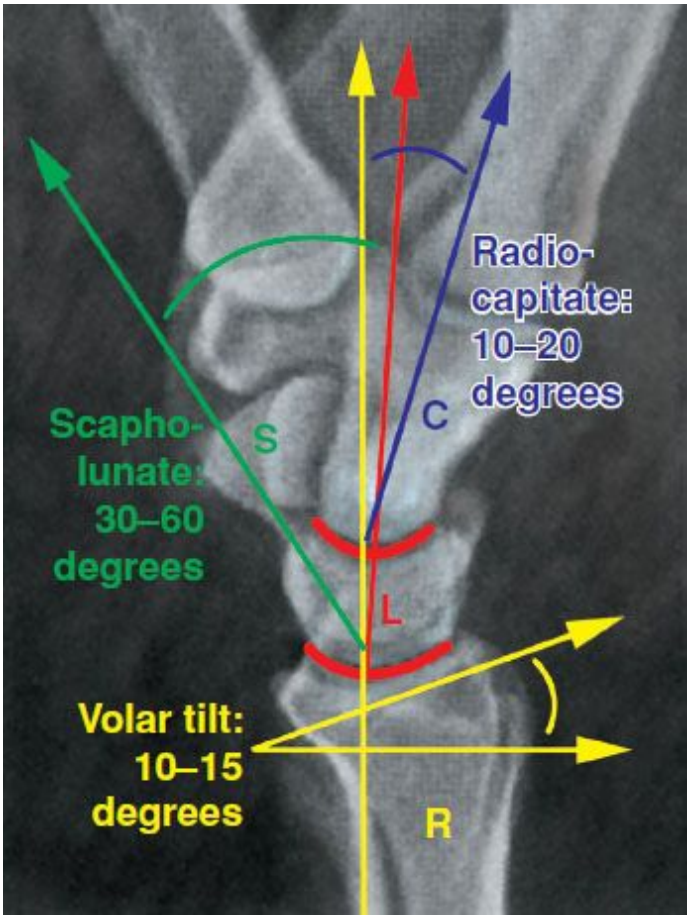

FIGURE 40.3 Lateral radiograph of wrist. Note 10 to 15 degrees of volar tilt of the distal radius (R); smooth "C"-shaped articulations between the radius, lunate (L), and capitate (C); 10 to 20 degrees of axial variance between the radius and capitate; and 30 to 60 degrees of axial variance between the scaphoid (S) and lunate. (Graphic overlay by Dr. Gardner JR. X-ray courtesy of Dr. E. Becker, University of Toronto, Toronto, Ontario, Canada.)

Oblique radiographs project the pisiform and triquetrum away from the other carpal bones making identification of fractures to

these bones easier. Additional radiographic views (e.g., scaphoid view, carpal tunnel view) may be helpful in certain cases; however, CT imaging is increasingly being utilized to evaluate more subtle or complex injuries.

KEY TESTING

- Wrist x-rays (PA and lateral views; other views as needed)
- Forearm and elbow x-rays, if indicated
- Evaluate for ligamentous instability
- Evaluate for tendon disruption
- Evaluate for associated neurovascular compromise

ED MANAGEMENT

During evaluation, the EP should temporarily immobilize, elevate, and apply ice packs to the injured wrist. Analgesics should be administered to control pain and intravenous antibiotics administered for open fractures and dislocations and for severely contaminated or infected wounds. The EP should provide tetanus immunization as needed (see Chapter 21) and cover open wounds with sterile, moist gauze pending radiographs, surgical consultation, or wound closure.

Carpal Fractures

Carpal fractures account for 8% to 19% of all hand and wrist injuries. They are far more common in adults than in pediatric patients in whom the carpal bones remain largely cartilaginous. If not recognized and properly treated, carpal fractures may lead to significant disability, including arthritis, nonunion, loss of function, and *avascular necrosis* (*AVN*).

As noted previously, *scaphoid fractures* are the most common carpal bone fractures (60% to 80%). The injury is most often caused by an axial load or "*fall-on-an-outstretched-hand*" *(FOOSH),* with the main impact on the thenar eminence. Patients usually complain of pain in the radial wrist, particularly with pressure or movement. Tenderness on palpation of the ASB is a common feature. Examining

the wrist in ulnar deviation brings the scaphoid up from the floor of the ASB, making it easier to assess. Scaphoid loading (applying axial pressure on the thumb) elicits pain in many patients (eFig. 40.1).

The blood supply to the scaphoid is notoriously fragile, entering the bone distally via small branches off the radial artery. As a result, scaphoid fractures have an increased risk of proximal AVN, nonunion, and pseudoarthrosis (4).

Isolated *lunate fractures* are relatively rare; they occur more commonly in association with other wrist injuries. Given the anatomic location of the lunate in the space of Poirier, the application of significant force to the lunate is more likely to produce a perilunate or lunate dislocation (see Carpal Ligamentous Injury below). Patients will complain of pain in the middle of the wrist and axial loading of the third metacarpal causes pain. Examination reveals tenderness over the lunate.

Like the scaphoid, the blood supply to the lunate enters distally, giving these injuries a high incidence of AVN (known as *Kienböck disease*), nonunion, and subsequent carpal instability. Patients with Kienböck disease present with pain localized in the area of the lunate, stiffness, occasional swelling, and marked loss of grip strength; a history of significant wrist trauma is often lacking. Plain radiographs demonstrate sclerosis and collapse of the lunate.

Trapezium fractures are often due to a direct blow to the thumb or forced dorsiflexion. There is tenderness at the ASB and thenar eminence; decreased thumb pinch strength secondary to pain is another diagnostic clue. These fractures are often intra-articular and can extend distally, where they are analogous to a *Bennett* or *Rolando* fracture of the thumb metacarpal (see Chapter 41, “Hand Injuries”).

Nondisplaced scaphoid, lunate, or trapezium fractures are treated with immobilization in a thumb spica splint and timely follow up with a hand surgeon. Immediate consultation should be obtained for open and/or unstable fractures, fractures with displacement of ≥ 1 mm, and those associated with other wrist fractures or dislocations.

On the ulnar side of the wrist, *triquetrum fractures* are most often dorsal avulsion fractures due to a FOOSH, or they occur when rotation of the hand is suddenly resisted, causing the hamate or ulnar

styloid to forcefully impact the triquetrum. Patients complain of dorsal wrist pain and are maximally tender just distal to the ulnar styloid. Dorsal triquetrum fractures are best seen on lateral or oblique radiographs of the wrist with the hand in slight pronation (a "triquetral view") where the fractured fragment appears as a small piece of bone dorsal to the triquetrum. Triquetrum body fractures are less common and imply significant force. They are frequently accompanied by other fractures and/or ligamentous injuries.

Though rare, *hamate fractures* usually present with sudden pain to the ulnar wrist when a swinging motion (i.e., golf club, bat) has been abruptly interrupted. Pain is maximal over the hamate, which is located 1 cm distal and just radial to the pisiform. Pain is also often noted in the fourth and fifth fingers with active grasp or when flexion is resisted. The hook is fractured much more frequently than the body of the hamate; hook fractures are best demonstrated on a "carpal tunnel" view.

For both triquetrum and hamate fractures, the EP should carefully assess the integrity of the ulnar nerve and artery. Fractures of the hamate hook in particular may be associated with compression of Guyon's canal. Treat uncomplicated fractures of the triquetrum or hamate with volar splinting in the neutral position and close hand surgery follow-up. Fractures that are unstable, displaced, open, or associated with other wrist injuries or neurovascular compromise require immediate specialty consultation.

Fractures of the pisiform, capitate, and trapezoid are extremely rare. *Capitate fractures* bear mention for two reasons: The capitate has a distal blood supply, placing it at risk for AVN, and the fracture is often missed owing to the more obvious surrounding bony and ligamentous injuries that frequently accompany it. The EP should splint these injuries in a short-arm thumb spica with the wrist in slight dorsiflexion and the thumb immobilized to the IP joint and be sure to consult with a hand specialist prior to discharge (8,9).

Occult Carpal Fractures

Studies have shown that 23% to 36% of patients with concerning examination findings after wrist trauma (e.g., ASB tenderness,

significant wrist pain, or swelling) will have fractures that are not appreciated on initial x-rays (10,11). Consequently, the diagnosis of "wrist sprain" should be made with trepidation. About one-third of occult fractures involve the scaphoid; less-common sites include the distal radius, other carpal bones, and proximal metacarpals. MRI has been touted as the gold standard for diagnosis in such cases. Nevertheless, in the hands of an experienced radiologist, CT has also been found to have excellent sensitivity (95% to 100%) and negative-predictive value (12,13).

Traditional therapy for suspected occult fractures has been immobilization and close outpatient follow-up for repeat examination and plain radiographs. Recently, advanced imaging (e.g., MRI, CT) in the ED has been advocated as a more accurate and possibly more cost effective treatment option (14). Until definitive studies are performed, therapy for occult fractures is best guided by institutional policies, local practice, or personal preference.

Carpal Ligamentous Injury

Injuries to the carpal ligaments range from partial tears ("sprains") to complete disruption accompanied by carpal dissociation or dislocation. As with carpal fractures, most ligamentous injuries are caused by a FOOSH mechanism. In 1980, Mayfield et al. (15) observed that such ligamentous injuries tend to develop in a predictable pattern that begins radially and proceeds in a circular fashion around Poirier's space as more force is applied.

In Mayfield's model, the proximal scaphoid ligaments are the first to be damaged, causing scapholunate dissociation. This leads to forward flexion and radial displacement of the scaphoid. Because of the resulting unopposed action of the triquetrum, the lunate and distal row rotate dorsally. This pattern is known as *dorsal intercalary segment instability* (DISI) (eFig. 40.2).

Clinically, patients complain of wrist pain, dorsal swelling, and wrist weakness. They may also note an unpleasant snapping sensation with wrist movement. However, overall range of motion may be preserved and the injury may appear relatively minor.

The PA wrist x-ray demonstrates widening of the scapholunate joint to >2 mm ("Terry Thomas sign") (Fig. 40.4), as well as foreshortening of the scaphoid as it rotates into forward flexion causing the appearance of the "scaphoid ring" sign. On the lateral view, the scapholunate angle increases to >60 degrees, while the axis of the lunate becomes angled dorsally to the axis of the radius. Of note, isolated rupture of the scapholunate ligament may occur without causing these radiographic findings—the presence of such changes means that secondary supporting ligaments have been torn as well (16).

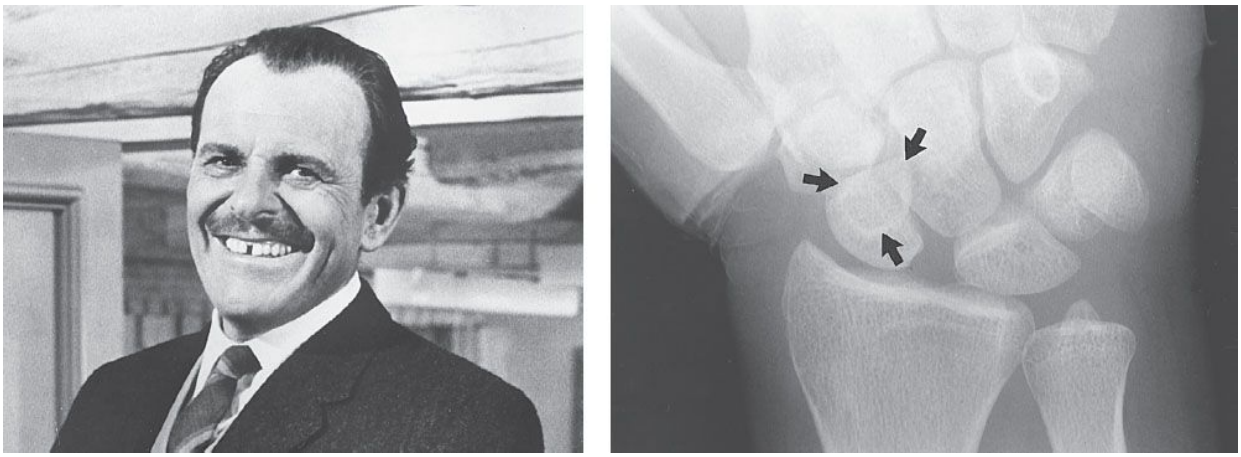

FIGURE 40.4 Scapholunate dissociation. Note the widened scapholunate space ("Terry Thomas" sign) and the foreshortened scaphoid with a "scaphoid ring" sign (arrows). Adjacent is British comedian Terry Thomas and his famous teeth. (Courtesy of the Bettmann Archive.)

If further stress is applied to the wrist, the path of ligamentous disruption travels to the distal carpal ligaments, leading to dorsal dislocation of the distal row, particularly the capitate. When this occurs, the capitate may be palpated dorsally and there is usually significant wrist pain and swelling. On a PA view the capitate and lunate overlap, whereas on the lateral view the capitate now lies dorsal to the lunate.

With continued stress, the pattern of ligamentous damage circles back around to the triquetrolunate ligament. When this ligament

ruptures, the triquetrum dislocates dorsally as well, leaving the lunate attached only to the radius, thus completing a full *perilunate dislocation.* On lateral view the axis of the lunate now angles forward.

In the final stage, the dorsal radiolunate ligaments rupture, and the lunate, now tethered only by its volar attachments, flips forward out of its RCJ socket, while the capitate falls into the space that the lunate had previously occupied. This is a *lunate dislocation.* On PA view the lunate will appear triangular (the "Piece of Pie" sign) and there may be substantial overlap of the capitate and lunate (Fig. 40.5A). On lateral view the lunate is pushed forward off the radius, creating the "spilled teacup" sign (Fig. 40.5B). It should be noted that the lunate dislocates into the space of the carpal tunnel, causing median nerve impingement in 16% to 46% of cases (3,16).

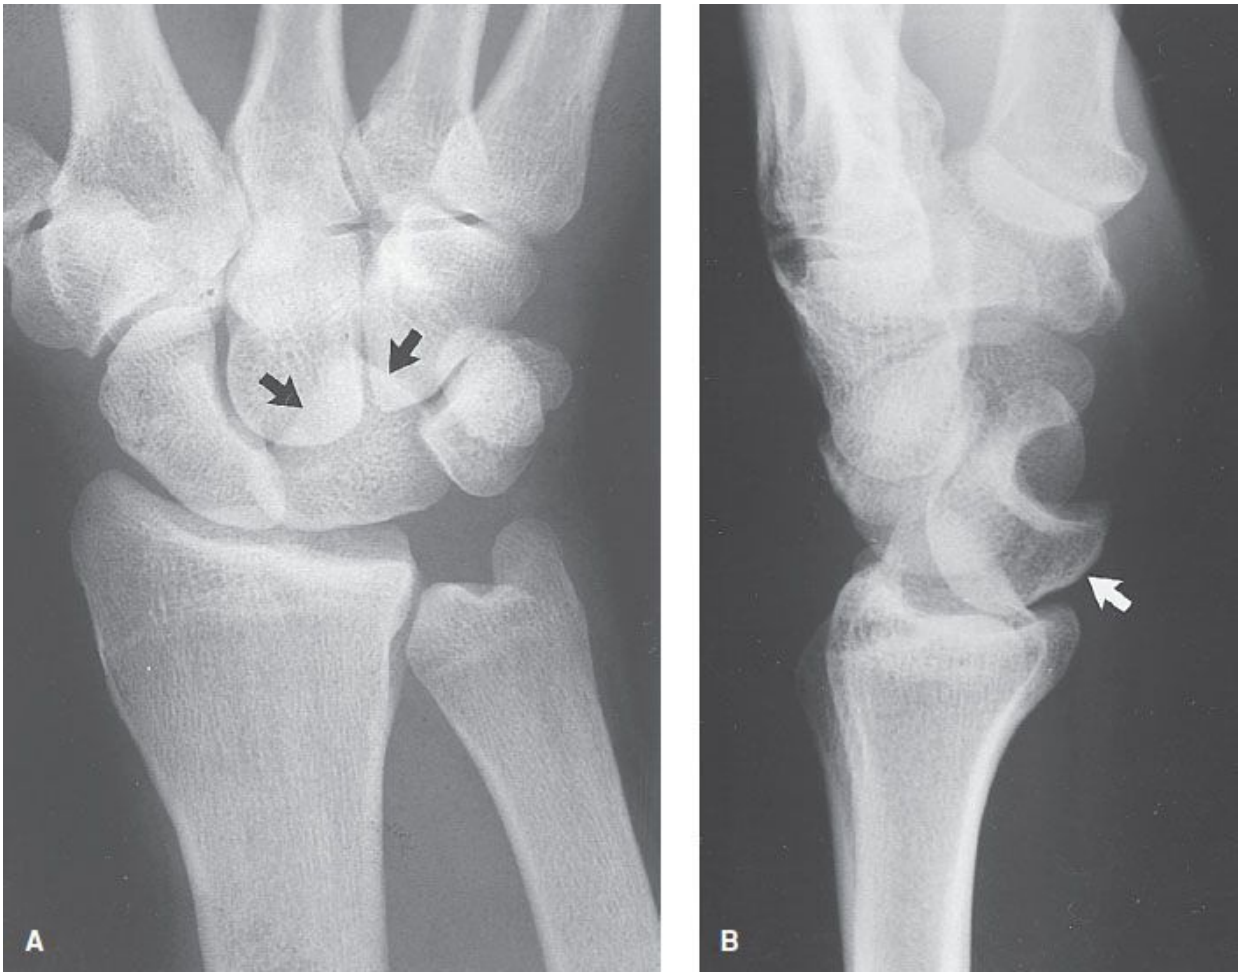

FIGURE 40.5 Lunate dislocation. On PA view (A), note the triangular shape of the lunate ("piece of pie" sign, black arrows) and the overlap of the lunate and other carpals. On lateral view (B), note how the lunate has rotated forward almost 90 degrees ("spilled teacup" sign, white arrow). (From Terry R. Yochum, Lindsay J. Rowe. Yochum and Rowe's Essentials of Skeletal Radiology. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004.)

Mayfield's progression may also occur in the reverse order, starting with triquetrolunate disruption and proceeding radially around Poirier's space. In this scenario, the initial injury is an isolated triquetrolunate rupture, which in many respects is the ulnar equivalent of a scapholunate rupture. When this occurs, the lunate will be subjected to unopposed forward flexion by the scaphoid. Thus, on lateral radiographs the lunate axis will be angled volarly, but the scapholunate angle will be unchanged. This pattern is known as *volar intercalary segment instability* (VISI).

Isolated scapholunate or triquetrolunate ligamentous ruptures should be treated with radial or ulnar gutter splints, respectively, and referral for timely hand surgery follow-up. However, perilunate dislocations, perilunate fracture–dislocations, and lunate dislocations all require immediate specialty consultation. These injuries represent the end point of extensive ligamentous and bony disruption, and as such may be accompanied by significant neural compromise and serious long-term disability. Many hand surgeons will attempt closed reduction in the ED, but definitive treatment requires ORIF.

Distal Radial Fractures

Distal radius fractures are common, accounting for about one-sixth of all adult fractures seen in the ED. They are even more common in children, accounting for 20% to 35% of all pediatric fractures and 25% to 50% of pediatric physeal fractures. Radiographically occult Salter–Harris type 1 fractures are common in this population. Therefore, as with adults, the diagnosis of a simple wrist "sprain" in children should be made with great caution (17).

A *Colles* fracture is a dorsally displaced radial metaphyseal fracture, usually caused by a FOOSH, and is the most common of all wrist fractures. Dorsal bone comminution is often seen, and extension into the RCJ or DRUJ can occur. A fracture of the ulnar styloid is seen in up to 60% of cases suggesting associated injury to the TFCC. On examination, the wrist will have the classic "dinner fork" or dorsiflexion deformity. Associated pressure on the median nerve may produce palmar paresthesias. On PA radiograph, the distal radius may appear shortened. The lateral radiograph provides the best view of the angulation and comminution (eFig. 40.3).

Uncomplicated Colles fractures may be reduced in the ED, but fractures associated with postreduction instability, intra-articular involvement, marked comminution, >20 degrees of angulation, or >5 mm of radial shortening usually require surgical intervention. Hence, these injuries require emergent consultation. In addition, any neurovascular compromise or an open fracture requires immediate surgical evaluation (18).

A *Smith* fracture, also known as a *reverse Colles,* is a fracture of the distal radius with volar angulation of the distal fracture fragment. This injury is produced by a blow to the dorsum of the wrist or a FOOSH in supination. The hand is palmarly displaced, creating the so-called *garden spade* deformity. PA and lateral radiographs are diagnostic. The complications and treatment are similar to those for a Colles fracture (eFig. 40.4).

A *Barton* fracture is an oblique intra-articular fracture of the volar or dorsal rim of the distal radius. The more common dorsal rim fracture results from forced pronation and dorsiflexion of the wrist, whereas the volar rim fracture results from a fall on the supinated outstretched hand. Associated ligamentous injuries may produce radiocarpal instability. Treat nondisplaced fractures with immobilization in a short-arm volar splint. Fractures involving more than 50% of the articular surface, fractures associated with carpal subluxation, and displaced fractures require emergent consultation as they frequently require ORIF (eFig. 40.5).

A direct blow along the radial side of the wrist can produce an oblique or transverse fracture of the radial styloid. Intra-articular

radial styloid fractures are also known as *Hutchinson* or *Chauffeur's* fractures. These are most easily seen on a PA radiograph and appear as a thin, lucent line proximal to the radial styloid. Because the major carpal ligaments of the radial wrist insert on the radial styloid, these fractures can produce carpal instability. ORIF is often required for even minimal displacement. Posttraumatic arthritis may be worsened if associated intercarpal ligament tears go unrecognized and untreated.

Distal radius fractures are associated with a number of potential complications. Acute carpal tunnel syndrome with median nerve impingement may develop in 5% to 8% of patients. Symptoms include pain, paresthesias and numbness in the median nerve distribution, and weakness of thumb opposition. More generalized *forearm compartment syndromes* are rare, but can be potentially devastating if not promptly recognized and treated. A compartment syndrome will primarily produce severe pain, but examination may also reveal tense compartments on palpation, pain with passive finger flexion and extension, and diffuse paresthesias or numbness distally. These symptoms necessitate emergent specialty consultation to prevent permanent disability (19).

Up to 10% of adults with distal radius fractures will go on to develop some degree of *complex regional pain syndrome*. This disabling condition is characterized by persistent pain and hyperalgesia accompanied by vasomotor and sudomotor changes in the affected extremity. The etiology is not well understood, though abnormal distal nerve regeneration is thought to play a role. Women in their 50s to 70s are particularly at risk. Several studies have demonstrated that the prophylactic administration of Vitamin C, 500 mg PO daily for up to 2 months (a dose commonly found in over-the-counter supplements) helps to reduce the incidence of this syndrome, possibly through its antioxidant effects. Consider this treatment for at-risk patients (20,21).

Distal Ulnar Fractures

Ulnar shaft fractures (also known as *nightstick fractures*) most often result from direct blows to the forearm. Nondisplaced nonangulated

fractures are immobilized in a sugar tong splint with the elbow in 90 degrees of flexion and the forearm neutral. Close follow-up should be arranged and the patient instructed to watch closely for further swelling. Fractures with >10 degrees of angulation or with displacement >50% of the width of the bone usually require ORIF.

Ulnar styloid fractures are produced by forced radial dorsiflexion, radial deviation, and rotary stress. These fractures may be isolated or accompany other injuries, such as a Colles fracture. Patients often complain of a painful clicking or locking sensation in the wrist. Delineation of an accompanying TFCC injury may require wrist arthroscopy or magnetic resonance imaging. Ulnar styloid fractures should be immobilized with a volar or ulnar gutter splint in the neutral position with slight ulnar deviation and timely outpatient follow-up should be arranged.

Ligamentous Injuries

Disruption of the DRUJ ligaments frequently accompanies forearm fractures, but may also act as an isolated injury (eFig. 40.6). Because attention is usually given to the more obvious fracture, DRUJ disruption is missed in almost half the cases. The diagnosis is often not made until chronic pain and decreased wrist mobility are noted. Localized tenderness is present over the wrist and distal radius. Examination reveals weak grip strength and decreased pronation and supination; subtle prominence of the ulnar head may also be noted. The more commonly seen dorsal dislocation is usually produced by falls on a hyperpronated wrist, whereas volar dislocation is produced by forced hypersupination. Dorsal or volar displacement of the ulna can be seen on lateral films. PA radiography demonstrates narrowing of the distal radioulnar joint, which may be subtle. ED management includes immobilization (in supination to reduce dorsal ulnar dislocation; in pronation to reduce volar ulnar dislocation) and orthopedic follow-up within 7 to 10 days.

Forearm Fracture–Dislocations

As noted above, the radius and ulna have tight ligamentous connections at the DRUJ, the proximal radial ulnar joint, and the interosseous membrane. Thus, when a forearm bone fractures, a concomitant dislocation may also occur at one or more of these ligamentous attachments. Such fracture–dislocation injuries carry the potential for significant morbidity, and accurate ED diagnosis is critical for a positive outcome. The usual mechanism for all of these fracture–dislocations is an axial load or FOOSH-type injury.

A fracture of the middle or distal radius, coupled with an associated DRUJ dislocation or subluxation, is called a *Galeazzi fracture* (eFig. 40.7). Similar DRUJ disruptions can also occur when both the radius and ulna are fractured. Approximately 20% to 25% of diaphyseal radius fractures will in fact be Galeazzi fractures. Clinically, there is often angulation of the radial forearm, along with prominence and mobility of the ulnar head. On PA films there is narrowing of the DRUJ, whereas the lateral view demonstrates dorsal or volar displacement of the ulna (which is normally overlapping the radius) (22).

A fracture of the ulnar shaft with associated radial head dislocation is referred to as a *Monteggia fracture–dislocation* (eFig. 40.8). This is usually a diaphyseal fracture in the proximal one-third of the ulna, with an associated anterior dislocation of the radial head. Clinically, the forearm may appear angulated and shortened. Although less obvious than the ulnar findings, there is usually pain and swelling at the elbow, and the radial head may be palpated in a posterior or anterior location. On plain radiography, the apex of the ulnar fracture points toward the radial head dislocation, and the radial head will not line up with the capitellum on all views. Monteggia fracture–dislocations may be associated with other injuries, including radial head fractures, coronoid fractures, lateral collateral ligament instability, and posterior interosseous nerve palsies (23).

A third injury pattern that combines features of both Galeazzia and Monteggia injuries is the *Essex-Lopresti lesion.* This is a rare and often underdiagnosed entity that can lead to significant long-term disability. It is characterized by a radial head fracture at the elbow

along with DRUJ disruption at the wrist and interosseous membrane disruption throughout the forearm. Elbow pain due to the radial head fracture usually predominates clinically, but tenderness is also present throughout the forearm and DRUJ, and excessive mobility between the radius and ulna may be noted distally. DRUJ disruption in these cases may be detected radiographically in the same manner as with a Galeazzi injury (24).

Galeazzi, Monteggia, and Essex-Lopresti fracture–dislocations all require specialist consultation in the ED. These injuries can be subtle, and therefore must be actively sought by the emergency physician. It is critical to obtain true lateral distal forearm views to detect DRUJ dislocation in radius fractures and true lateral elbow views to detect radial head dislocation in ulna fractures. In addition, pediatric patients may sustain Monteggia-variant injuries with only plastic deformation (e.g., buckle fracture, greenstick fracture) of the ulna—these may be mistaken for simple radial head dislocations if not properly evaluated (25).

Tendon Lacerations

Detailed examination and careful wound exploration are essential for detecting tendon injuries in the wrist. It is important to note that partial tendon lacerations may have entirely normal function passively. Frequently, the only clue to their presence is pain with active motion. Only meticulous wound exploration that includes evaluating tendon integrity through the entire range of motion will prevent complications associated with a missed partial tendon laceration (e.g., adhesions, delayed rupture, triggering, and bow-stringing). Once identified, management depends on the type and location of injury. Consultation with an appropriate surgeon is recommended for almost all tendon lacerations, although emergency physicians experienced and comfortable with these injuries can perform simple extensor tendon repairs.

Multiple tendon lacerations, those associated with underlying fractures, those requiring extension of the wound to locate the retracted ends, and all flexor tendon lacerations require repair in the operating suite. The repair does not have to be performed at the time

of injury but should be accomplished within 72 hours whenever possible.

Patients whose tendon lacerations are not repaired at initial presentation should be seen by the hand specialist within 24 hours. Prior to discharge, thoroughly clean and irrigate the wound, approximate the skin edges, and immobilize the wrist and hand in a well-padded splint. Many emergency physicians will also administer an intravenous dose of an antistaphylococcal antibiotic (e.g., cephazolin), followed by a short course of an oral antibiotic with similar coverage. However, there is no evidence that this practice improves outcome. Patients who undergo tendon repair in the ED require similar immobilization and should be referred to a hand specialist within 48 hours for a wound check.

Nerve Injuries

The emergency physician should be proficient in the diagnosis of hand and wrist injuries complicated by nerve injury, because outcome is improved with early diagnosis. Nerve injuries may occur secondary to bony impingement, compartment syndrome, or direct laceration. It is imperative that a careful examination of the hand and wrist be performed before the instillation of any local anesthetics. If there is suspicion of a peripheral nerve injury, anesthetics should be withheld until consultation with the hand surgeon. Immediate operative intervention may be required, depending on the etiology of the nerve injury.

Arterial Injuries

Arterial injuries may complicate either blunt or penetrating trauma and are frequently associated with nerve injuries owing to their close proximity to peripheral nerves. Though most cases are obvious (i.e., a history or observation of pulsating hemorrhage), others require recognition of more subtle signs of impaired perfusion (e.g., capillary refill, Allen test). Careful wound exploration is essential as even complete arterial lacerations may spasm, and the bleeding will have stopped by the time the patient is evaluated.

Management of arterial injuries depends on the structures involved and the extent and location of the injury. Because the hand has a dual blood supply, ischemia is uncommon with a single artery injury. Consequently, isolated injury to the radial or ulnar arteries without distal ischemia or sensory impairment is often managed by simple ligation. In contrast, arterial injuries with distal ischemia or associated nerve injury usually require surgical repair. If a severed digital artery is not repaired, ligate both the proximal and distal ends to avoid rebleeding. Consultation with a specialist is strongly recommended prior to repair or discharge.

CRITICAL INTERVENTIONS

- For patients with clinical signs of a wrist fracture but negative radiographs, immobilize the wrist and refer the patient for follow-up in 7–10 days or obtain advanced imaging in the ED.
- Obtain immediate orthopedic consultation in the ED for lunate and perilunate dislocations, and fractures at risk for carpal instability.
- Arrange timely (i.e., within 1 week) follow-up for forearm fractures to minimize long-term complications.
- Screen for associated neurovascular compromise with all fractures or dislocations.

DISPOSITION

The disposition of patients with wrist or forearm injuries depends on the nature and severity of the injury. Institutional and regional protocols may influence the indications and timing of consultation as well as the specialty background of surgical consultants (e.g., orthopedic surgeon, plastic surgeon). However, certain injuries (discussed earlier) require immediate specialty evaluation and treatment; consultation in these cases should occur in the ED before the patient is discharged.

For discharged patients, emphasize elevation and intermittent ice application for the initial 24 to 48 hours. As appropriate, discharge instructions should address splint and wound care; the timing of

return visits for wound checks or specialty follow-up; and indications for immediate return to the ED, such as symptoms of infection or compartment syndrome. Timely follow-up arrangements should be provided for all patients treated in the ED.

Common Pitfalls

- Failure to immobilize the wrist and arrange close follow-up or order advanced imaging studies when plain films are negative and there is clinical suspicion for a fracture.
- Failure to diagnose and immobilize a scapholunate or triquetrolunate dissociation.
- Failure to identify a lunate or perilunate dislocation and obtain immediate consultation.
- Failure to identify a forearm fracture–dislocation and obtain immediate consultation.
- Failure to appreciate a Salter–Harris I or plastic deformation fracture in pediatric patients.
- Failure to diagnose compartment syndrome.
- Failure to perform a thorough neurologic evaluation prior to the use of local anesthesia.

CHAPTER 41

Hand Injuries

David Q. Bell and Douglas Doehrman

Hand injuries account for 5% to 20% of emergency department (ED) visits (1). The outcome depends on accurate assessment of the injury, appropriate initial management, and prompt recognition of those injuries that require immediate specialty consultation or outpatient referral.

An understanding of the anatomy and terminology of the hand is crucial for the evaluation and treatment of hand injuries. The surfaces of the hand and digits are referred to as dorsal, palmar, ulnar, and radial. The palmar surface anatomy is shown in Figure 41.1. Finger motion is described as extension, flexion, abduction, and adduction. Motion is related to the midline of the long finger. The thumb can perform opposition to touch the pads of all the fingers.

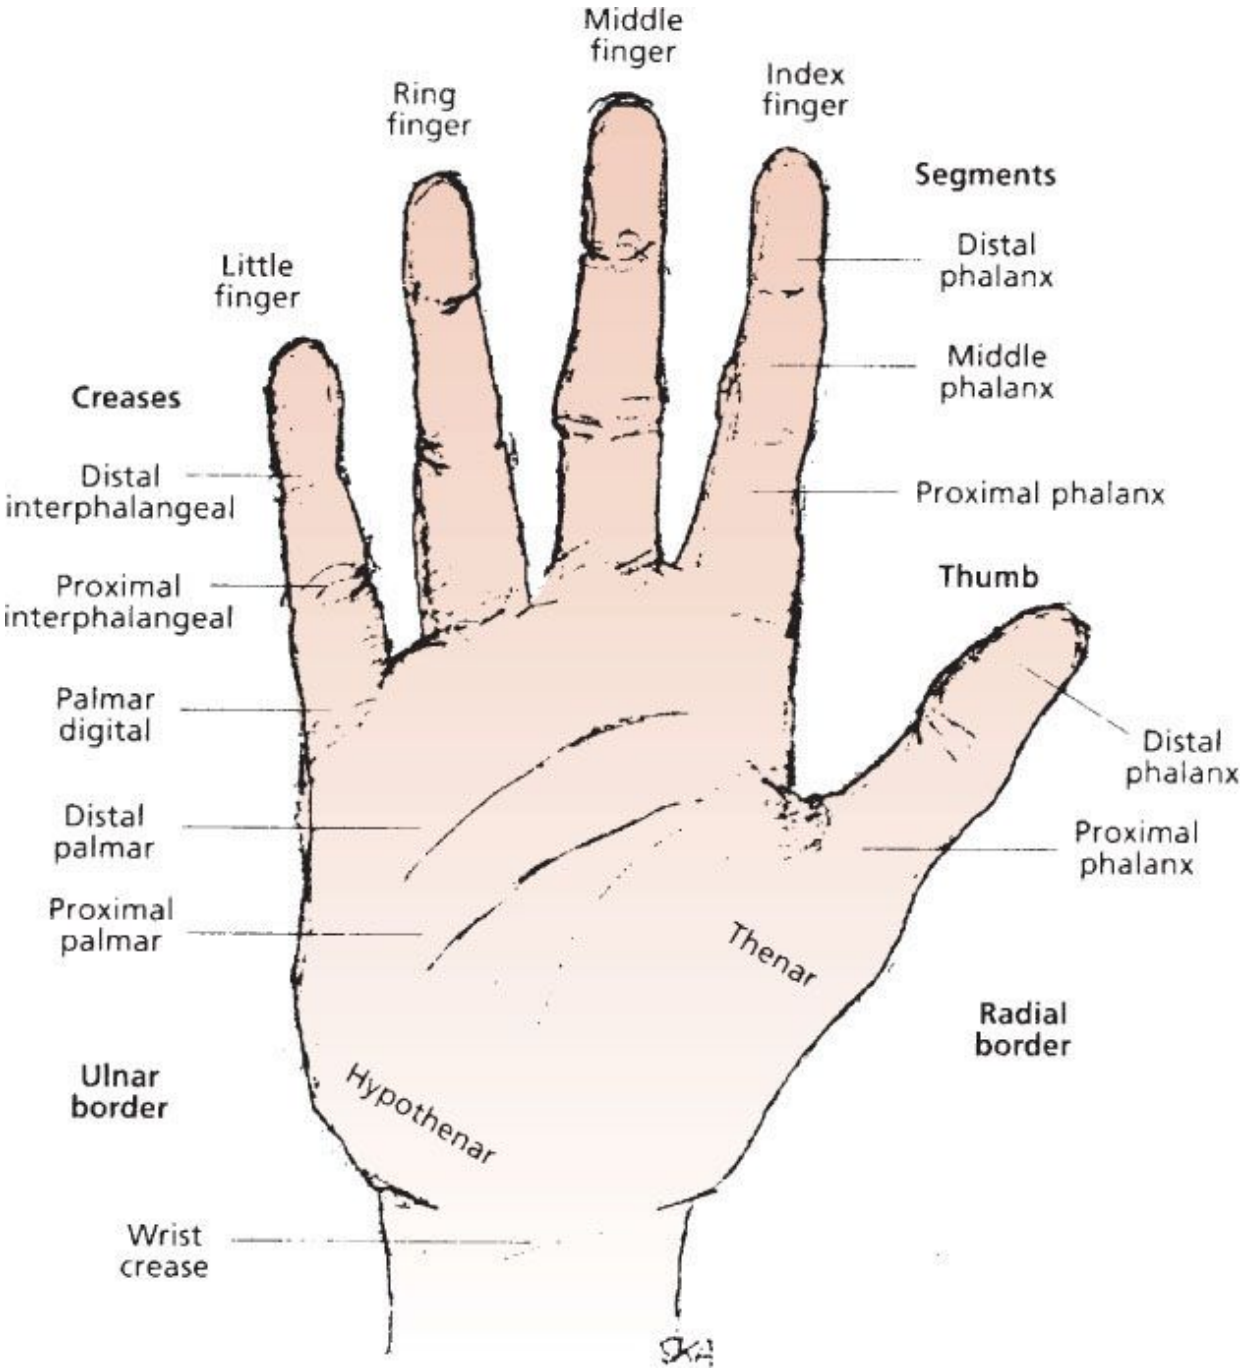

FIGURE 41.1 Palmar (volar) surface anatomy.

Muscles that control hand motions are divided into flexors and extensors, each of which may be intrinsic or extrinsic to the hand. The intrinsic muscles have their origins and insertions within the hand. The thenar muscles and adductor pollicis are tested by flexing, adducting, and abducting the thumb. The four dorsal and three

palmar interossei originate from the lateral metacarpals and insert on the base of the proximal phalanges and extensor expansion (Fig. 41.2). Motor function of the lumbricals and interossei is tested by placing the hand on a flat surface and moving each finger from side to side. The hypothenar muscles are tested by adducting the little finger.

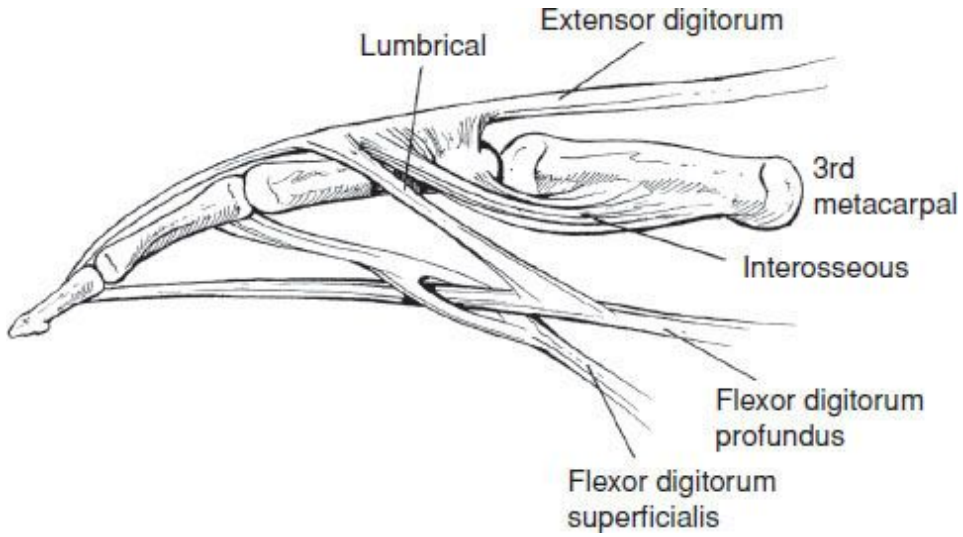

FIGURE 41.2 Musculotendinous anatomy of the finger.

The extrinsic muscles have their origins in the forearm. The extensor tendons pass under the extensor retinaculum at the wrist. The extensor tendons produce extension of the fingers by their dorsal attachments on the metacarpals and phalanges. Because there are many interconnections between the extensors, care must be taken in evaluating suspected extensor tendon injuries. Normal movement may be preserved via these interconnecting bands. The extrinsic finger flexors enter the hand via the carpal tunnel. The flexor pollicis longus of the thumb is tested by flexing the thumb against resistance. All four fingers have two flexors. The flexor digitorum superficialis (FDS) attaches to the base of the middle phalanx. The flexor digitorum profundus (FDP) attaches at the base of the distal phalanx. The FDS and FDP tendons of each finger are tested individually by flexing the distal interphalangeal (DIP) joint and the proximal interphalangeal (PIP) joint against resistance with the other fingers

held in extension. It is important to test both FDS and FDP function in each finger individually to avoid missing an isolated injury.

The median, radial, and ulnar nerves provide the sensory and motor innervation to the hand. The sensory innervation of the hand is detailed in Figure 41.3. The median nerve supplies motor function to the extrinsic flexors of the hand, the intrinsic thenar muscles, and the first and second lumbricals. The ulnar nerve innervates the flexor carpi ulnaris, the ulnar portion of the FDP, and all the remaining intrinsic muscles of the hand. The radial nerve innervates those muscles of the forearm that provide extension of the wrist and digits, as well as extension and abduction of the thumb.

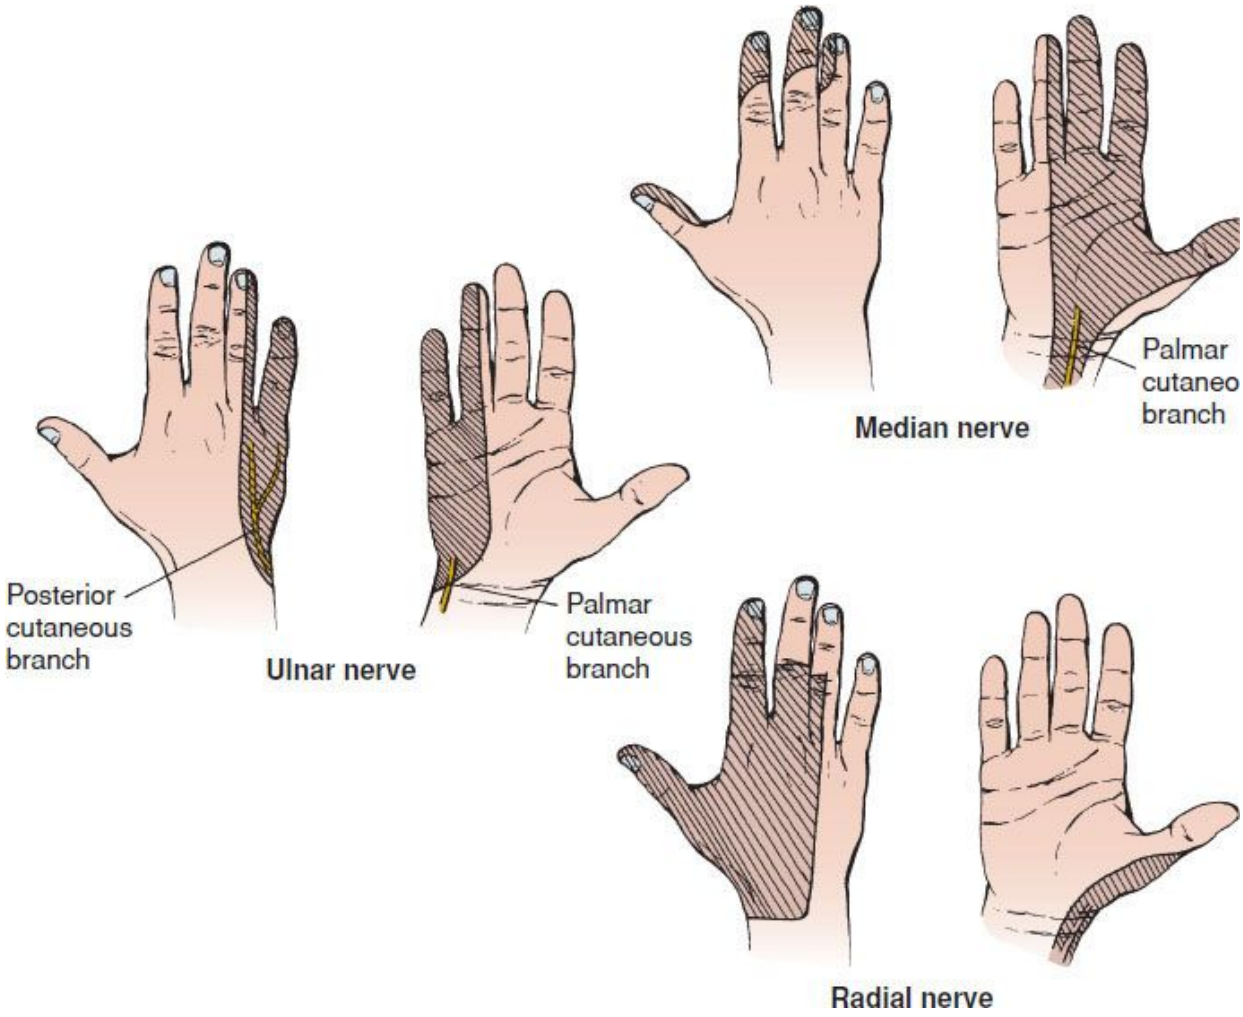

FIGURE 41.3 Sensory innervation of the hand.

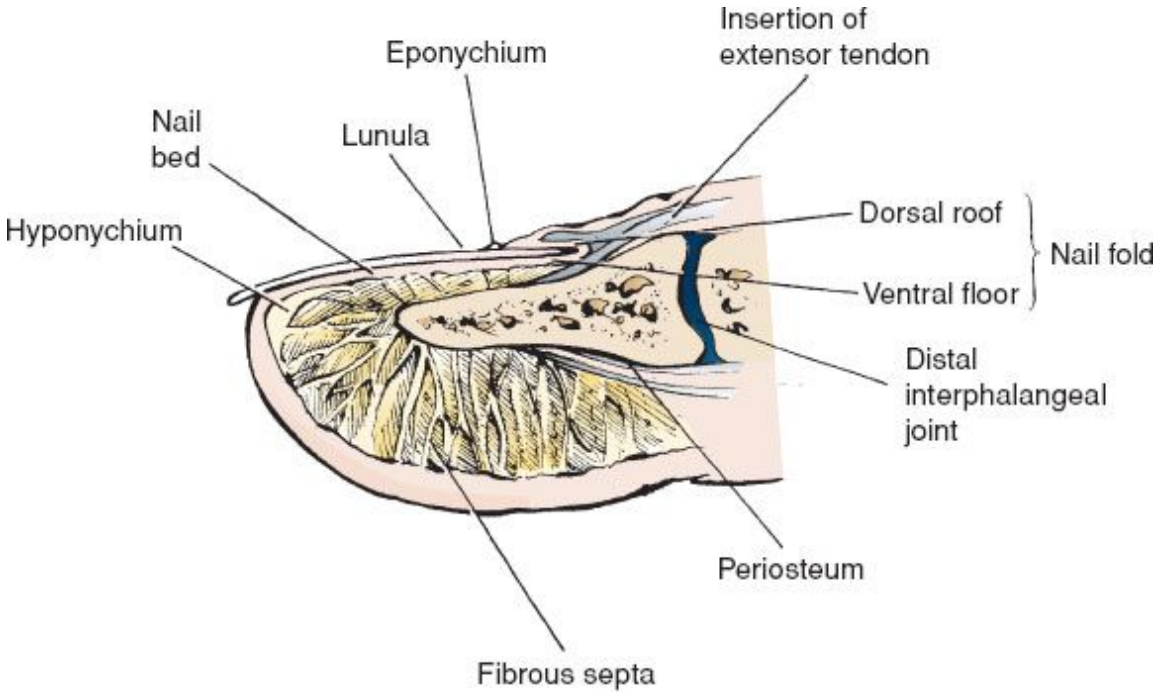
The arterial supply to the hand is provided by the radial and ulnar arteries. The radial artery terminates where the deep palmar arch and the ulnar artery forms the superficial palmar arch. Extensive collateralization occurs between the two vessels. The four common digital arteries arise from the superficial palmar arch where they divide to form the proper digital arteries.

The thick palmar skin is tightly adherent to the deep fascia of the palm. The dorsal skin of the hand is thin and supple with little underlying adipose or fibrous tissue. These qualities cause edema from hand injuries to be more pronounced on the dorsal surface.

Knowledge of fingertip and nail bed anatomy is essential when evaluating distal finger injuries **(eFig. 41.1)**.



eFIGURE 41.1 Fingertip and nail bed anatomy.

CLINICAL PRESENTATION

Patients with acute hand injuries present with varying degrees of pain, swelling, and loss of function. Injuries resulting from repetitive motions and systemic or bone diseases usually present more insidiously with chronic waxing and waning symptoms (see Chapter 145).

Patients with metacarpal injuries generally present with pain, swelling, and limitation of movement. Finding the place of maximal tenderness or deformity will help localize the area of injury. In patients with a metacarpal head fracture, axial compression of the extended digit causes severe discomfort. In patients with a metacarpal base fracture, movement of the wrist or longitudinal compression exacerbates the pain. Metacarpal fractures 2 through 5 are classified together. They are divided into head, neck, shaft, and base fractures. First metacarpal fractures are classified separately as shaft fractures and extra-articular or intra-articular base fractures.

Patients with phalangeal injuries present with varying degrees of pain, limited mobility, and deformity of the involved digit.

Hand lacerations range from clean, superficial wounds to severely contaminated crush injuries or amputations. Associated tendon injuries may cause a partial or complete loss of motor function, and injury to surrounding nerves may result in loss of both motor and sensory function.

Patients with fingertip injuries may present with a minor laceration or a severe injury with significant tissue loss or destruction.

DIFFERENTIAL DIAGNOSIS

Metacarpal injuries include fractures, dislocations, or combinations of the two. If an injury is associated with an open wound, the possibility of infection of the underlying structures should be considered (see Chapter 147). The differential diagnosis of acute phalangeal injuries includes fractures, fracture–dislocations, and ligamentous injuries.

The diagnostic challenge of hand lacerations lies in the detection of underlying injuries that may threaten the function of the hand. Tendon lacerations and injuries to bones, joints, nerves, and arteries must be excluded by examination, radiography, and direct exploration of the wound. Older wounds must be evaluated for the possibility of a developing deep space infection. Wounds that do not heal or have persistent pain with movement should be evaluated for an occult foreign body.

ED EVALUATION

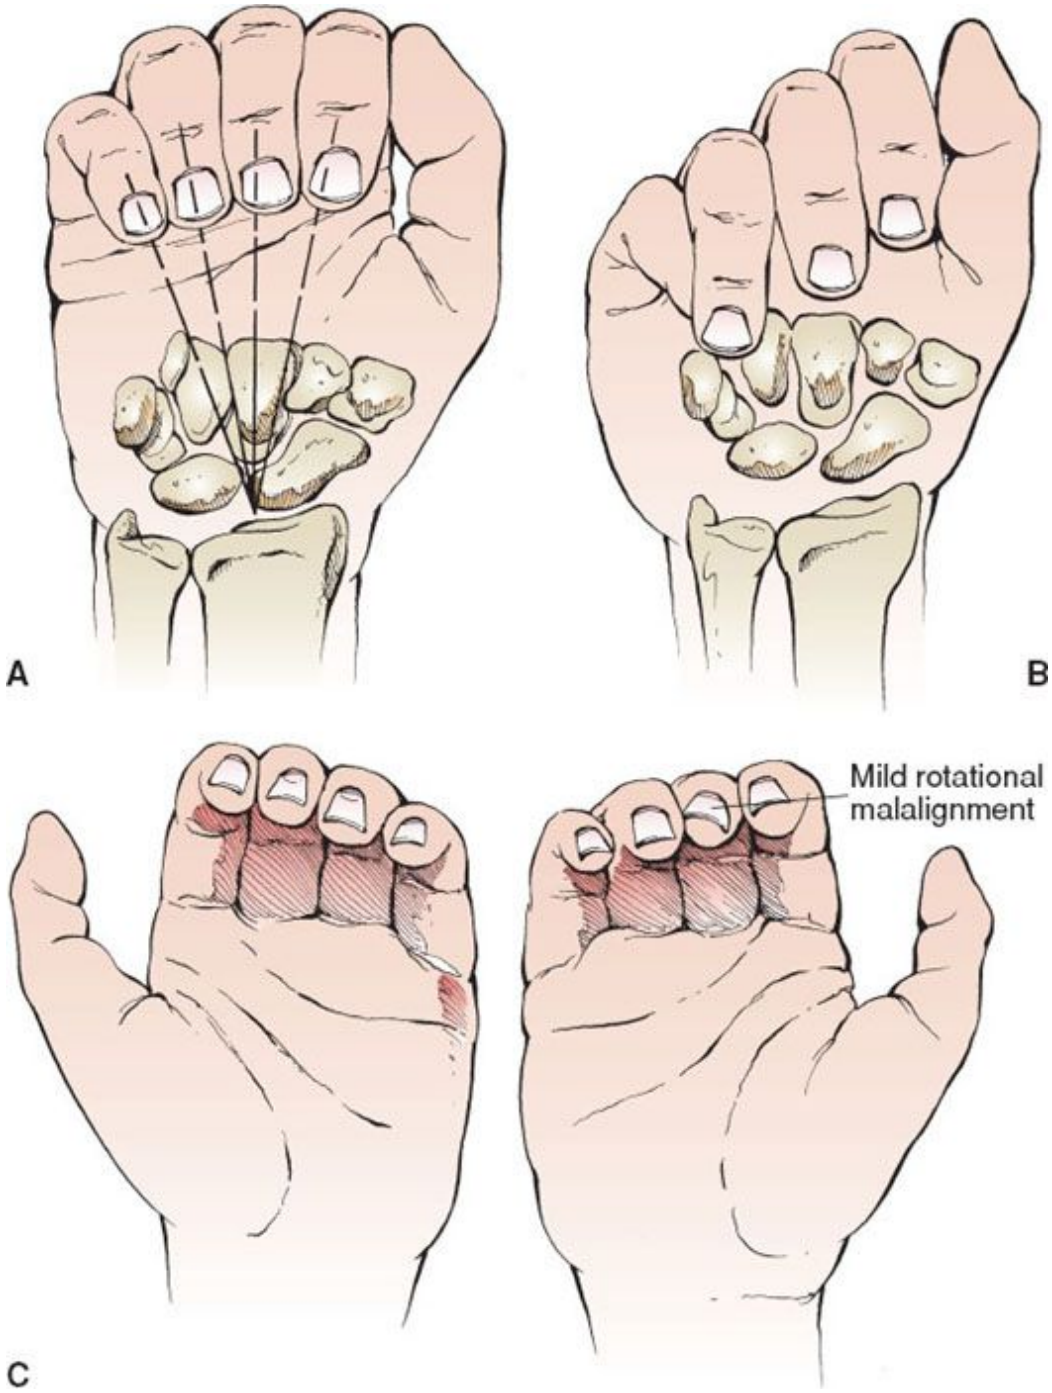
Evaluation and treatment of potentially life-threatening injuries should precede any evaluation of the hand. Once evaluation and treatment have been accomplished, assessment of the hand can begin. Direct pressure should be used to control bleeding. In rare instances when direct pressure is not sufficient, careful and intermittent use of a tourniquet will usually gain control of the bleeding and allow adequate visualization of the wound. Blind clamping of bleeding vessels should be avoided, because adjacent nerves and tendons may be injured.

A focused history is essential. Important historical information includes the patient's age, dominant hand, occupation, prior hand injuries, previous tetanus immunization, and past medical history. Details of the traumatic event should include time and mechanism of the injury, position of the hand during the accident, and treatment administered before arrival.

All dressings should be removed to completely expose the hand. Rings should be removed, because swelling may create a tourniquet effect. The location and type of wounds, skin loss, ecchymosis, pallor, swelling, and the resting attitude of the digits should be noted. The normal resting cascade of the fingers reveals progressive flexion of the digits from the index to the little finger. The normal resting cascade is generally symmetric.

Alterations in the resting cascade may indicate an underlying tendon injury. For example, a flexor tendon injury may appear as an extended digit because of unopposed extensor tone, and an extensor tendon injury may reveal a flexion deformity. The hand should also be observed during passive flexion and extension of the wrist. With wrist extension, the fingers naturally assume a flexed posture. With wrist flexion, the fingers will passively extend (2). This method may be particularly helpful in evaluating children or uncooperative patients. Emergency physicians may misdiagnose up to 35% of tendon injuries based on clinical examination alone (3). Bedside ultrasound has been shown to aid in the detection of tendon injuries (4).

The hand should be carefully palpated to identify areas of tenderness, deformity, and crepitus. In patients with phalangeal or metacarpal fractures, the presence of rotational malalignment must be sought. Rotational deformity may be diagnosed by having the patient make a fist. Normally, all of the fingers point to a single spot on the scaphoid **(eFig. 41.2)**.



eFIGURE 41.2 Clinical signs of rotational malalignment. A: Normally, all fingers point to the same spot on the scaphoid when making a fist. B: With rotational malalignment, the affected finger does not point to the scaphoid. C: Loss of the usual parallel relationship of the finger nails with rotational malalignment. (Redrawn from Simon RR, Koenigsknecht SJ. Emergency Orthopedics: The Extremities. 3rd ed. Norwalk, CT: Appleton and Lange; 1995:64.)

Nerve integrity is assessed by testing both sensory and motor functions. Sensation should always be evaluated and documented before the administration of any anesthetic agent. Digital nerve sensory function is best assessed by two-point tactile discrimination. The volar lateral aspects of the digits are lightly stroked in a longitudinal direction at the two points. Comparison with the opposite hand may be helpful. Motor function of the median nerve is tested by touching the thumb to the little finger and elevating the thumb of the pronated hand as the hand is lying on a flat surface. Radial nerve function is checked by extending the wrist and fingers. Ulnar function is tested by spreading the fingers apart against resistance. Emergency physicians may fail to identify up to 55% of nerve injuries (3).

In young children or uncooperative patients, it can be difficult to accurately perform two-point tactile discrimination. In these circumstances, nerve integrity can be assessed by testing for the presence of sympathetically mediated skin wrinkling and skin sweating. Soaking the hand in warm water for 30 minutes should cause wrinkling of the normally innervated skin. Skin sweating can be assessed by stroking the digit with a smooth object (such as the barrel of a pen). Less resistance (shown by loss of sweating) should be noted over the denervated area.

Vascular integrity of the hand is evaluated by looking for pallor, noting skin temperature, assessing capillary refill, and palpating the ulnar and radial arteries at the wrist (2). The Allen test is utilized to evaluate the patency of the radial and ulnar arteries and the palmar arches. The test is performed by having the patient clench the fist to

exsanguinate the hand while the examiner occludes the radial and ulnar arteries. When the hand is blanched, pressure over one of the arteries is released. Normal hand color should return in 3 to 5 seconds. The test is repeated, releasing the other artery.

Testing for tendon integrity is another important aspect of the hand examination. When evaluating finger lacerations, the digit should be moved through a full range of motion against light resistance. A tendon laceration may be proximal or distal to the skin wound depending on the position of the hand when the injury occurred. Partial tendon lacerations may have full function, so these lacerations are easily missed. If there is any concern about the possibility of a foreign body or injury to a deep structure, the wound should be evaluated under bright lighting with a dry field. A bloodless field is obtained by first emptying the veins. The veins are emptied by elevating the extremity and inflating a proximally placed blood pressure cuff above systolic pressure. The blood pressure cuff may be left in place for up to 20 minutes as the wound is explored. A dry field can be obtained in individual digits by placing a sterile glove on the injured hand, cutting off the tip of the glove on the injured finger, and rolling the end of the cut glove proximally to simultaneously exsanguinate and tourniquet the finger.

Radiographs of the hand should be obtained whenever the mechanism might result in fracture, joint instability, or a retained foreign body. If a thumb injury is suspected, posteroanterior (PA) and lateral views of the thumb should be obtained, because the thumb is not adequately visualized on standard hand radiographs. If there is suspicion of a foreign body despite negative plain radiographs, ultrasonography, computed tomography, or magnetic resonance imaging may be required to visualize the object (5).

KEY TESTING

- Assess sensation and motor function in the distribution of the medial, ulnar, and radial nerves. Document two-point discrimination when possible.
- Examine wounds in a clean bloodless field through passive range of motion to evaluate for tendon injury.

- Assess both flexor digitorum superficialis and flexor digitorum profundus integrity.
- Evaluate and document vascular integrity of hands and digits.
- Evaluate for rotational deformity.

ED MANAGEMENT

ED management of hand injuries includes application of ice and elevation of the extremity to reduce swelling. The liberal use of analgesics is also recommended. IV antibiotics are indicated for tendon lacerations, open fractures, dislocations, and severely contaminated or infected wounds. Tetanus immunization should be updated appropriately. Open wounds should be covered with a sterile, moist gauze dressing pending radiographs, surgical consultation, or wound closure. Suspected fractures should be temporarily immobilized with a bulky hand dressing or a splint while awaiting radiographs, reduction, or surgical consultation.

The patient's disposition depends on the nature and severity of the injury. A hand surgeon should evaluate the patient in the ED when there is an irreducible dislocation, any vascular injury with ischemia, or grossly contaminated open wounds. The remainder of most fractures, tendon, nerve, and soft tissue injuries can be splinted and seen on a prioritized basis. There are regional variations in the aggressiveness with which hand surgery consultants perform primary repair of injuries in the ED.

Anesthetic Techniques

Anesthesia for the evaluation and repair of hand injuries can be provided by a local infiltration digital nerve block or a regional nerve block at the wrist. A hematoma block is useful for the reduction of metacarpal fractures (6). Lidocaine without epinephrine should be used in 2% concentration for nerve blocks and in 1% or 2% concentration for infiltration. Lidocaine with epinephrine can be safely used for digital blocks. Lidocaine with epinephrine has the advantages of providing improved hemostasis and a longer duration of anesthesia than lidocaine alone (7).

A digital block is performed by injecting 2 to 3 mL of local anesthetic at the medial and lateral aspects of the base of the proximal phalanx. Infiltration of the proximal dorsal surface of the digit is also required to anesthetize the dorsal digital nerve. Complete anesthesia usually requires 5 to 10 minutes. Bupivacaine may be a more appropriate agent for digital nerve blocks. It can provide anesthesia for up to 8 hours and is ideal for situations where prolonged anesthesia is preferred (8). Circumferential infiltration of the digit is not recommended, because circumferential infiltration may result in distal necrosis. Small randomized controlled studies have demonstrated that a single volar injection method achieves similar anesthesia with less patient discomfort. A 25-gauge needle should be injected at the volar metacarpophalangeal (MCP) skin crease while the physician is slightly pinching the proximal aspect of the proximal phalanx. The needle should be advanced until it hits the bone then retracted 1 to 2 mm; 2 to 3 cc of anesthetic should be injected (9).

Regional nerve blocks at the wrist can anesthetize the median, ulnar, and radial nerves. A median nerve block is performed by injecting 5 mL of local anesthetic 1 cm proximal to the distal wrist flexion crease, radial and deep to the palmaris longus tendon, or deep to the ulnar aspect of the flexor carpi radialis tendon in those individuals lacking a palmaris longus tendon. An ulnar nerve block is accomplished by injecting 5 mL of local anesthetic 1 cm proximal to the distal wrist flexion crease just radial and deep to the flexor carpi ulnaris tendon. The ulnar artery at this level lies in close proximity to the ulnar nerve. Aspiration before injection is important to avoid intravascular injection of the anesthetic. The dorsal sensory branch of the ulnar nerve is blocked by subcutaneous infiltration of anesthetic just distal to the ulnar styloid. A radial nerve block is performed by subcutaneous infiltration of 5 mL of anesthetic agent just distal to the radial styloid. Ultrasound is a useful adjunct to performing forearm nerve blocks and is within the scope of practice for an appropriately trained emergency physician to perform (9). A hematoma block is performed by injecting a local anesthetic into the hematoma surrounding a fracture. A 27-gauge needle is inserted over

the fracture site. When blood is aspirated into the syringe, indicating correct needle placement, 5 to 10 mL of anesthetic is injected. Ten minutes are often required before complete anesthesia is obtained with regional and hematoma nerve blocks.

Metacarpal Neck Fractures

Most commonly seen in the fifth metacarpal (i.e., boxer fracture), neck fractures are usually the result of striking an object with a closed fist. Metacarpal neck fractures are easily reduced, but reduction may be difficult to maintain. Because metacarpals 2 and 3 are relatively fixed and immobile, reduction of these fractures must be nearly anatomic. Any volar angulation will project the metacarpal head into the palm and impair grip strength. Greater angulation is acceptable in metacarpals 4 and 5. These digits have greater mobility, and they can move dorsally without impairment of grip strength. Most hand surgeons will allow up to 40 degrees of angulation in fractures of the fifth metacarpal neck and 20 degrees of angulation in fractures of the fourth metacarpal neck. In contrast, as little as 10 degrees of angulation is unacceptable for metacarpals 2 and 3. Even minor rotational deformity can lead to impaired grip strength and requires referral to hand surgery for possible surgical correction.

The technique for reduction of metacarpal neck fractures is the same regardless of which metacarpal is fractured. Surgical consultation is recommended before reduction of metacarpals 2 and 3, because some surgeons prefer operative fixation. After adequate anesthesia has been obtained, the MCP and PIP joints are flexed to 90 degrees. Pressure is applied to the PIP joint in a dorsal direction to force the metacarpal head into its normal position. Stabilizing volar pressure should be applied with the physician's other thumb just proximal to the fracture site (Fig. 41.4). If reduction is difficult, longitudinal distraction may be needed to disimpact the fracture before successful reduction can be accomplished.

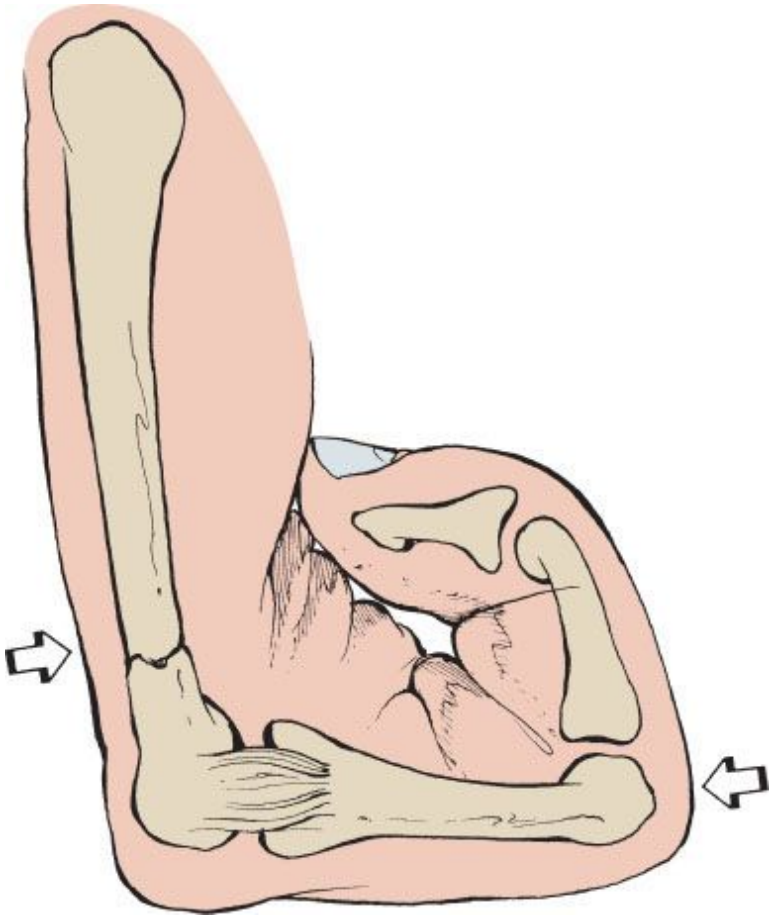


FIGURE 41.4 The 90–90 method of reduction for metacarpal neck fractures.

After reduction, a gutter splint incorporating the adjacent finger should be placed while keeping the MCP joint flexed to maintain reduction. The wrist should be splinted in 20 degrees of extension, the MCP at 90 degrees of flexion, and the interphalangeal (IP) joints in extension. It is important to immobilize the MCP joint as close to 90 degrees as possible, so contraction of the collateral ligaments does not occur. This contraction would permanently limit flexion of the MCP joint. Follow-up should be arranged within 7 days. If loss of reduction occurs, operative fixation may be needed.

Metacarpal Head Fractures

Metacarpal head fractures are rare injuries that are usually the result of a direct blow or crush injury. Management consists of temporary

immobilization in a well-padded volar splint. Evaluation by a hand surgeon is indicated for most metacarpal head fractures, because anatomic reduction frequently requires operative intervention. Even with optimal management, severe metacarpal head fractures may have a poor functional outcome.

Metacarpal Shaft Fractures

Metacarpal shaft fractures may be transverse, comminuted, oblique, or spiral. Nondisplaced transverse fractures are treated by immobilization in a gutter splint with the wrist in 20 degrees of extension, the MCP joint in 60 degrees of flexion, the PIP joint in 20 degrees of flexion, and the DIP joint in 15 degrees of flexion (10). Displaced transverse metacarpal shaft fractures should, whenever possible, be reduced by a hand surgeon. If consultation is not available, the emergency physician may attempt reduction by applying volar force over the dorsal apex of the fracture and dorsal pressure on the flexed MCP joint. If reduction is successful, the hand is splinted as described earlier, and the patient is referred for follow-up within 7 days. If a transverse fracture cannot be reduced, or if an oblique, spiral, or comminuted fracture is present, refer the patient to a hand surgeon for operative repair.

Metacarpal Base Fractures

Fractures of the base of the metacarpals are generally stable, but slight rotational deformity will be greatly amplified at the fingertip (11). Nondisplaced fractures without rotational deformity may be treated by immobilization in a gutter or volar splint and by surgical referral. Displaced or intra-articular base fractures require hand surgery consultation for open reduction and internal fixation.

First Metacarpal Fractures

First metacarpal fractures are uncommon. These fractures most often occur at or near the base of the thumb. Extra-articular fractures are more common, and the fractures may be transverse or oblique. Transverse fractures with <30 degrees of angulation are treated with

immobilization in a short-arm thumb spica splint and prompt follow-up. A transverse fracture with >30 degrees of angulation requires reduction. After reduction, the thumb is splinted, and the patient is referred for follow-up. Oblique fractures are often unstable, and they frequently require percutaneous pinning for adequate immobilization. Consultation is advised before manipulation or discharge.

There are two types of intra-articular fractures: the Bennett fracture and the Rolando fracture. A Bennett fracture is a two-part intra-articular fracture of the metacarpal base with subluxation or dislocation at the carpometacarpal (CMC) joint. A Rolando fracture is a comminuted, often T- or Y-shaped intra-articular fracture of the base of the first metacarpal. Both fractures result from an axial blow to the metacarpal, commonly sustained by striking an object with a closed fist. Management includes immobilization in a thumb spica splint and expeditious follow-up with a hand surgeon. Bennett fractures frequently require pinning for a stable anatomic reduction. Rolando fractures often require open reduction. Rolando fractures have a poor prognosis, even with optimal management (11,12).

Metacarpal Dislocations

Dislocations involving the metacarpals are either CMC or MCP. CMC dislocations are uncommon, and they require a significant force. These dislocations are generally dorsal, and they are often associated with metacarpal or carpal fractures and significant soft tissue trauma. The presence of a displaced proximal metacarpal fracture should prompt a careful search for an associated CMC dislocation. The lateral view is the most helpful standard view for diagnosing CMC dislocations. However, overlapping densities on standard wrist radiographs may make the detection of CMC dislocations difficult, so special views may be needed to detect CMC dislocations. CMC dislocations are easily reduced, but operative fixation is usually required to maintain reduction. Complications of CMC dislocations are ulnar and median nerve injuries, extensor tendon injuries, and circulatory compromise.

MCP joint dislocations usually occur dorsally. These dislocations are generally well visualized on standard radiographs of the hand. Reducible dorsal dislocations are the most common, and this injury can usually be treated by the emergency physician. Irreducible dorsal dislocations occur when the volar plate is interposed between the metacarpal head and the proximal phalanx. This dislocation traps the metacarpal head between the flexor tendons and the lumbricals, making the injury irreducible by closed techniques. Radiographically, the presence of a sesamoid bone within the MCP joint space is pathognomonic of a complex dislocation (11). Simple dorsal MCP dislocations are reduced by slight flexion of the wrist to relax the extrinsic flexors, followed by gentle hyperextension of the MCP joint and firm pressure on the dorsal aspect of the proximal phalanx. Longitudinal traction and extreme hyperextension should be avoided because this may entrap the volar plate, thus converting a simple dislocation into a complex one. After reduction, the hand is immobilized, with the wrist in 20 degrees of extension, the MCP joint in 60 degrees of flexion, the PIP joint in 20 degrees of flexion, and the DIP joint in 15 degrees of flexion. One attempt at reduction of a complex MCP dislocation may be warranted, but multiple attempts should be avoided. These patients usually require open reduction and repair of the volar plate injury.

Collateral MCP ligament injuries occur infrequently, and are often missed. The presence of an avulsion fracture from the metacarpal head or corner fracture of the base of the proximal phalanx suggests an MCP collateral ligament injury. Consultation with a hand surgeon is recommended for patients with a collateral ligament injury (11). ED care involves immobilization in a gutter splint, with the MCP in 60 degrees of flexion, and appropriate referral.

Ulnar Collateral Ligament Injury (Gamekeeper's Thumb, Skier's Thumb)

Ulnar collateral ligament injury is an acute rupture of the ulnar collateral ligament caused by sudden forced abduction of the thumb.

Plain radiographs may be normal or may reveal an avulsion fracture from the ulnar aspect of the base of the proximal phalanx. If plain radiographs do not reveal a fracture, stressing the ligament may help determine if a complete tear has occurred.

ED management includes immobilization in a thumb spica splint and early referral to a hand surgeon. A frequent complication of ulnar collateral ligament rupture is chronic laxity of the MCP joint because of interposition of the adductor aponeurosis between the ends of the torn ligament. This injury is referred to as a Stener lesion (13). Because of this complication, many surgeons prefer routine operative repair of ulnar collateral ligament tears.

Proximal and Middle Phalangeal Fractures

Stable, nondisplaced middle and proximal phalangeal fractures without angulation or rotational deformity can be managed with dynamic splinting (i.e., "buddy taping") to an adjacent normal digit. Padding should be placed between the digits to prevent maceration of the skin. The patient should bend the fingers normally and use the hand as comfort allows. Radiographs are obtained in 7 to 14 days to assess angulation and healing. Unstable fractures of the proximal and middle phalanges (e.g., oblique, condylar, displaced, or angulated transverse fractures) and displaced intra-articular fractures generally require operative reduction or fixation. ED management of these fractures includes immobilization in a gutter splint and consultation.

Avulsion fractures off the dorsal aspect of the base of the middle phalanx are of special concern. If not recognized and treated appropriately, these fractures can result in a *boutonnière* deformity (i.e., fixed flexion of the PIP joint and fixed hyperextension of the DIP joint). This deformity is caused by avulsion of the central slip of the extensor tendon with loss of extensor function at the PIP joint and unopposed force from the FDS (Fig. 41.2). With time, the lateral bands of the extensor expansion sublux laterally and volarly, and the lateral bands will become PIP joint flexors and DIP joint extensors. Contractures make this injury a fixed deformity. These fractures should be immobilized in a volar splint with the PIP joint in extension, and the patient should be promptly referred to a hand

surgeon for evaluation. If more than 40% of the articular surface is involved then the fracture may require surgical stabilization (14).

Avulsion fractures from the volar aspect of the base of the middle phalanx may be indicative of a volar plate injury. These injuries should be immobilized in a volar splint in 15 degrees of flexion. Immobilization should be followed by appropriate referral.

Volar plate avulsion fractures are of special concern. The volar plate is a strong fibrous structure joining and stabilizing the middle and proximal phalanges. It primarily acts by limiting hyperextension. Injury typically occurs with forced hyperextension. The diagnosis is made by obtaining plain x-rays of the digit. The lateral view is the most useful for making this diagnosis that is characterized by an avulsion fracture at the base of the middle phalanx. Absence of this fracture, however, does not rule out volar plate injury. In the absence of a fracture, signs such as subtle subluxation or an abnormal crescent-shaped gap at the dorsal aspect of the PIP joint (V sign) may indicate injury. These injuries should be immobilized in a volar splint in 15 degrees of flexion and referred to a specialist (14).

Distal Phalanx Fractures

Distal phalanx fractures are divided into intra- and extra-articular fractures. Extra-articular fractures usually result from a direct blow to the distal phalanx. These injuries are often associated with injury to the fingernail or nail bed. Extra-articular fractures are managed with oral analgesics and placement in a protective splint for 3 to 4 weeks. A U-shaped splint can be constructed using an aluminum and foam splint.

Intra-articular fractures often involve the dorsal surface of the joint and may result in loss of extension of the DIP, an injury commonly referred to as a mallet finger. This injury may occur when an object strikes the tip of an extended finger resulting in forced flexion of the distal phalanx with the finger in taut extension. The extensor tendon ruptures, or the dorsal aspect of the distal phalanx snaps. Patients typically present with tenderness over the dorsal aspect of the DIP joint and loss of extension at the DIP joint. Management includes immobilization using a padded dorsal aluminum splint with the DIP

joint in extension. If the fracture involves <25% of the articular surface, immobilization is maintained for 8 weeks to coapt the tendon or fracture segments. If the fracture involves >25% of the articular surface, the patient should be referred for surgical fixation. Untreated mallet finger may result in a swan-neck deformity characterized by hyperextension of the PIP joint and flexion at the DIP joint (15). Open distal phalanx fractures are treated by copious irrigation and wound closure, ensuring complete soft tissue coverage of exposed bone. If the nail bed has been injured it must be repaired.

FDP avulsion (jersey finger) requires urgent hand surgery referral. FDP function must be checked in all patients with DIP injuries. FDP avulsion may occur with forced sudden extension of a flexed DIP joint. Patients will be unable to flex their DIP when their PIP is locked in extension. Avulsion fractures on the palmar aspect of the DIP are often seen on plain films; however, this injury may have no radiographic abnormality. Early surgical intervention is necessary to restore normal DIP function. Primary repair is often impossible after 7 days (14).

Proximal Interphalangeal Joint Dislocations

Dislocations at the PIP joint are the most common dislocations of the hand. Dorsal dislocations result from hyperextension forces, such as those that occur when the outstretched finger is struck by a ball. Dorsal PIP dislocations are accompanied by partial or complete rupture of the volar plate or collateral ligaments. Volar dislocations occur less often, but they are associated with complete rupture of the volar plate and collateral ligaments, as well as the central slip of the extensor mechanism. Patients usually present with pain and deformity of the PIP joint. The presence of pain and a locking sensation with flexion suggests a volar plate injury. Radiographs are diagnostic for acute dislocations, but small avulsions of the volar plate may not be visible. Most dorsal dislocations are easily reduced, but the volar plate may become interposed in the joint space, which prevents reduction by closed techniques. If this complication occurs, open reduction is required. For closed reduction, a digital nerve block provides adequate anesthesia. The distal portion of the digit is

firmly grasped and slightly hyperextended. With gentle traction parallel to the middle phalanx, the base of the middle phalanx is pressed back into position and the PIP joint is flexed. The PIP joint should be immobilized using a volar splint, in 20 degrees of flexion for 2 to 5 weeks. If there is instability after reduction, the patient should be immobilized in a gutter splint and expeditiously referred to a hand surgeon.

Volar PIP dislocations can be problematic. They can be reduced by traction with both the MCP and PIP joints flexed. Consultation with a hand surgeon before reduction is recommended, because some surgeons prefer to treat these dislocations operatively. Joint stiffness is a common complication after both volar and dorsal dislocations.

Distal Interphalangeal Joint Dislocations

Dislocations of the DIP joint are relatively uncommon injuries. These injuries are almost exclusively dorsal, and they are often associated with an open wound. DIP joint dislocations can usually be reduced with digital block anesthesia and simple traction. After reduction, the DIP joint should be immobilized in extension using a dorsal splint, and the patient should be referred to a hand surgeon.

Hand Lacerations

The objectives of ED care of hand lacerations are to preserve function, prevent infection, minimize scar formation, and provide the optimal wound environment for rapid healing. Simple lacerations (clean, <6 hours old, and not involving tendons, joints, or neurovascular structures) are managed in the same manner as lacerations elsewhere. In many areas of the hand, vital structures are extremely superficial, and injuries to these structures are not always readily apparent.

Evaluation of a hand laceration begins with a pertinent history and meticulous examination. Adequate exploration of the wound requires a clean, bloodless, well-illuminated field and adequate anesthesia. A proximal blood pressure cuff (for hand wounds) or finger tourniquet (for digit wounds) provides optimal visualization of the wound.

Anesthesia may be obtained by direct infiltration of a local anesthetic or regional nerve block but should not be attempted until a sensory examination has been performed. Radiographs are indicated in cases in which the mechanism of injury could produce a fracture, dislocation, joint capsule injury, or retained foreign body. Exploration should be carried out through a full range of motion, otherwise injury to underlying structures, particularly tendon lacerations, may be missed. Simple lacerations are cleaned, irrigated, and repaired in the same fashion as in other areas of the body. Deep sutures should be avoided. After repair, lacerations over areas of motion should be splinted until the skin edges are well adherent. Antibiotics are not required for simple hand lacerations in otherwise healthy patients, for there is no convincing evidence for their use in this setting (16).

Clenched Fist Injuries (Fight Bites)

Lacerations over the MCP joints are often a result of striking an object with a clenched fist. Lacerations may be associated with extensor tendon injury, joint capsule violation, or metacarpal neck fracture. Because infection or septic arthritis may occur with any laceration over the MCP joints, these lacerations must be approached with suspicion. The laceration should be assumed to be a human bite wound until proven otherwise. Human bites are particularly prone to infection, usually with *Staphylococcus aureus* and *Streptococcus* sp or anaerobes such as *Eikenella corrodens* (12,17). Patients with an uncomplicated wound (i.e., no tendon or joint capsule damage) who present within 24 hours with uninfected wounds may be treated with copious irrigation, immobilization, and follow-up within 24 hours. Antibiotics should be prescribed. One option for outpatient treatment is amoxicillin–clavulanic acid (500/125 mg/tid). All other patients with clenched fist injuries are copiously irrigated, splinted in the ED, and admitted for possible debridement in the operating room by a hand surgeon. Admitted patients receive parenteral antibiotics. One option for inpatient therapy is ampicillin–sulbactam IV (1.5 g/q6h).

Tendon Lacerations

Tendon injuries are frequently associated with hand lacerations. A detailed examination and careful wound exploration are essential for detecting these injuries, for a partially cut tendon may demonstrate normal function. Once identified, management of a tendon laceration depends on the type of tendon injured, the cross-sectional area of tendon involved, and the location of the laceration.

Because of their complex structure, deep location, and high complication rate after injury, all suspected flexor tendon lacerations require consultation and repair by a hand surgeon. When a hand surgeon is not immediately available, the wound can be copiously irrigated and the skin closed primarily without tendon repair. The hand is then immobilized in a volar splint with the wrist in 20 degrees of flexion, the MCP joint in 60 degrees of flexion, and the IP joints in 15 degrees of flexion. The patient is referred for delayed repair within 5 days. Broad-spectrum antibiotic coverage is generally recommended for tendon lacerations.

In contrast to flexor tendons, extensor tendons are anatomically less complex, have a more superficial location, and are associated with fewer complications after repair. Tendon lacerations not involving the PIP joint are amenable to ED repair. Once a lacerated extensor tendon is identified, a holding stitch can be placed through the proximal tendon for traction during repair. The tendon can then be repaired with 4-0 or 5-0 nonabsorbable sutures using simple, interrupted sutures or a horizontal mattress suture with the knot "buried" between the ends of the tendon. Sutures should be placed 5 to 10 mm from the cut edge of the tendon to avoid the suture tearing through the end of the tendon. Lacerations over the PIP joint may involve the lateral bands or the central slip of the extensor mechanism. If this laceration is not repaired meticulously and followed closely, the injury can result in a *boutonnière* deformity. Patients with extensor tendon injuries over the PIP joint should be referred to a hand surgeon for repair.

The patient with a lacerated extensor tendon should be splinted in a position with the extensor mechanism relaxed. Tendon repairs at

the DIP joint can be treated with a mallet finger splint while leaving the PIP joint mobile. Injuries at, or proximal to, the PIP joint should be splinted with the wrist in 30 degrees of extension, the MCP joint in 20 degrees of flexion, and the IP joints in slight flexion.

Nerve Injuries

A careful examination of the hand is performed before the instillation of any local anesthetics. If there is a suspected peripheral nerve injury, anesthetics should be withheld until consultation with the hand surgeon to decide if microsurgical repair is needed and to determine the timing of the repair of the injury.

Arterial Injuries

Because of the extensive collateral flow of the palmar arches, ischemic injuries to the hand are rare. Arterial lacerations may spasm and stop bleeding by the time the patient is evaluated, so careful wound exploration is important. Arterial injuries with distal ischemia or associated nerve injury usually require surgical repair. Isolated injuries to the radial or ulnar artery without distal ischemia or sensory impairment require hand surgery consultation for possible repair or ligation.

Fingertip Lacerations, Avulsions, and Amputations

Fingertip injuries are classified by the extent and level of injury. Simple lacerations and small avulsion injuries are easily managed by the emergency physician. Injuries that involve significant tissue loss or bony exposure should be referred to a hand surgeon for repair. Partial or complete amputations should also be managed by a hand surgeon (see Chapter 47).

These injuries frequently necessitate skin grafts or skin flaps for adequate coverage. Pending consultation, ED care includes administration of a parenteral antistaphylcoccal antibiotic, appropriate analgesia, and wound cleansing. Avulsion injuries with minimal soft tissue loss (wound area <10 mm^2) and no bone loss or exposure may be allowed to heal by secondary intention with

excellent cosmetic and functional results. This method works particularly well in children, who have excellent regenerative capacity. The digit is debrided of dead and devitalized tissue, and it is copiously irrigated. The digit is then bandaged with a nonadherent dressing (e.g., Xeroform) and splinted. The patient performs daily dressing changes.

Subungual Hematoma

A subungual hematoma is a collection of blood under the nail plate. This hematoma commonly occurs after a direct blow to the fingertip, and it may be associated with a nail bed laceration or distal phalanx fracture. Patients may complain of severe throbbing pain and a variable amount of blood will be visible beneath the nail plate. There may also be associated injury to the nail bed and surrounding nail folds. When distal phalanx pain and swelling are not related to a recent traumatic event, the possibility of an infection such as a felon or paronychia should be considered (see Chapter 147).

Most subungual hematomas may be treated conservatively. More extensive subungual hematomas may be treated by simple nail trephination as long as the nail plate and surrounding nail folds are intact (18). The use of a battery-operated microcautery device is one effective and painless method to drain a subungual hematoma. After trephination, the digit should be dressed with absorbent gauze. If a distal phalanx fracture is present, it should be splinted. If there is extensive disruption of the nail plate or surrounding nail folds, the nail plate should be removed, and proper alignment of the nail bed should be restored by careful wound repair.

Nail Bed Lacerations

Crush and avulsion injuries that result in nail plate avulsion or deformity to the nail bed should be repaired. Failure to properly repair these lacerations can result in a split nail deformity, irregular nail surface, or failure of the nail to adhere to the nail bed. These deformities may be significant from both a cosmetic and a functional standpoint.

Complex lacerations may require repair by a hand surgeon. Management of simple and stellate lacerations may be performed in the ED under digital block anesthesia and tourniquet hemostasis. The broken nail can be removed with a small hemostat or iris scissors by gently opening and closing the instrument beneath the distal free edge of the nail until the nail plate is loose. The distal end of the nail is then grasped with a hemostat and gently removed. The lacerations should be explored carefully for foreign bodies and irrigated copiously. Debridement of the wound margins should be avoided, because removal of small amounts of tissue can lead to increased scar formation. Lacerations should be closed with interrupted 6–0 absorbable sutures. The sutures should be tied with only three to four knots, so they do not interfere with nail replacement.

After repair, the involved nail (if available) should be used as a protective covering for the injured nail bed. The nail should be inspected for debris or foreign matter, and the nail should be rinsed in normal saline before replacement. No tissue should be removed from the undersurface of the nail, because replacing the nail in its normal position often replaces avulsed tissue as well. A hole should be placed in the center of the nail to permit blood drainage. The proximal end of the nail is inserted under the eponychium until the nail is in its normal position on the nail bed. A 5-0 monofilament nylon suture placed through the fingertip and the distal free border of the nail secures the nail plate. The suture is cut in 2 to 3 weeks, allowing growth of the new nail to push out the old one. If the nail is missing or damaged, metal foil or a nonadherent sterile dressing can be used to cover the injured nail bed. It is important to insert foil or other material into the proximal nail fold between the eponychium and the nail, so adhesions do not impair normal nail regrowth. An absorbent gauze dressing and application of a splint for comfort and protection are important adjunctive measures.

High-Pressure Injection Injuries

A high-pressure injection injury of the hand may at first appear innocuous, but clinical sequelae are devastating, if the initial recognition or management is inadequate or delayed. Three types of

industrial equipment (grease guns, spray guns, and diesel injectors) account for most injection injuries (19). Injection often occurs as the operator uses a finger to wipe the plugged nozzle. At the time of the injury, the patient may feel temporary stinging or no pain at all, which may result in delay in seeking treatment (20).

Several factors determine the type and degree of high-pressure injection injury (21). The type of material is the most important element in determining the subsequent morbidity. Paint and paint thinner create the greatest tissue inflammatory response, and high-pressure injection injuries involving them result in a high rate of amputation.

At the time of injury, the patient may only feel a stinging sensation at the site of penetration, and a small puncture wound will be present at the site. Within several hours, increased discoloration and swelling occur, accompanied by severe pain. Patients usually present to the ED in significant pain. The amount and location of swelling, tendon function, and joint range of motion are evaluated. Plain radiographs of the involved extremity are useful in determining the extent of the dispersed material, and the radiographs may help guide the extent of surgical debridement. Material can be dispersed at a considerable distance from the site of penetration. Imaging to the elbow is mandatory (19).

The time from injury to proper treatment is the prime determinant of prognosis (22). ED care includes elevation of the extremity, administration of broad-spectrum antibiotics, tetanus prophylaxis, and preparation for surgery. Pain control is provided through opiates or proximal extremity nerve blocks. Digital nerve blocks are absolutely contraindicated because of the additional fluid volume and tissue and vascular compression added to the already compromised digit (19,21). Warm soaks are contraindicated since they increase blood flow to the compromised extremity, and they cause increased tissue compression. Immediate surgical consultation is mandatory.

Compartment Syndrome of the Hand

Compartment syndrome in the hand is rare, but should be considered in patients with high-risk mechanisms such as crush injuries, high-pressure injection injuries, or IV extravasation injuries. Signs and symptoms include pain, tightness of the skin, paresthesias, palor, and vascular compromise as a late finding. The classic presentation of compartment syndrome of the hand may be complicated by nerve injuries or regional anesthesia. There are 10 separate compartments of the hand: thenar, hypothenar, and adductor pollicis in addition to 4 dorsal and 3 volar interossei compartments. If there is concern for compartment syndrome, consultation with a hand specialist should occur immediately. Measurement of the thenar and hypothenar compartments should occur by inserting the needle of a measurement device perpendicular to the skin at the site of maximal swelling. Measurement of the adductor pollicis compartment is taken on the radial side of the second metacarpal in the muscle belly of the thumb-index webspace. To measure the dorsal interosseous compartments the needle is placed 1 cm proximal to the metacarpal head and advanced until the needle rests in the muscle belly. The needle is advanced approximately 0.5 cm further to obtain volar interossei compartment pressures. Compartment pressures greater than 30 are generally considered to be diagnostic of compartment syndrome. If one compartment pressure is found to be elevated all compartments of the hand should be released (23).

CRITICAL INTERVENTIONS

- Perform a systematic examination including a careful neurovascular assessment in all patients with hand injuries, and document the results.
- Carefully explore all wounds for tendon lacerations and foreign bodies using a tourniquet to obtain a bloodless field, and document the results.
- For patients with a fight bite, copiously irrigate and splint in the ED, obtain hand surgery consultation, and admit for intravenous antibiotics and possible operative debridement.
- For most injuries, splint the hand with the wrist in 20 degrees of extension, the MCP joint in 60 degrees of flexion, and the IP

joints in 15 degrees of flexion.

DISPOSITION

Most patients with metacarpal injuries can be discharged from the ED with appropriate immobilization and instructions. Those patients with open fractures, irreducible fractures or dislocations, or circulatory compromise should be evaluated by a hand surgeon. Patients with stable fractures, anatomically reduced dislocations, or ligamentous injuries can be discharged with early follow-up.

Patients with stable, anatomically reduced phalangeal injuries can be discharged from the ED with appropriate follow-up. Patients with open fractures, nonreducible or unstable fractures, or dislocations require consultation with a hand surgeon.

Patients with simple hand or extensor tendon lacerations repaired in the ED can be discharged. Reevaluation in 48 hours for signs of wound infection is advisable for all but minor lacerations. Surgical referral should be made for any complex injury. Discharge instructions should include strict hand elevation, intermittent application of ice for the first 24 hours, and splint precautions. Patients should receive written instructions on specific signs or symptoms which should prompt a return to the ED.

Patients with simple fingertip lacerations and minor avulsion injuries may be discharged from the ED. A follow-up visit at 48 hours to check for infection is advised. Patients with more significant injuries require surgical consultation.

Patients with a subungual hematoma may be discharged from the ED. If a fracture was detected on radiographs, the digit should be immobilized. The patient should be informed about the possibility of nail loss or deformity. Patients with a significantly avulsed nail matrix should be referred to a hand surgeon. Follow-up in 48 hours is recommended for patients with a distal phalanx fracture and those with nail bed lacerations who required nail removal and suturing. Antibiotics are unnecessary in immunocompetent patients with clean, fresh wounds. For high-risk patients, prophylactic use of an antibiotic, such as cephalexin 250 mg, given every 6 hours for 3 days is recommended.

The patient with a high-pressure injection injury should receive immediate surgical consultation with expectation of wide debridement and copious irrigation of all involved areas.

Discharge instructions for all patients with hand injuries should include elevation of the extremity and the use of ice for the initial 24 hours. Instructions regarding signs of infection, the timing of return visits for complications, wound checks, and suture removal are mandatory. Patients with injuries who are splinted should also receive instructions regarding splint care and problems that should prompt an immediate return to the ED. Appropriate and timely follow-up arrangements should be provided for all patients treated in the ED.

Common Pitfalls

- Failure to appreciate the extent of a PIP joint injury, which may lead to a *boutonnière* deformity, or failure to appreciate the extent of a DIP injury which may lead to a swan-neck deformity.
- Failure to perform a detailed neurologic assessment prior to regional anesthesia.
- Failure to recognize and treat MCP lacerations as potential human bite injury.
- Failure to recognize a partial tendon laceration due to inadequate wound exploration.
- Failure to identify a foreign body in a wound as a result of inadequate exploration or omission of a radiograph.
- Failure to appreciate the significance of a high-pressure injection injury.

CHAPTER 42 Pelvic Fractures

Carrie D. Tibbles and Michael Gibbs

Pelvic fractures are a common and often life-threatening consequence of major trauma. A pelvic fracture suggests a significant force of injury, mandating a careful evaluation for multisystem involvement. Many of these patients are hemodynamically unstable, requiring aggressive volume resuscitation. These patients are at increased risk for associated injuries and significant morbidity and mortality (1). Motor vehicle collisions and automobile–pedestrian trauma are responsible for 60% to 70% of pelvic fractures. Falls from a height account for 10% to 20% of pelvic fractures, and the rest are made up of athletic and direct crush injuries (2). Early resuscitation, accurate fracture classification, stabilization of the pelvis, diagnosis of associated injuries, and coordination of key specialists are the priorities in the emergency department (ED) management of these complex injuries.

CLINICAL PRESENTATION

An understanding of both the anatomy of the pelvis and the mechanism of injury is necessary to manage patients with significant pelvic trauma. It is useful to visualize the pelvis as a ring with anterior and posterior components (Fig. 42.1). The posterior pelvic ring, which is critical for stability, is strengthened by several ligaments: the anterior and posterior sacroiliac (SI) ligaments, sacrospinous ligament, and sacrotuberous ligament (Fig. 42.2A,B). Disruption of this powerful ligamentous complex is a marker of tremendous energy transfer. Major blood vessels traversing the posterior pelvic ring are vulnerable when fractures occur here.

Anteriorly, the pubic symphysis is the weakest link in the pelvic ring. Disruption of the symphysis alone does not lead to instability, provided the posterior ligamentous structures remain intact. Because the pelvis is a ring structure, if one fracture is identified, there is almost always a second disruption of the ring.

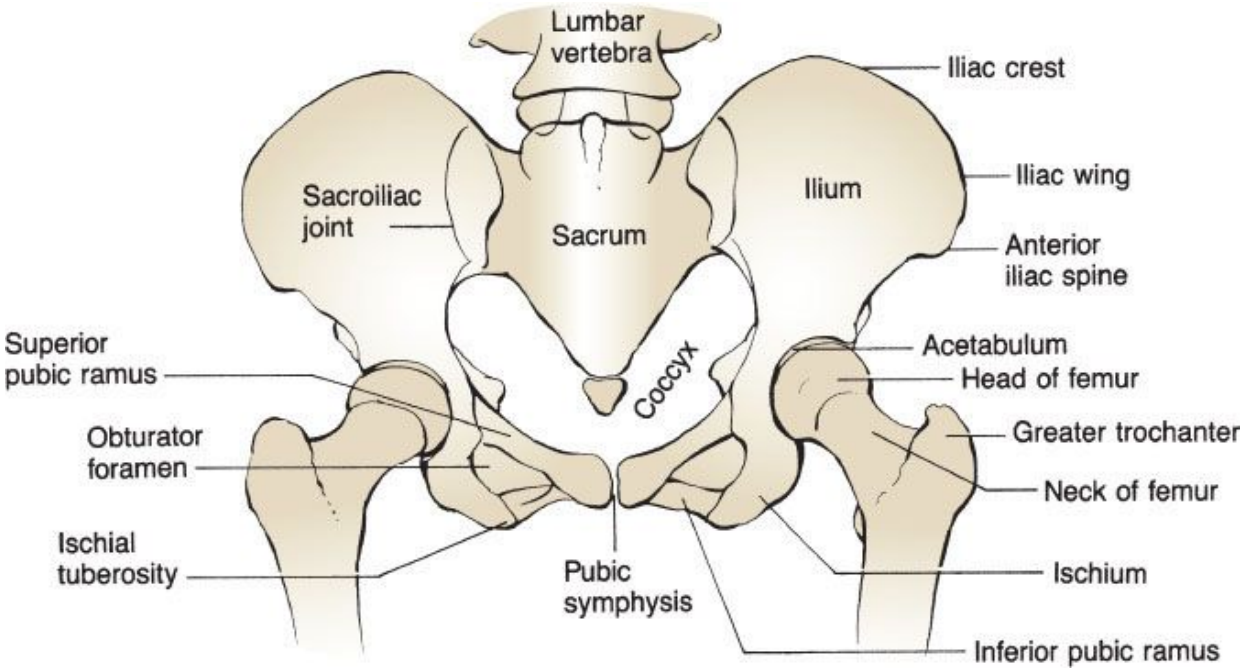

FIGURE 42.1 The pelvis.

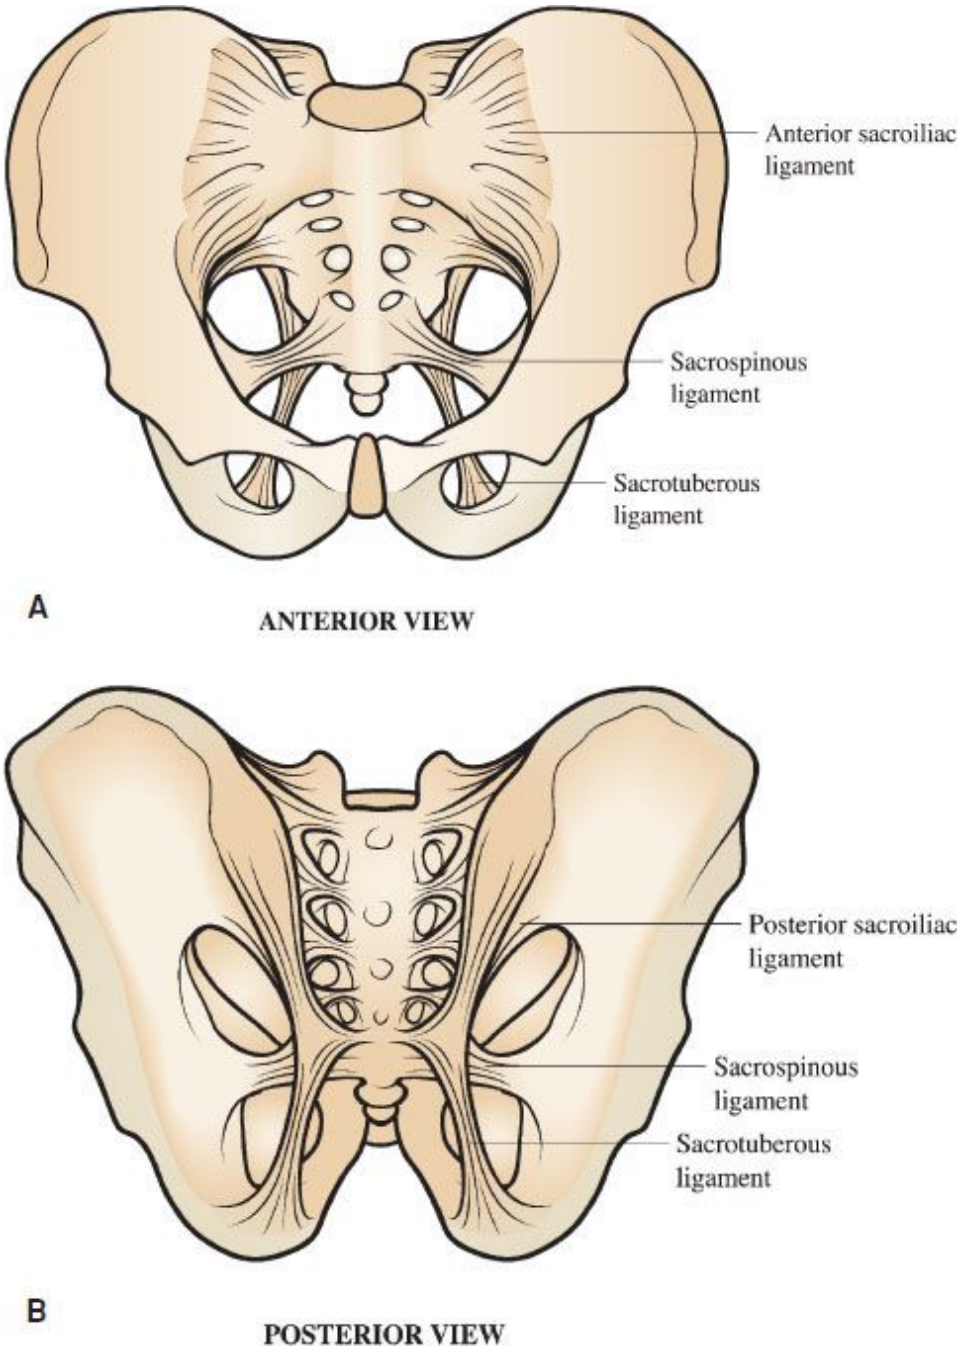

FIGURE 42.2 Ligamentous support of the bony pelvis, (A) anterior, and (B) posterior views. The posterior pelvic ring is stabilized by several strong ligaments. Disruption in this region implies major energy transfer and the potential for significant multisystem injury.

Several different pelvic fracture classification systems have been developed. The most widely used system was developed by Young

and Burgess and is based on the mechanism of injury (3). Three force vectors are described: lateral compression (LC), anteroposterior (AP) compression, and vertical shear (VS). "Complex patterns" describe injuries that are the result of more than one force vector. Each of these vectors breaks or dislocates the pelvic ring in a predictable pattern and is associated with varying degrees of mechanical instability (Table 42.1) and potential for hemorrhage. Each injury force vector has a unique effect on "pelvic volume": that is, the potential space created after injury that may accommodate pelvic hemorrhage. Injury vectors that increase pelvic volume (e.g., AP compression, VS) are much more likely to be associated with brisk pelvic bleeding and hemodynamic instability than injury vectors that decrease pelvic volume (e.g., LC).

TABLE 42.1
Young–Burgess Classification of Pelvic Fractures

Lateral Compression (LC)
Anterior injury—rami fractures
(a) LC I: Sacral fracture on side of impact
(b) LC II: Crescent fracture on side of impact
(c) LC III: Type I or type II injury on side of impact with contralateral open-book injury
anteroposterior compression (APC)
Anterior injury—symphysis diastasis/rami fractures
(a) APC I: Minor opening of the symphysis and sacroiliac (SI) joint anteriorly
(b) APC II: Opening of anterior SI, intact posterior SI ligaments
(c) APC III: Complete disruption of the SI joint
Vertical Shear (VS type)
Vertical displacement of the hemipelvis with symphysis, diastasis or rami fractures anteriorly, iliac wing, sacral fracture, or SI dislocation posteriorly
Combination (CM type)
Any combination of above injuries

Lateral Compression

LC fractures account for almost 50% of pelvic fractures. The force is delivered to the pelvis from the side. LC fractures are common after a

"T-bone" motor vehicle collision or when a pedestrian is struck from the side. The affected hemipelvis is crushed inward (Fig. 42.3). Stability is usually maintained, and therefore, LC injuries are less likely than other pelvic fractures to have associated major hemorrhage. Morbidity is secondary to coincident blunt force trauma to the head and torso, rather than the pelvic fracture itself.

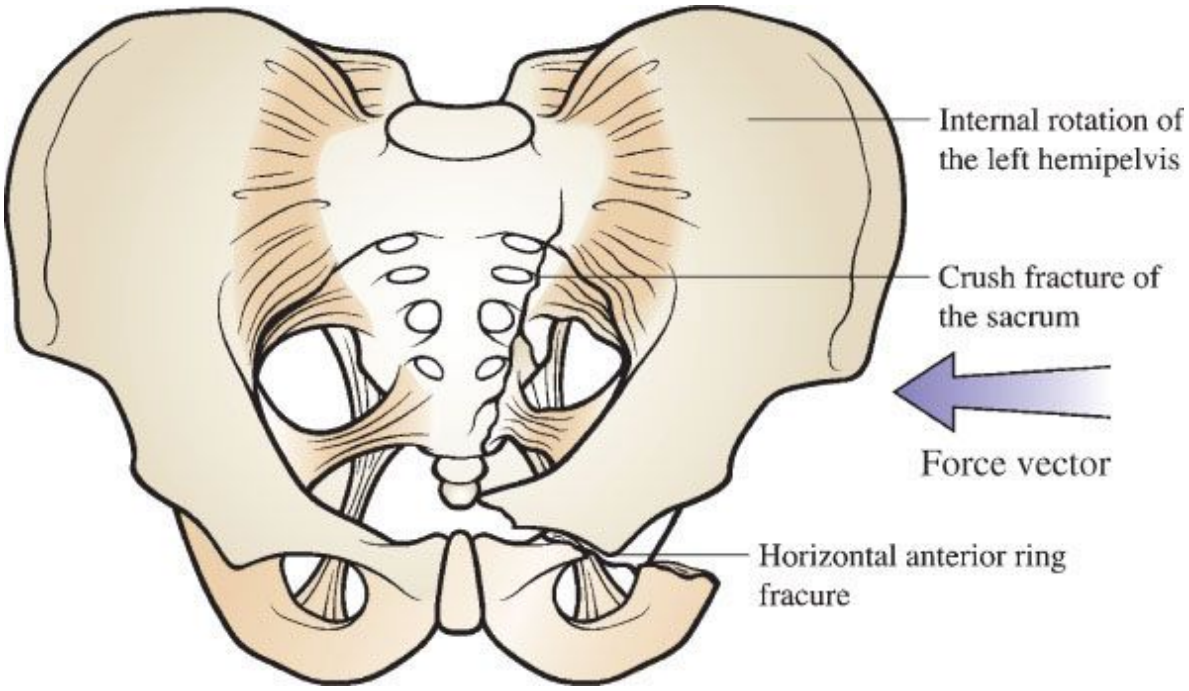

FIGURE 42.3 Lateral compression injury. The causative force vector is delivered from the side, crushing the affected hemipelvis inward. Lateral compression injuries typically reduce pelvic volume. Instability is variable.

Essential radiographic features of LC fractures include horizontal pubic rami fractures. These fractures are visible 80% of time on the AP view, and this feature alone is highly suggestive of LC injury. Crush fractures of the sacrum are seen in 88% of cases. This fracture may only be visible as a disruption of the arcuate lines. The combination of a crush fracture of the sacrum and a horizontal pubic ramus fracture is diagnostic for a LC injury. Fractures of the acetabulum or hip dislocations can also be seen. SI joint diastasis in combination with any of the other findings also suggests a LC injury.

Another type of fracture that results from LC is the “stove-in” or pelvic wing fracture that was first described by Duverney in 1751 (Fig. 42.4). This fracture may produce an unstable fragment off the iliac crest, but the load-bearing stability of the pelvic ring is not jeopardized.

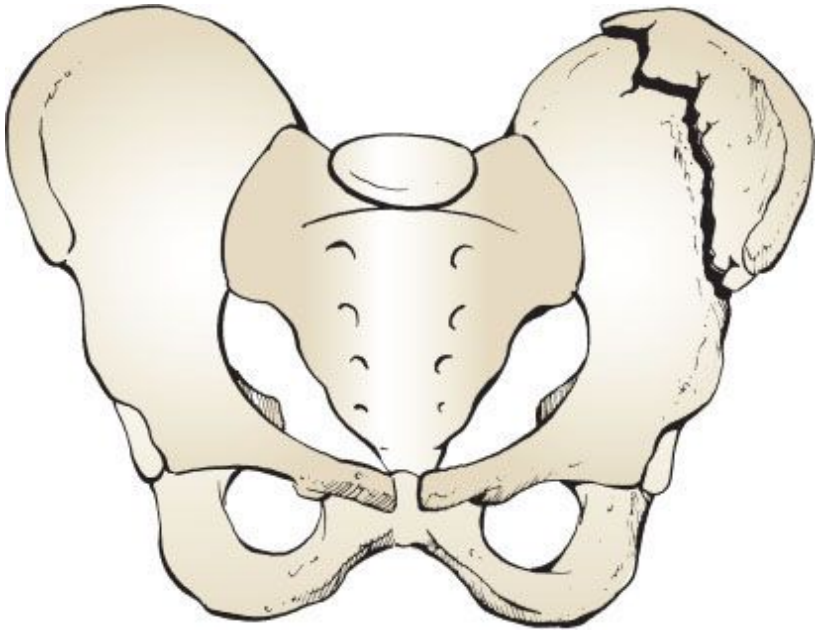

FIGURE 42.4 Duverney fracture. Pelvic wing or “stove-in” fracture.

Anteroposterior Compression

Nearly one-third of pelvic fractures are AP compression injuries. An anterior compressive force causes rupture of the symphyseal ligament and diastasis of the anterior pelvic ring. The posterior ligaments will tolerate up to 2.5 cm of symphyseal diastasis. Progressive widening of the symphysis beyond this point results in disruption of the anterior SI and sacrospinous ligaments. This injury is commonly referred to as an “open-book” pelvic fracture. Severe trauma will disrupt the posterior SI ligaments as well. In these circumstances, the SI joint is shown widely displaced on radiographs.

AP compression fractures are seen following head-on motor vehicle collisions or as a pedestrian is struck head-on by an oncoming vehicle. Forces may also be delivered in a posterior–anterior direction. Both iliac wings are forced outward (Fig. 42.5).

AP compression injuries are unstable, and are often associated with brisk pelvic and retroperitoneal hemorrhage. Coincident injuries of the thorax and abdomen are the rule.

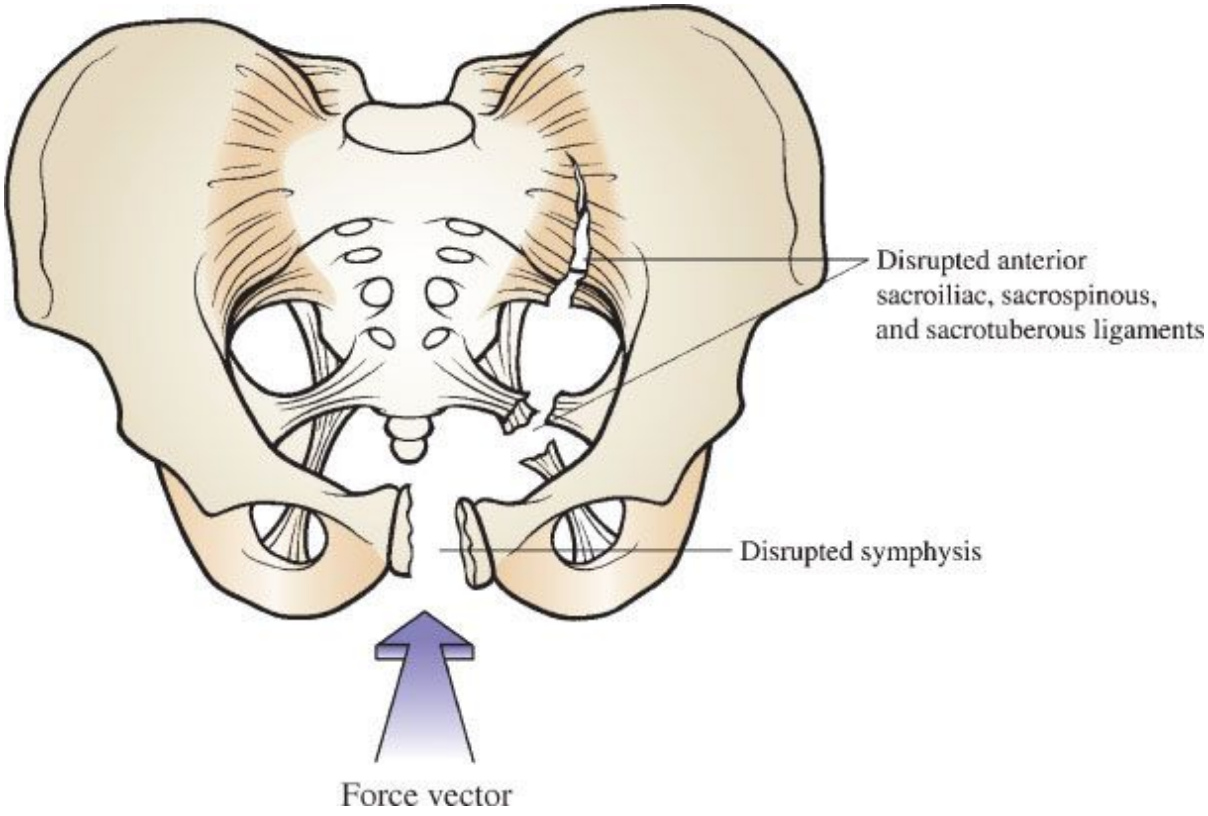

FIGURE 42.5 AP compression injury. The causative force vector is delivered from the front (or back), causing the pelvic ring to "open like a book." These injuries are mechanically unstable, and associated with increases in pelvic volume.

Radiographs of anterior compression injuries will demonstrate vertically oriented pubic rami fractures, symphyseal diastasis, or both, and a variable degree of SI joint disruption. An acetabular fracture is seen in up to one half of patients.

Vertical Shear Fractures

VS injuries occur when a vertically oriented force is delivered to the pelvis via the extended femurs. These rare injuries are usually the result of a fall from a height or follow a head-on motor vehicle

collision in which the occupant had the legs fully extended. VS injuries can also result from a downward force delivered to the pelvis via the spine, which may occur when a heavy object falls on the back or shoulders. Because one hemipelvis is driven up (or down) compared to the other (Fig. 42.6), these injuries produce major instability. The hemodynamic consequences are similar to those associated with AP compression injuries. Radiographs of a VS fracture demonstrate severe posterior disruption. This injury appears as either complete SI joint disruption, a vertical sacral fracture, or a medial iliac wing fracture with associated symphyseal disruption or pubic rami fractures.

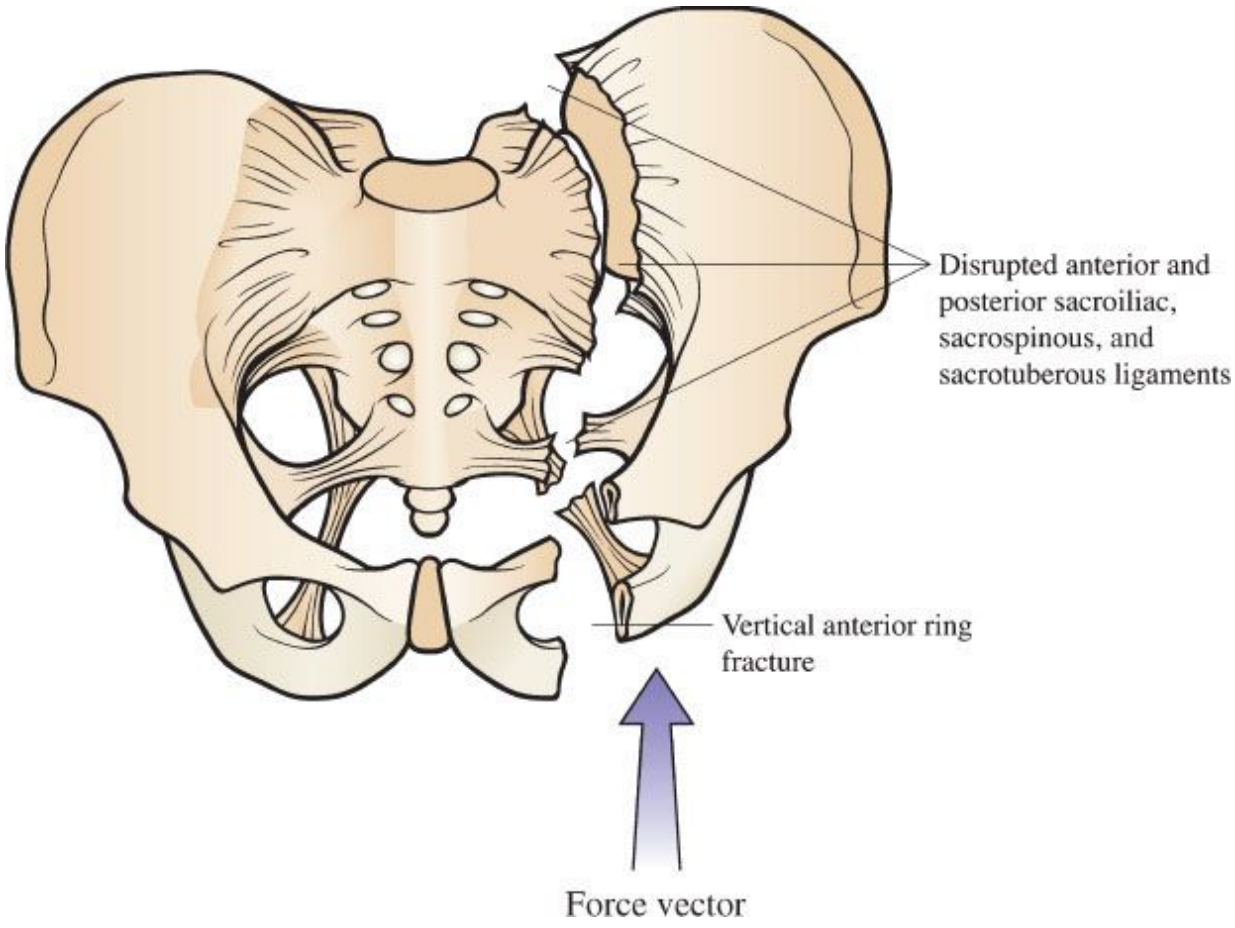

FIGURE 42.6 Vertical shear injury. The causative force is transmitted up the ipsilateral femur, driving the affected hemipelvis upward. Vertical shear injuries are extremely unstable and associated with increases in pelvic volume.

The Malgaigne fracture, first described in 1859, is characterized by anterior disruption of the pubic symphysis or two to four pubic rami fractures and ipsilateral SI joint disruption. Because of involvement of the posterior arch, these injuries can be complicated by significant neurologic and vascular injury. These patients are often hypotensive, and the mortality rate approaches 20%.

Other Types of Pelvic Fractures

Straddle Injuries

A straddle injury is an unstable injury characterized by bilateral double pubic rami fractures. Classically, this fracture results from falling while straddling a solid object between the legs. Both lateral and AP compressive forces can cause straddle injuries as well. The lower genitourinary tract is particularly susceptible to injury by this mechanism. These injuries are usually closed fractures. Patients will have perineal tenderness, ecchymosis, and gross hematuria. Male patients may be unable to void. The incidence of hemorrhage and bowel injury is high.

Avulsion Fractures

These injuries are among the most trivial of pelvic fractures and are often sustained by athletes who stress the muscular or ligamentous insertions onto the bony pelvis (Fig. 42.7). Avulsions of the anterior superior iliac spine generally occur in adolescent hurdlers and long jumpers. These injuries reflect forceful contraction of the sartorius muscle or abdominal musculature transmitted to the iliac epiphysis. Less commonly, the anterior inferior iliac spine may be avulsed by intense contraction of the straight head of the rectus femoris muscle. This injury may occur in athletes playing sports that involve kicking (e.g., soccer and rugby). Avulsion fractures of the ischial tuberosity are even less common. This injury usually results from strenuous stretching of the pelvic ring, as in hurdling or pole vaulting. Patients with avulsion fractures generally present with a characteristic history and local tenderness. In isolated trauma, there are usually no associated complaints or injuries. These are stable fractures, because the integrity of the pelvic ring remains intact.

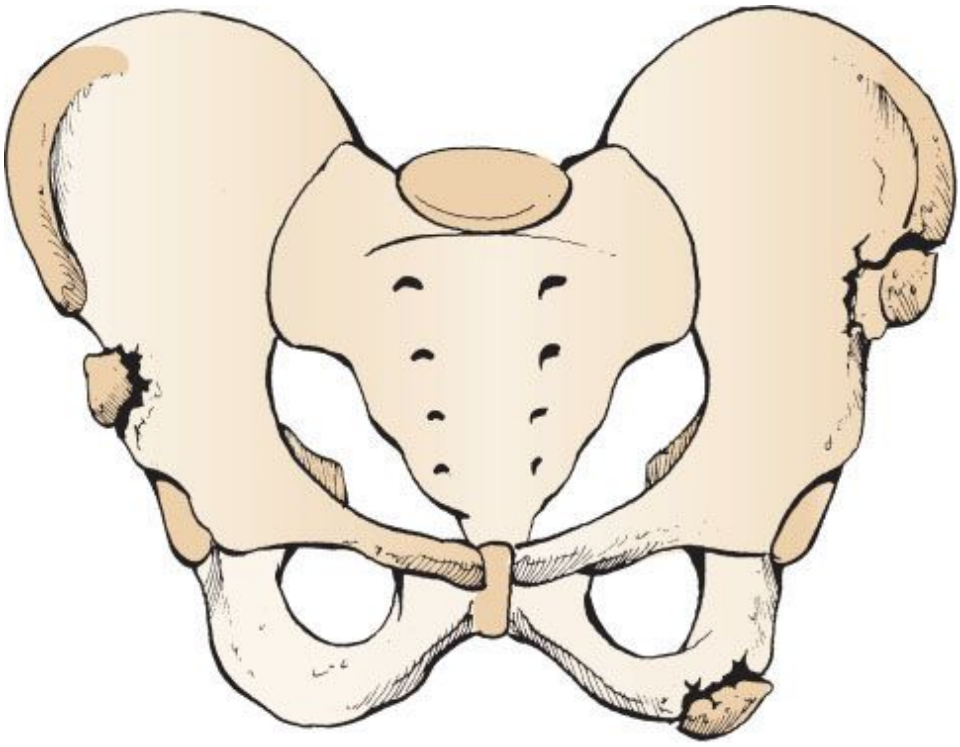

FIGURE 42.7 Fractures due to stress on muscular or ligamentous insertions onto the bony pelvis.

Sacral Fractures

Sacral fractures are defined by the orientation of the fracture line and occur in transverse upper, transverse lower, and vertical planes. Upper sacral fractures are frequently difficult to recognize both radiographically and clinically. These fractures often present only as buttock and perianal pain. These fractures may injure sacral nerve roots resulting in decreased anal sphincter tone and loss of perineal sensation. Lower sacral fractures are equally painful but are rarely complicated by neurologic injury. A careful physical examination to exclude rectal tears is important. Vertical sacral fractures occur as a result of VS injury.

Patients who fall from a standing height frequently present with pelvic pain localized to the bony prominences. Areas such as the iliac spine, ischial tuberosities, superior pubic rami, and coccyx are particularly susceptible to direct trauma. These fractures are stable injuries and are particularly common in elderly osteopenic patients.

Presentation involves localized pain, swelling, and ecchymosis. There are usually no associated injuries.

Associated Injuries

Significant force is required to disrupt the pelvic ring. Consequently, associated injuries, both to adjacent viscera as well as organs distant to the pelvis, are common following major pelvic trauma. The Injury Severity Score, as a surrogate marker of organ injury, is an important predictor of mortality in patients with pelvic fractures (4).

Approximately one-fourth of pelvic fractures are complicated by injuries to the urethra or bladder (5). More than 95% of patients with an injury to the posterior urethra and 70% to 95% of patients with a bladder injury following blunt trauma have a pelvic fracture. Bladder injury is usually the result of perforation by fracture fragments and is found in patients with symphyseal diastasis and those with multiple pubic rami fractures. The posterior urethra is also prone to injury following anterior pelvic fractures because it is firmly attached to the pubis by the puboprostatic ligament.

Upper sacral fractures, VS fractures, fractures of the sciatic notch, and SI joint injuries are frequently complicated by injuries to the lumbosacral plexus. The overall incidence of neurologic injury in patients with pelvic fractures is reported to be 10% to 21%. The incidence of neurologic injury is as high as 50% in fractures with posterior disruption (4). Such patients may present with distal motor weakness (impaired dorsiflexion or plantar flexion of the great toe), numbness on the dorsal and lateral aspect of the foot, a diminished Achilles tendon reflex, or evidence of cauda equina syndrome, including perianal anesthesia and loss of sphincter tone.

Open pelvic fractures are defined as a fracture with direct communication with a vaginal, rectal, or skin wound. These fractures are invariably associated with severe injuries of the pelvic viscera. Early mortality is attributed to severe blood loss or associated chest or intracranial injuries. Historically, mortality may be as high as 30% to 50% (6). Following the initial resuscitation phase, heavy contamination of perineal wounds resulting from damage of the rectum and genitourinary tract increases the risk of delayed

complications, including abscess formation, sepsis, and multiorgan failure.

ED EVALUATION

Physical Examination

During the initial resuscitation of the severely injured trauma patient, the priorities are to rapidly identify immediate life-threatening injuries and to initiate resuscitation. In the patient with a pelvic fracture, hypotension is an ominous sign, and a search for the cause should be rapidly initiated.

The objectives of the physical examination of the pelvis are to estimate the likelihood of a pelvic fracture and to identify any complications and associated injuries. The physician should inspect and palpate the front and back of the pelvis noting any abrasions, contusions, lacerations, tenderness, or crepitus. Although the identification of an unstable pelvic ring is important, overzealous rocking of the disrupted pelvis may cause additional retroperitoneal bleeding. It is preferable to apply gentle steady downward and lateral pressure on the iliac wings to detect or exclude tenderness. If tenderness is present, appropriate imaging should follow. In the obtunded blunt trauma patient with a possible pelvis injury, imaging should be performed.

Signs of urethral injury include blood at the urethral meatus, penile or scrotal hematoma, and a high-riding prostate. Patients with these findings should have a retrograde urethrogram before insertion of a Foley catheter to avoid worsening of an incomplete urethral tear. A careful vaginal examination should be performed in female patients. Perineal lacerations may have associated intravaginal mucosal tears. Bleeding is the hallmark of vaginal trauma, although it may not be immediately apparent because of muscle spasm. Vaginal injury should also be suspected if hematuria is present, or it is difficult to pass a Foley catheter.

The lumbosacral plexus is prone to injury in pelvic fractures, and a neurologic examination of the lower extremity should be performed with particular attention to the L5 and S1 nerve roots. In the patient

who is awake, motor function of the L5 nerve root is assessed by dorsiflexion of the great toe against resistance. The S1 nerve root is tested by having the patient plantar flex the great toe. L5 supplies sensation to the dorsum of the foot, and S1 supplies sensation to the lateral aspect of the foot. The Achilles tendon reflex, perianal sensation, and sphincter tone should also be assessed.

Indications for Pelvic Imaging

The severely injured blunt trauma patient who is either hemodynamically unstable or obtunded or who has clinical evidence of lower abdominal or pelvic injury requires pelvic imaging. For less severely injured patients, a thorough physical examination can be used to identify the patient at low risk for pelvic fracture who can be managed safely without imaging. In a prospective trial of 2,176 alert blunt trauma patients, Gonzalez et al. (7) demonstrated that the physical examination was 93% sensitive for detecting pelvic fractures and 100% sensitive for detecting those requiring operative repair. Pelvic imaging in blunt trauma patients is recommended for patients who:

1. Are clinically unstable.
2. Have lower abdominal or pelvic tenderness.
3. Have other signs of pelvic trauma (perineal hematoma, blood at the urethral meatus, gross hematuria).

Pelvic x-Rays

A single AP radiograph will identify the large majority of pelvic fractures and can provide sufficient information to guide early management. The AP radiograph provides specific clues that will help identify the various injury patterns and fractures described in the previous section (Figs. 42.8–42.12). The film should visualize the iliac crests, each hip joint, the fifth lumbar vertebrae, and the proximal portion of each femur. Important landmarks include the pubic symphysis, superior and inferior rami, anterior superior and anterior inferior iliac spines, SI joints, sacral ala, sacral foramen, and L5 transverse processes.

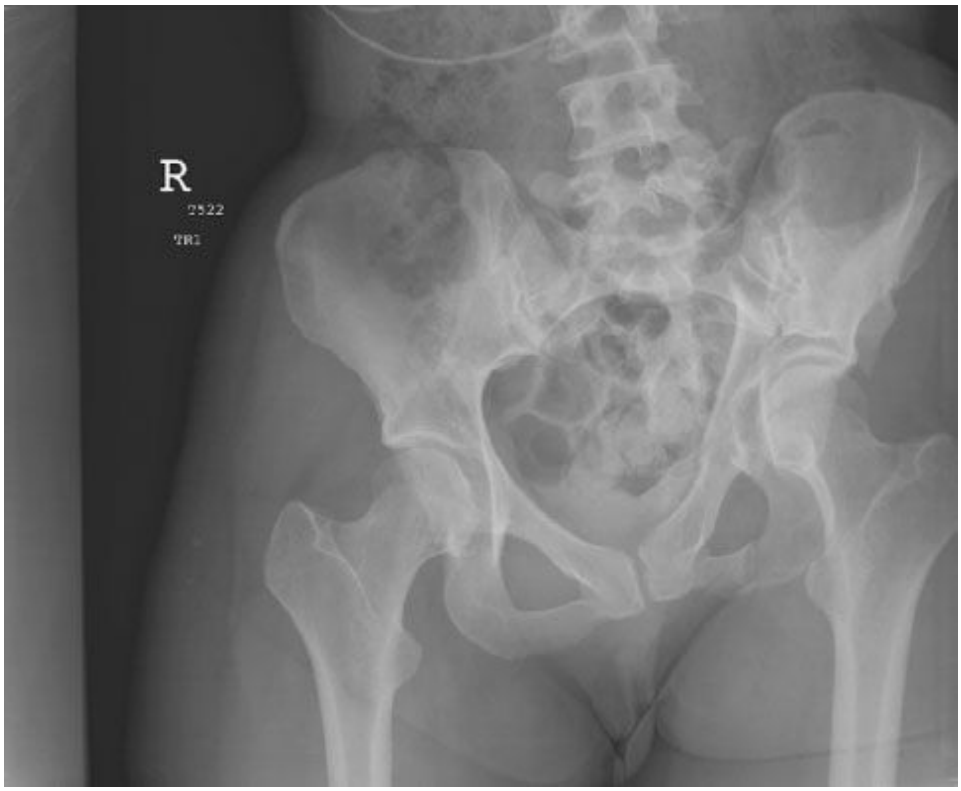

FIGURE 42.8 AP plain film of a severe lateral compression injury. The left hemipelvis is crushed inward.

FIGURE 42.9 CT scan of a left lateral compression injury with a crush fracture of the affected sacrum.

FIGURE 42.10 AP plain film of a severe AP compression injury with symphysis diastasis and left posterior SI joint disruption.

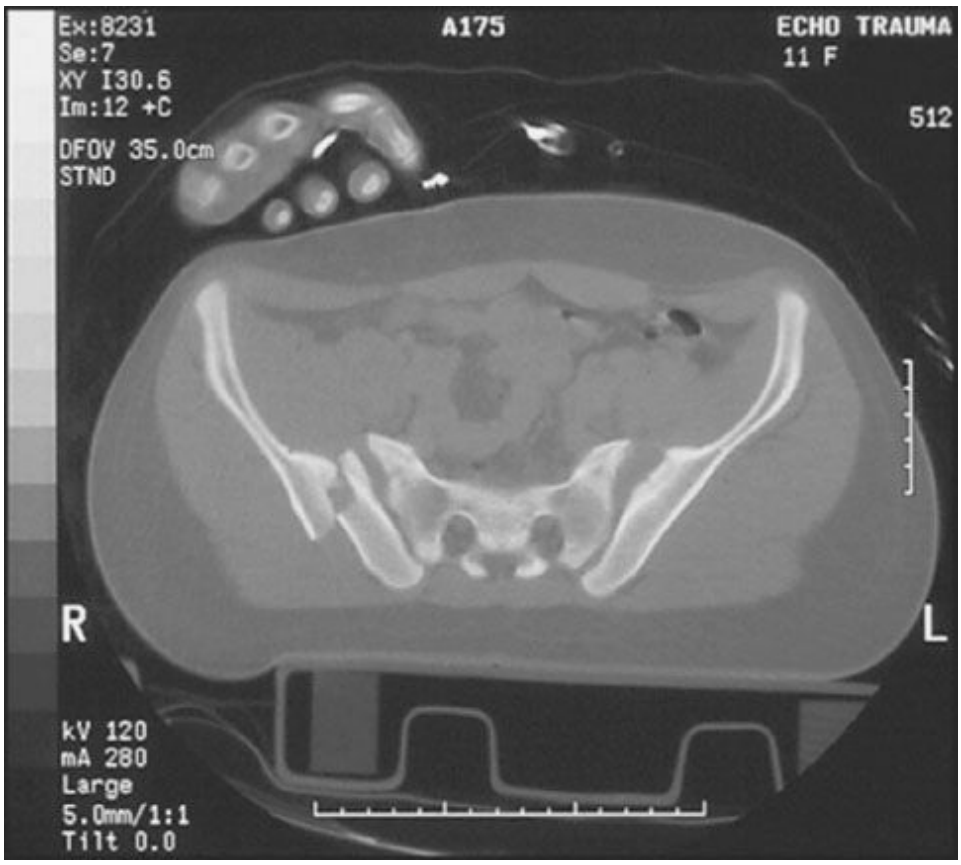

FIGURE 42.11 CT scan of an AP compression injury with major disruption of the posterior pelvic ring.

FIGURE 42.12 AP plain film of vertical shear injury with symphysis diastasis and upward migration of the left hemipelvis.

The increased use of abdominopelvic computed tomography (CT) scan in trauma patients has diminished the role of pelvic x-rays. A pelvic x-ray may be omitted in the hemodynamically stable patient who will have an abdominopelvic CT scan. An x-ray of the pelvis plays an important role in the hemodynamically unstable patient; as it may reveal the presence of an unstable pelvic fracture, suggesting a likely source of hemorrhage (8,9).

Computed Tomography

The use of CT has revolutionized the assessment of injured patients, and pelvic trauma is no exception. When compared to plain films, CT has a higher sensitivity for the detection of fracture in both adults and children. Other advantages include a more accurate assessment of pelvic instability, the ability to provide reconstructed three-dimensional images, and visualization of adjacent pelvic and abdominal viscera. Contrast extravasation seen on abdominopelvic

CT is useful for the detection of arterial bleeding and accurately predicts the need for therapeutic angiography (10,11). Blackmore et al. (12) demonstrated that visualization on CT of pelvic hematoma volume greater that 500 mL was predictive of the need for angiography compared to patients with volumes less than 200 mL.

ED MANAGEMENT

Initial ED management of the severely injured patient with a pelvic fracture can be challenging and requires a multidisciplinary approach with trauma surgery, emergency medicine, orthopedics, and interventional radiology (13). Aggressive resuscitation, pelvic fracture stabilization, and determination of the most likely source of hemorrhage to guide subsequent management are the immediate priorities in the ED. In the unstable trauma patient with a pelvic injury, the critical decision is summarized as follows: Does this patient have ongoing arterial bleeding related to the pelvic fracture, therefore, warranting angiography and therapeutic embolization, or is there intra-abdominal hemorrhage where urgent laparotomy is indicated? Rapid detection of intraperitoneal hemorrhage, an understanding of fracture patterns and stability, and local protocols and available resources guide decision making.

Resuscitation

During the initial resuscitation of the patient with significant pelvic injury, the physician should anticipate hypotension and initiate early aggressive resuscitation. Adequate intravenous access and careful monitoring are crucial. A blood sample should be sent for a cross match for type-specific blood. Hemoglobin, serum lactate, and the base deficit are also used to guide resuscitation. The critically ill patient requires vigorous resuscitation with warmed crystalloid and early transfusion, as well as precautions to prevent hypothermia.

Pelvic Stabilization

Vascular injuries and substantial blood loss often complicate displaced pelvic fractures. Venous bleeding accounts for the majority

of blood loss associated with pelvic fractures. Mechanically unstable injuries and those that increase pelvic volume create a potential space for ongoing hemorrhage. Pelvic stabilization can reduce pelvic volume. This practice can stabilize displaced fracture segments, which can also decrease fracture-related bleeding. Pelvic stabilization can be accomplished by several simple measures in the ED. Wrapping a sheet tightly around the pelvis will close the pelvic ring to some degree. Commercial pelvic binders are also available, and they are recommended with fractures amenable to compression, such as fractures with a widened symphysis (14).
